This journal and the individual contributions contained in it are protected under copyright, and the following terms and conditions apply to their use in addition to the terms of any Creative Commons or other user license that has been applied by the publisher and the European Association for the Study of the Liver to an individual article:

Photocopying: Single photocopies of single articles may be made for personal use as allowed by national copyright laws. Permission is not required for photocopying of articles published under the CC BY license nor for photocopying for non-commercial purposes in accordance with any other user license applied by the publisher and the European Association for the Study of the Liver. Permission of the publisher and the European Association for the Study of the Liver and payment of a fee is required for all other photocopying, including multiple or systematic copying, copying for advertising or promotional purposes, resale, and all forms of document delivery. Special rates are available for educational institutions that wish to make photocopies for non-profit educational classroom use.

Derivative Works: Users may reproduce tables of contents or prepare lists of articles including abstracts for internal circulation within their institutions or companies. Other than for articles published under the CC BY license, permission of the publisher and the European Association for the Study of the Liver is required for resale or distribution outside the subscribing institution or company. For any subscribed articles or articles published under a CC BY-NC-ND license, permission of the publisher and the European Association for the Study of the Liver is required for all other derivative works, including compilations and translations.

Storage or Usage: Except as outlined above or as set out in the relevant user license, no part of this publication may be reproduced, stored in a retrieval system or transmitted in any form or by any means, electronic, mechanical, photocopying, recording or otherwise, without prior written permission of the publisher and the European Association for the Study of the Liver.

Permissions: For information on how to seek permission visit www.elsevier.com/permissions.

Author rights: Author(s) may have additional rights in their articles as set out in their agreement with the publisher and the European Association for the Study of the Liver (more information at http://www.elsevier.com/authorsrights).

Notice: Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds or experiments described herein. Because of rapid advances in the medical sciences, in particular, independent verification of diagnoses and drug dosages should be made. To the fullest extent of the law, no responsibility is assumed by the publisher or the European Association for the Study of the Liver for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions or ideas contained in the material herein.

Although all advertising material is expected to conform to ethical (medical) standards, inclusion in this publication does not constitute a guarantee or endorsement of the quality or value of such product or of the claims made of it by its manufacturer.

Publication information: Journal of Hepatology (ISSN 0168-8278). For 2022, volumes 76 and 77 are scheduled for publication. Subscription prices are available upon request from the Publisher or from the Elsevier Customer Service Department nearest you or from this journal's website (http://www.elsevier.com/locate/jhep). Further information is available on this journal and other Elsevier products through Elsevier's website: (http://www.elsevier.com). Subscriptions are accepted on a prepaid basis only and are entered on a calendar year basis. Issues are sent by standard mail (surface within Europe, air delivery outside Europe). Priority rates are available upon request. Claims for missing issues should be made within six months of the date of dispatch.

Orders, claims, and journal enquiries: Please visit our Support Hub page https://service.elsevier.com for assistance.

Advertising information: Advertising orders and enquiries can be sent to: **USA, Canada and South America:** Elsevier Inc., 360 Park Avenue, Suite 800, New York, NY 10169-0901, USA; phone: (+1) (212) 989 5800. **Europe and ROW:** Robert Bayliss, Pharma Solutions, Elsevier Ltd., 125 London Wall, London EC2Y 5AS, UK; phone: (+44) 207 424 4454; e-mail: r.bayliss@elsevier.com.

Author enquiries: You can track your submitted article at http://www.elsevier.com/track-submission. You can track your accepted article at http://www.elsevier.com/trackarticle. You are also welcome to contact Customer Support via http://service.elsevier.com.

Funding body agreements and policies: Elsevier has established agreements and developed policies to allow authors whose articles appear in journals published by Elsevier, to comply with potential manuscript archiving requirements as specified as conditions of their grant awards. To learn more about existing agreements and policies please visit http://www.elsevier.com/fundingbodies.

Special regulations for authors: Upon acceptance of an article by the journal, the author(s) will be asked to transfer copyright of the article to EASL. Transfer will ensure the widest possible dissemination of information.

Registration of Clinical Trials
The *Journal of Hepatology* endorses the policy of the WHO and the International Committee of Medical Journal Editors (ICMJE) on the registration of clinical trials. Therefore, any trial that starts recruiting on or after July 1, 2005 should be registered in a publicly owned, publicly accessible registry and should satisfy a minimal standard dataset. Trials that started recruiting before that date will be considered for publication if registered before September 13, 2005.
More detailed information regarding clinical trials and registration can be found in New Engl J Med 2004; 351:1250–1251 and New Engl J Med 2005; 352:2437–2438.

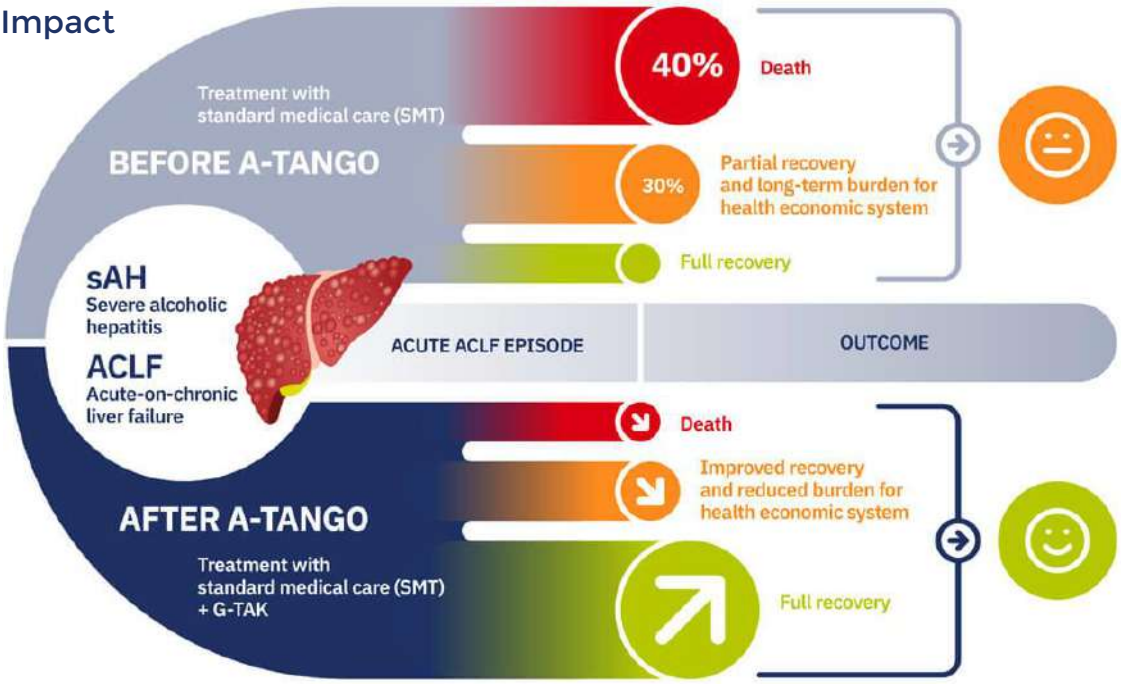
The A-TANGO project - featuring G-TAK, a novel combinatorial therapy for acute-on-chronic liver failure (ACLF)

Expected Impact



- More than **10 million people** suffer from **decompensated cirrhosis** worldwide.
- Effective treatment of ACLF is an urgent and unmet need.
- A-TANGO performs **Phase II clinical studies of G-TAK,** a novel and innovative therapeutic strategy that aims to **reduce inflammation** and **improve hepatocyte proliferation.**
- A-TANGO also strives to identify **reliable biomarkers** for better patient stratification and increased survival.

project duration	grant amount	8 countries	kick-off
5.0 years	6.0 million €	14 institutions	1st March 2021

14 partners, one goal: Helping cirrhosis patients in Europe!

www.a-tango.eu
info@atango.eu

This project has received funding from the European Union's Horizon 2020 research and innovation programme under grant agreement No 945096.

Decision4Liver

decision-project

The objective of **DECISION** is to better understand the pathophysiology of decompensated cirrhosis leading to acute-on-chronic liver failure (ACLF) or death. This consortium will take advantage of already existing large and clinically well-characterised patient cohorts to develop reliable prognostic and response tests and combinatorial therapies tailored to the needs of individual patients to decrease the risk of short-term death.

- Pathophysiologic elucidation of acute decompensated cirrhosis at the systems level (genetics, epigenetics, transcriptomics, metabolomics, lipidomics, miR, and analysis of extracellular vesicles)
- Integration of existing clinical data and new multi-omics data from 2,200 patients with more than 8,600 measurements
- Development of new combinatorial therapies
- Optimization of therapies using existing and new animal models
- Development of novel and robust tests for prediction of outcome following traditional treatment versus response to new therapies
- Phase II clinical trials to test new combination therapies
- Creation of new guidelines for outcome prediction and personalized treatment of acute decompensated cirrhosis to prevent ACLF to death

This project has received funding from the European Union's Horizon 2020 research and innovation programme under grant agreement No 847949.

22 Partners

www.microb-predict.eu

MICROB-PREDICT will investigate

the human microbiome to identify predictors and mechanisms associated with the development of decompensation of cirrhosis and progression to acute-on-chronic liver failure (ACLF) and death.

- → New microbiome-based tests for better stratification of cirrhosis patients
- → Personalized prediction and prevention of decompensation and ACLF
- → Clinical trial to predict response to treatment
- → Modern, effective nanobiosensors as clinical tools with improved specificity
- → More personalized treatment
- → Increased survival times
- → Decreased costs for the health systems

Efficacy and safety of ALXN1840 versus standard of care in Wilson disease: primary results from an ongoing phase 3, randomized, controlled, rater-blinded trial

Email: karlheinz.weiss@stadtmission-hd.de

Background and aims: ALXN1840 is an oral, copper (Cu)-binding agent that forms a stable tripartite (tetrathiomolybdate-Cu-albumin) complex. This study investigated the efficacy and safety of ALXN1840 for treating Wilson disease (WD) using a novel plasma biomarker of Cu sequestration.

Method: Patients with WD aged ≥12 years (Leipzig score ≥4; model for end-stage liver disease score ≤13) were randomized 2:1 to ALXN1840 at a starting dose of 15 mg QD with dose adjustments up to 60 mg QD permitted, or standard of care (SoC; penicillamine, trientine and/or zinc) for 48 weeks (W).

Prior SoC for >28 days and 0–28 days determined enrolment to Cohorts 1 and 2, respectively. Primary end point: mean daily area under the effect-time curve of directly measured non-ceruloplasmin-bound Cu 0–48W (dNCC $AUEC_{0-48W}$). Secondary end points: 0–48W change in neurological Unified WD rating scale (UWDRS) Part II and III scores, and Clinical Global Impression-Improvement (CGI-I) scores. A pre-specified hierarchical statistical testing method was used to control multiplicity across primary and key secondary end points. Adverse events (AEs) were summarized.

Results: 214 patients enrolled; all had preserved liver function and 79% had neurological symptoms. 207 were treated, 137 with ALXN1840 and 70 with SoC; mean age was 34.3 and 32.1 years, and 59.9% and 52.9% were male, respectively. Mean daily dNCC $AUEC_{0-48W}$ (μmol/L) was 3.2 times greater with ALXN1840 than with SoC overall (least-squares mean [LSM] difference, 2.18 [standard error (SE), 0.244], $p < 0.0001$), and 2.5 times greater with ALXN1840 for Cohort 1, despite a mean prior SoC duration of >12 years (Figure). UWDRS scores reduced modestly from 0 to 48W (mean [95% confidence interval] change in Part III score for symptomatic patients: ALXN1840, −2.91 [−4.74, −1.09]; SoC, −1.17 [−3.20, 0.86]). No significant between-group differences occurred by 48W. Transformed CGI-I scores improved with ALXN1840 vs SoC at 48W; LSM difference, −0.3 [SE, 0.15], $p = 0.0316$; outside the multiplicity testing sequence). For 0–48W, 100.1 (ALXN1840) and 86.5 (SoC) patients experienced AEs per 100 patient-years. Most AEs (ALXN1840, 94.1%; SoC, 92.7%) were not serious. The most frequent AE with ALXN1840 was alanine aminotransferase increase (14.6%). Two deaths, considered unrelated to ALXN1840, were reported.

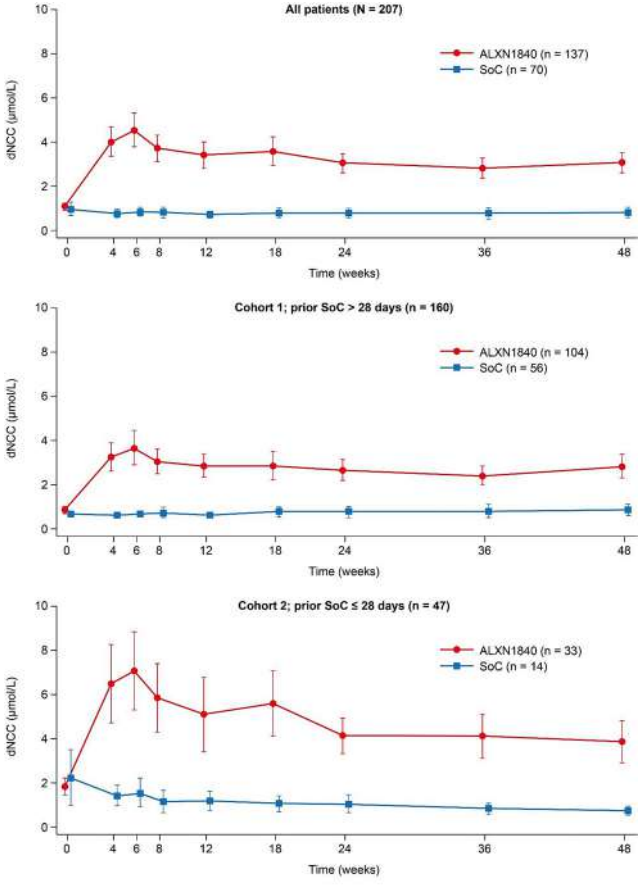

Figure: dNCC values by treatment group from 0 to 48 weeks.
dNCC, directly measured non-ceruloplasmin-bound copper; SoC, standard of care.

Conclusion: ALXN1840 treatment for 48W provided superior Cu control to SoC and was generally well tolerated. Future data analysis of the 60-month open-label extension of this study will evaluate long-term efficacy and safety of ALXN1840.

Anti-fibrotic effect of rifaximin in early alcohol-related liver disease: a double-blind, randomised, placebo-controlled trial

Mads Israelsen[1], Bjørn Stæhr Madsen[1], Nikolaj Torp[1,2], Stine Johansen[1,2], Camilla Dalby Hansen[1,2], Sönke Detlefsen[1,2], Peter Andersen[1], Johanne Kragh Hansen[1,2], Katrine Prier Lindvig[1,2], Ditlev Nytoft Rasmussen[1], Katrine Thorhauge[1,2], Maria Kjærgaard[1,2], Manimozhiyan Arumugam[1,3], Torben Hansen[3], Jonel Trebicka[1,4,5], Maja Thiele[1,2], Aleksander Krag[1,2]. *[1]Odense University Hospital, Odense, Denmark; [2]University of Southern Denmark, Faculty of Health Sciences; [3]Copenhagen University, CBMR, København, Denmark; [4]Goethe University Frankfurt, Gastroenterology, Frankfurt, Germany; [5]European Foundation for the study of chronic liver failure, Barcelona, Spain*
Email: mads.egerod.israelsen@rsyd.dk

Background and aims: Alcohol is the leading cause of liver cirrhosis and liver-related mortality. Alcohol abstinence remains the only therapeutic option. The gut-liver axis with gut dysbiosis and "leaky gut" is considered a key driver of inflammation and fibrogenesis in alcohol-related liver disease (ALD). Rifaximin-α is known to reduce recurrent hepatic encephalopathy and has been linked to improved gut barrier function and reduced systemic inflammation in cirrhosis. We hypothesized that long term rifaximin-αwould reduce inflammation and fibrosis in patients with ALD.
Method: We conducted an 18-months randomised double-blind trial in patients with biopsy-verified ALD and no previous decompensation. We stratified patients according to fibrosis stage and alcohol abstinence within the previous six months. Patients were randomly allocated 1:1 to 550 mg rifaximin-α twice daily or placebo. The primary end point was an improvement of at least one fibrosis stage. Secondary outcomes included progression in fibrosis stage, lobular inflammation, ballooning, steatosis, and transient elastography (TE). We assessed liver biopsies and performed the statistical analyses blinded.
Results: We randomised 136 patients, 108 (79%) completed the trial with paired liver biopsies of adequate quality and 14 dropped out in each group. At baseline, the distribution of fibrosis stages (F0/F1/F2/F3/F4) were 5/31/49/17/6, 84% were male, median TE 8.7 kPa (IQR = 6.5–11.8) and mean age was 59 ± 6 years. The proportion of patients who improved according to fibrosis stage was 26% in the rifaximin-α group and 28% in the placebo group (OR = 1.10, p = 0.821). The proportion who remained stable or progressed in fibrosis stage was 48% and 26% in the rifaximin-α group, versus 30% and 43% in the placebo group and consequently, rifaximin-α reduced the risk of progression compared to placebo (OR = 0.37, p = 0.035) (Figure). Rifaximin-α reduced lobular inflammation compared to placebo (OR = 0.48, p = 0.067), but did not affect hepatic steatosis or ballooning. TE decreased from a median of 8.8 kPa to 8.3 kPa in the rifaximin-α group and 8.7 kPa to 8.3 kPa in the placebo group (p = 0.757). In total, 13 SAEs were reported, and the most frequent reported adverse event (n = 20) was diarrhoea with no difference between the groups.

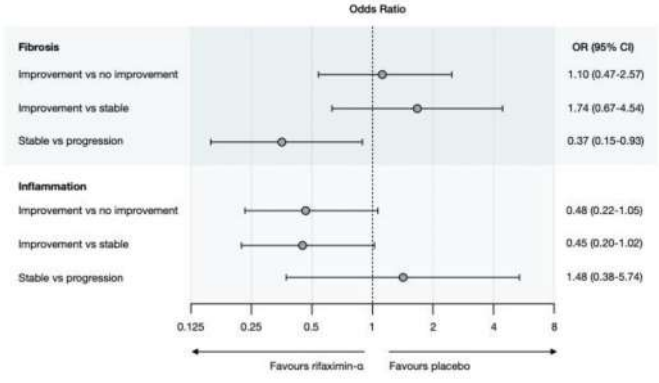

Figure: Rifaximin-α protects against fibrosis progression and reduces lobular inflammation compared to placebo.

Conclusion: Our results show that 18 months treatment with rifaximin-α does not improve fibrosis in early ALD. However, rifaximin-α seems to prevent histological progression of liver fibrosis and tends to decrease hepatic inflammation.

GS003

The spatial distribution and detailed composition of infiltrating immune cells define autoimmune- and checkpoint-therapy associated hepatitis

Laurenz Krimmel[1], Henrike Salie[1], Saskia Killmer[1], Marilyn Salvat Lago[1], Nisha Rana[1], Peter Bronsert[2], David Rafei-Shamsabadi[3], Frank Meiss[3], Ursula Ehmer[4], Angela Krackhardt[5], Marius Schwabenland[6], Marco Prinz[6,7], Christoph Neumann-Haefelin[1], Maike Hofmann[1], Michael Schultheiss[1], Robert Thimme[1], Carolin Mogler[8], Bertram Bengsch[1,7]. *[1]Freiburg University Medical Center, Department of Internal Medicine II (Gastroenterology, Hepatology, Endocrinology und Infectiology), Freiburg, Germany; [2]Freiburg University Medical Center, Institute of Pathology, Freiburg, Germany; [3]Freiburg University Medical Center, Department of Dermatology, Freiburg, Germany; [4]Klinikum rechts der Isar Technical University Munich, Department of Internal Medicine II, Munich, Germany; [5]Klinikum rechts der Isar Technical University Munich, Department of Internal Medicine III, Munich, Germany; [6]Freiburg University Medical Center, Institute of Neuropathology, Freiburg, Germany; [7]Signalling Research Centres BIOSS and CIBSS, Freiburg, Germany; [8]Technical University Munich, Institute of Pathology, Munich, Germany*
Email: bertram.bengsch@uniklinik-freiburg.de

Background and aims: Immune-checkpoint blockade (ICB) therapy has revolutionized clinical oncology, but frequently results in immune-related adverse events (irAE), such as ICB-Hepatitis. To date, there is limited information regarding key involved immune subsets and their spatial interaction in ICB-Hepatitis-moreover, differences to spontaneous autoimmune hepatitis (AIH) remain unclear. We therefore set out to perform a detailed analysis of the immune cell composition and their spatial interaction in the liver in in both disease entities.
Method: We performed high dimensional, spatially resolved analysis of immune cell populations in liver biopsies of patients with ICB-Hepatitis (n = 15), AIH (n = 22) or control tissue (n = 10), using a 40-marker Imaging Mass Cytometry (IMC) panel with single-cell resolution (1 μm^2). Single cells were segmented and normalized utilizing a machine learning pipeline and subsequently classified high dimensionally. In addition, PBMCs from ICB-Hepatitis- and AIH-patients were analyzed by mass cytometry.
Results: Analysis of the composition of the immune infiltrate revealed major differences between ICB-Hepatitis and AIH. An unbiased clustering identified disease-specific, phenotypically well defined, immune cell cluster, which show distinct spatial interaction patterns. Specifically, $CD8^+$ T cell clustering resulted in enrichment of several Ki-67^+ Granzyme B^+ T-bet^+ Cluster in ICB-Hepatitis. In contrast, AIH was defined by a higher expression of exhaustion markers (PD-1^+ TOX^+ $Eomes^+$ cluster) as well as a tissue resident memory (Trm) phenotype. Remarkably, one Granzyme B^+ $CD8^+$ T cell cluster and the Trm cluster correlated with ALT levels in ICB-Hepatitis and AIH, respectively.
Clustering of tissue phenotypes according to spatial liver zonation revealed a biased accumulation of $CD8^+$ T cells near the central vein in ICB-Hepatitis, while in AIH a closer interaction with the periportal triad was observed. Neighborhood analysis identified closely engaged immune cell clusters in both diseases. In ICB-Hepatitis, we observed significant interactions between myeloid clusters and $CD8^+$ T cells, especially between a Ki-67^+ CD8+ T cell cluster and metabolically distinct macrophage populations. In AIH, a stronger B-T cell interaction was noted.
Conclusion: The composition of the immune infiltrate, as well as a distinct spatial distribution and interaction between immune

subsets, points towards major differences in the immune mechanisms and pathogenesis between ICB-Hepatitis and AIH. Our results indicate T-cell-myeloid interactions as likely drivers of ICB-Hepatitis.

GS004

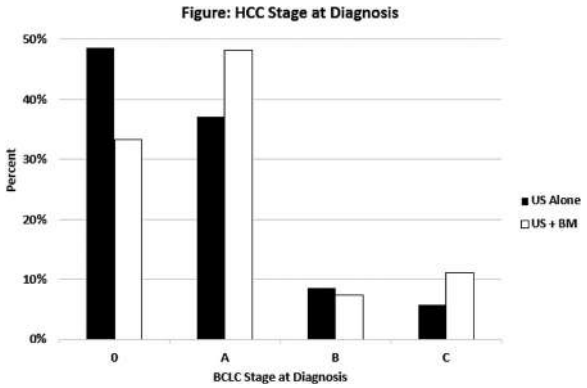
Prospective randomized controlled trial of biomarkers for early detection of hepatocellular carcinoma

Hooman Farhang Zangneh[1], Orlando Cerocchi[1], Korosh Khalili[2], Lima Awad El-Karim[2], Mara Vecchio[3], Jeffrey Winick[3], Yasuhiro Mori[4], Hiroyuki Yamada[4], Harry Janssen[1], Bettina Hansen[1,5], Morris Sherman[1], Jordan Feld[1]. *[1]University Health Network, Toronto General Hospital, Toronto Centre for Liver Disease, Toronto, Canada; [2]University Health Network, Joint Department of Medical Imaging, Toronto, Canada; [3]Fujifilm Healthcare Americas Corporation, United States; [4]Fujifilm Wako Pure Chemical Corporation, Osaka, Japan; [5]University of Toronto, Institute of Health Policy, Management and Evaluation, Toronto, Canada*
Email: jordan.feld@uhn.ca

Background and aims: Surveillance for hepatocellular carcinoma (HCC) is key to early diagnosis and access to potentially curative therapy. Small studies have suggested that addition of serum biomarkers (BM) to 6-monthly ultrasound (US) surveillance may allow for earlier HCC diagnosis. Prospective validation of the utility of BMs is lacking.

Method: Adults with cirrhosis or high-risk HBV infection (REACH-B score >8) followed at the Toronto Centre for Liver Disease were randomized to HCC surveillance with US alone (Group A) or US + BM (Group B) with measurement of alpha-fetoprotein (AFP), lectin-reactive fraction of AFP (AFP-L3) and des-gamma-carboxy prothrombin (DCP). Elevated BM levels and/or findings on US triggered CT/MRI for confirmation of HCC diagnosis. The primary outcome was the proportion of HCCs diagnosed at a curable stage (BCLC 0/A) within Milan criteria. Cox regression was used to evaluate the association of the GALAD score (BM + age/sex) with HCC.

Results: 1, 208 patients were enrolled with median age 59 (18–88) years; 72% were male. HBV and HCV were the most common underlying liver diseases (64% and 21%, respectively) and 770 (64%) were cirrhotic. In Group A, after a median follow-up of 34 (1.2–70.4) months and 9.2 US per patient, 35 HCCs were diagnosed, 31 (87%) in cirrhotics, of which the BCLC was 0 for 17 (49%), A for 13 (37%), B for 3 (9%) and C for 2 (6%). In Group B, after a median follow-up of 19 (0.1–60.4) months and 7.9 US per patient, 27 HCCs were diagnosed, 24 (89%) in cirrhotics, of which BCLC was 0 for 9 (33%), A for 13 (48%), B for 2 (7%) and C for 3 (11%). In Group A, 30/35 (86%) HCCs were diagnosed at a curable stage (BCLC 0/A), compared to 22/27 (81%) in group B ($p = 0.63$) (Figure). In group A, 32 (91%) HCCs were identified first by the study US, while 3 (9%) were found incidentally by imaging done for other reasons with a negative prior study US giving an overall sensitivity for US of 27/35 (77%). In group B, 21 (78%) HCCs were evident on US and 9 (33%) were associated with elevated BM of which 6 (22%) were found by BM with a negative corresponding US. Of these 6, BCLC was 0 for 2, A for 3 and C for 1, confirming that curable HCCs may be identified by BM when US is negative. The GALAD score was associated with HCC risk (HR 1.86, $CI_{95\%}$ 1.48–2.32, $p < 0.001$). The previously identified threshold of >-0.63 was associated with increased HCC risk (HR 6.05, $CI_{95\%}$ 2.4–15.3, $p < 0.001$) and 3 of the 5 advanced (BCLC B/C) HCCs in the BM group would have had imaging triggered by GALAD >–0.63 at an earlier visit.



Conclusion: The probability of diagnosing HCC in a curable stage was similar with US and US + BM. However, some HCCs were diagnosed by elevated BM with a negative US and the GALAD score may have identified additional HCCs earlier. Further analyses will determine if certain patient populations may benefit from use of these BM in routine HCC surveillance.

GS005

Development and validation of the gender-equity model for liver allocation (GEMA) to prioritize liver transplant candidates

Manuel Rodríguez-Perálvarez[1], Antonio M. Gómez-Orellana[2], Avik Majumdar[3], Geoff McCaughan[3], Paul Gow[4], David Guijo-Rubio[2], César Hervás[2], Michael Bailey[5], Emmanuel Tsochatzis[6]. *[1]Hospital Universitario Reina Sofía, University of Córdoba, IMIBIC, CIBERehd, Department of Hepatology and Liver Transplantation, Córdoba, Spain; [2]University of Córdoba, Department of Computer Science and Numerical Analysis, Córdoba, Spain; [3]Royal Prince Alfred Hospital, Morrow Gastroenterology and Liver Centre and Australian National Liver Transplant Unit, Sydney, Australia; [4]The University of Melbourne, Austin Health, Victorian Liver Transplant Unit, Melbourne, Australia; [5]Australian and New Zealand Intensive Care Research Centre (ANZIC RC), Department of Epidemiology and Preventive Medicine, Melbourne, Australia; [6]Royal Free Hospital and University College London (UCL), Sheila Sherlock Liver Unit and UCL Institute for Liver and Digestive Health, London, United Kingdom*
Email: ropeml@hotmail.com

Background and aims: The model for end stage liver disease (MELD) and its sodium-corrected variant (MELD-Na) have created gender disparities in accessing liver transplantation (LT). We derived and validated a new model that replaced creatinine with the Royal Free glomerular filtration rate (PMID: 27779785) within the MELD and MELD-Na formulas.

Method: The "Gender-Equity Model for liver Allocation" (GEMA) and its sodium-corrected variant (GEMA-Na) were trained and internally validated in adults listed for LT in the United Kingdom (2010–2020) using generalized additive multivariate Cox regression. The models were externally validated in an Australian cohort (1998–2020). The primary outcome was mortality or delisting due to clinical deterioration at 90 days. The Greenwood-Nam-D'Agostino test was used to test calibration.

Results: The study comprised 9, 320 patients: 5, 762 patients for model training, 1, 920 patients for internal validation, and 1, 638 patients for external validation. The prevalence of the primary outcome ranged from 5.3% to 6%. In the internal validation cohort, GEMA and GEMA-Na showed a Harrell's c-statistic = 0.752 and 0.766, respectively, for the primary outcome, which were significantly higher than those of the MELD score (0.712) and the MELD-Na score (0.742). Results were consistent in the external validation cohort. Among women, these differences were more pronounced (see Harrell's c-statistics in the table). GEMA and GEMA-Na were adequately calibrated and prioritized differently 43.9% and 41.8% of

LT patients, respectively. Patients prioritized by GEMA-Na were more often women, had higher prevalence of ascites and showed triple risk of the primary outcome compared to patients prioritized by MELD-Na. One in 15 deaths would be avoided by using GEMA instead of MELD, and 1 in 21 deaths would be avoided by using GEMA-Na instead of MELD-Na. Among women, 1 in 8 deaths would be avoided in either situation.

Conclusion: GEMA-Na predicts mortality or delisting due to clinical deterioration in patients awaiting LT more accurately than MELD-Na and its implementation may amend gender disparities.

COHORT	N	MELD	GEMA	MELD-Na	GEMA-Na
Training (overall)	5, 762	0.753 (0.723–0.783)	0.780 (0.751–0.808) p <0.001	0.783 (0.755–0.810)	0.796 (0.769–0.823) p = 0.022

Background and aims: Bulevirtide (BLV) is a novel first-in-class entry inhibitor for the treatment of chronic HDV infection (CHD) that was conditionally approved in the EU in July 2020 based on Phase 2 data. In a pre-specified, alpha-controlled, interim 24 week analysis of a phase 3 study (MYR301; NCT03852719) it was demonstrated that monotherapy with BLV at 2 mg or 10 mg once daily had a significantly greater combined virologic/biochemical response compared with control with no active anti-HDV treatment and had a favorable safety profile. Here, we present findings for the Week 48 primary end point analysis of Study MYR301.

Method: 150 patients with CHD were randomized to 3 treatment groups and stratified based on the absence or presence of compensated cirrhosis: Arm A (control): no active anti-HDV treatment for 48 weeks followed by BLV 10 mg/d for 96 weeks (n = 51), and Arms B or C: immediate treatment with BLV at 2 mg/d (n = 49) or 10 mg/d (n = 50), respectively, each for 144 weeks, after which all arms enter treatment-free follow-up for additional 96 weeks. The primary end point of combined response was defined as undetectable HDV RNA or decrease by $\geq 2\log_{10}$ IU/ml from baseline and ALT normalization at Week 48; other end points included viral response (undetectable HDV RNA or decrease by $\geq 2\log_{10}$ IU/ml from baseline), ALT normalization, change in HDV RNA levels and change in liver stiffness measured by elastography.

Table. Efficacy and safety results at week 48.

n (%)	Arm A Control (N – 51)	Arm B BLV 2 mg (N – 49)	Arm C BLV 10 mg (N – 50)
Combined Response[1]: Responder at Week 48	1 (2.0%)	22 (44.9%)	24 (48.0%)
95% CI	(0.0%, 10.4%)	(30.7%, 59.8%)	(33.7%, 62.6%)
p-value[2]	-	<.0001	<.0001
Viral Response[3]: Responder at Week 48	2 (3.9%)	35 (71.4%)	39 (78.0%)
95% CI	(0.5%, 13.5%)	(56.7%, 83.4%)	(64.0%, 88.5%)
p-value[4]	-	<.0001	<.0001
Biochemical Response[5]: Responder at Week 48	6 (11.8%)	25 (51.0%)	28 (56.0%)
95% CI	(4.4%, 23.9%)	(36.3%, 65.6%)	(41.3%, 70.0%)
p-value[4]	-	<.0001	<.0001
Change from BL in HDV RNA levels (log-10 scale): LS means (95% CI)	-0.019 (-0.391, 0.352)	-2.551 (-2.933, -2.169)	-3.101 (-3.482, -2.719)
p-value	-	<.0001	<.0001
Change from BL in liver stiffness (Fibroscan, kPa): LS means (95% CI)	0.88 (-0.80, 2.56)	-3.08 (-4.70, -1.46)	-3.17 (-4.90, -1.44)
p-value	-	0.001	0.001
Adverse Events Number (%) of participants with any:			
AE	39 (77%)	40 (82%)	44 (88%)
AE with Grade 3-4	3 (6%)	5 (10%)	4 (8%)
AE Related to BLV	0	24 (49)	36 (72%)
SAE[6]	1 (2%)	2 (4%)	1 (2%)

AE: adverse event, BL: baseline, BLV: bulevirtide, CI: confidence interval; LS: least squares, SAE: serious adverse event.
Undetectable HDV RNA defined as below limit of detection (6 IU/mL). ALT normalization defined as: ≤31 U/L for females and ≤41 U/L for males (Russian sites); or ≤34 U/L for females and ≤49 U/L for males (all other sites). Confidence intervals were calculated using Clopper-Pearson (exact) for proportions.
[1] Undetectable HDV RNA or decrease by ≥$2\log_{10}$ IU/ml from baseline and ALT normalization.
[2] Fisher's exact tests used for each comparison of Bulevirtide 2mg and 10mg vs. Control using a significance level of 0.04 at week 48.
[3] Undetectable HDV RNA or decrease by ≥$2\log_{10}$ IU/ml from baseline.
[4] Fisher's exact tests used for each comparison of Bulevirtide 2mg and 10mg vs. Control using a significance level of 0.05.
[5] ALT normalization.
[6] No SAEs assessed as related to BLV treatment

Results: Baseline characteristics included: mean (SD) age 41.8 (8.4) years, 57.3% males, 82.7% White, 47.3% with compensated cirrhosis, 60% were on nucleos (t)ide analogues therapy; mean (SD) HDV RNA 5.05 (1.35) $\log_{10}$ IU/ml and mean (SD) ALT 110.9 (69.0) U/L. At Week 48, similar combined responses were seen in the two BLV arms which were significantly greater than in the control arm (Table). Viral and biochemical responses were also similar in the BLV arms and significantly greater than control (p < 0.0001). BLV was safe and well tolerated during the 48-week treatment period. Asymptomatic elevations in total serum bile salts and injection site reactions occurred at a greater frequency at the higher BLV dose level. There

were no participants having an adverse event (AE) leading to discontinuation of BLV and no serious AEs attributed to BLV treatment. **Conclusion:** Results at Week 48 demonstrate that treatment with BLV resulted in a significantly greater combined response compared to control. Monotherapy with BLV was safe and well tolerated.

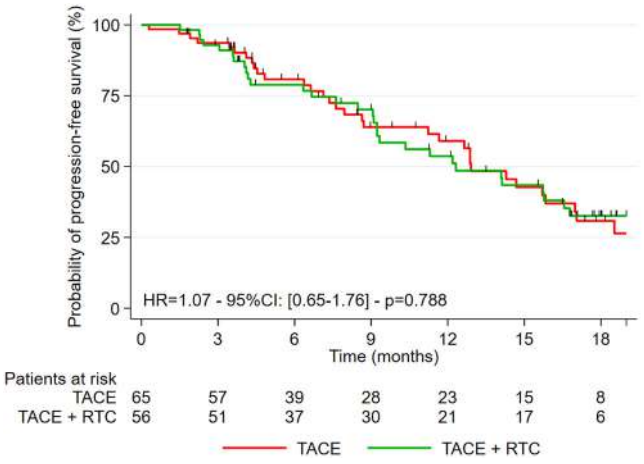
GS007

Transcatheter arterial chemoembolization (TACE) followed by conformal radiotherapy versus TACE alone for hepatocellular carcinoma: a western controlled trial

Cyrille Feray[1], Loic Campion[2], Isabelle Mabile-Archambeaud[3], Philippe Mathurin[4], Xavier Mirabel[5], Emmanuel Rio[2], Jean-Pierre Bronowicki[6], Yann Touchefeu[3], Jérôme Gournay[3], Agnès Rode[7], Francoise Mornex[8], Philippe Merle[9]. *[1]Centre Hepato Biliaire, Villejuif, France; [2]CRLCC, Nantes, France; [3]IMAD, Nantes, France; [4]Hepatology, Lille, France; [5]CRLCC, Lille, France; [6]Hepatology, Nancy, France; [7]Radiology, Lyon, France; [8]Radiotherapy, Lyon, France; [9]Hepatology, Lyon, France*
Email: cyrille.feray@gmail.com

Background: Transarterial chemoembolization (TACE) is a recommended treatment for patients with hepatocellular carcinoma and no possible ablative therapy. We aimed to compare the efficacy and safety of a combination of one TACE followed by external conformal radiotherapy (CRT) to the two TACE procedure.
Methods: TACERTE was an open-labelled randomized controlled trial with a 1:1 allocation rate. Patients had a mean age of 70 y, were male in 86 %. Etiology was HCV in 13%, HBV in 2% and alcohol for the others. The primary end point was progression-free survival (PFS; Kaplan-Meier analysis) in the intention-to-treat population. The typical schedule of CRT was 54 gy in 18 sessions. DC beads were used for TACE in 82/120 (68%). Study registered in clinical trial.gov (NCT01300143).
Results: Among the 120 randomized patients, 64 were in the arm TACE alone and 56 in the TACE-CRT arm. 91/120 (76%) did not have received any previous therapy. Eight patients (4 in each arm) had a rapid tumoral progression and did not received the planned therapy. The PFS at 12 and 18 months was 53% and 32 % in the TACE and CRT group and 59% and 30 % in TACE alone group (HR = 1.07; 95% CI: [0.65–1.76]-p = 0.78). A centralized blinded review of imaging was possible in 95 patients (79%) and confirmed the absence of significant differences between the two arms. The overall survival (OS) at 12, 18 and 60 months was 69%, 57% and 15% in the TACE and CRT group and 81%, 75% and 17% in the TACE alone group (HR = 1.23–95%CI: [0.83–1.82]-p = 0.297). The median OS was 22 months (95%CI:[15.7–26.2]) in the TACE-CRT arm and 30 months (95% IC:[23–35]) in the other. The cumulated number of grade III–IV adverse events (AE) was 83 in the TACE and CRT group and 59 in the TACE alone group. A propensity score analysis demonstrated that exposure to TACE and CRT was associated to more AE.



Conclusion: In contrast with the results of previous eastern randomized trials, this first western randomized controlled trial demonstrates that compared to the conventional TACE, the combination of TACE followed by CRT procedure has no positive effect on the PFS or the OS in patients with unresectable HCC.

The global burden of liver cancer (LC) and chronic liver diseases (CLD) is driven by non-alcoholic steatohepatitis (NASH) and alcohol liver disease (ALD)

James Paik[1,2], Linda Henry[1,2,3], Youssef Younossi[3], Janus Ong[3,4], Saleh Alqahtani[3,5,6], Zobair Younossi[1,2,7]. *[1]Inova Health System, Center for Liver Diseases, Department of Medicine; [2]Betty and Guy Beatty Center for Integrated Research, IHS; [3]Center for Outcomes Research in Liver Disease; [4]University of the Philippines, College of Medicine; [5]Johns Hopkins Medical Center; [6]King Faisal Specialist Hospital and Research Center; [7]Inova Health System, Medicine Service Line*
Email: zobair.younossi@inova.org

Background and aims: Although chronic viral hepatitis B and C (CHB and CHC) and ALD have been the main drivers of burden of chronic liver disease (CLD) and liver cancer (LC), NASH has recently become more prominent. **Aim:** To assess changes in the global prevalence, incidence, mortality and morbidity [disability-adjusted life-years (DALYs)] related to LC and CLD according to the etiology of CLD and 21 GBD regions of the world.
Method: The data was obtained from the Global Burden of Disease Study 2019 (GBD 2019). Incidence, prevalence, mortality and DALYs were calculated. Annual percent change (APC) was calculated by using Joinpoint regression program, National Cancer Institute.
Results: In 2019 globally, the prevalence, incidence, mortality and DALYs from liver disease was 1.69 billion (LC 0.04% and CLD 99.96%), 2.59 million (LC 20.7% and CLD 79.3%); 1.95 million (LC 24.8% and CLD 75.3%) and 58.7 million (LC 21.3% and CLD 78.7%). Over the last decade (2009 to 2019), there was +33.7% increase in prevalence of LC and +22.7% in the prevalence of CLD. Furthermore, there was +30.0% increase in the incidence of LC and +14.8% increase in the incidence of CLD. Finally, both deaths [LC (+27.2%) and CLD (+10.6%)] as well as DALYs [LC (+21.9%) and CLD (+5.1%)] increased.
During the past decade (2009–2019), the observed increases (APC = +1.33%) in global LC death rate (per 100, 000) were driven by NAFLD (from 0.36 to 0.45, APC = +2.47%), ALD (from 0.97 to 1.17, APC = +1.91%), HBV (from 2.25 to 2.48, APC = +0.21%) and HCV (from 1.64 to 1.83, APC = +1.12%) (Figure).
In contrast, between 2009 and 2019, the observed decreases (APC = –0.18%) in the global CLD death rate (per 100, 000) were driven by decrease in HBV (from 5.07 to 4.28, APC = –1.83%); while HCV (from

Improving, APC < 0%

Worsening, APC ≥ 0%

Figure: (abstract: GS008)

4.90 to 5.11, APC = +0.37%), ALD (from 4.67 to 4.81, APC = +0.45%); and NAFLD (1.53 to 1.74, APC = +1.33%) increased.
Analysis of GBD regions suggests that increases (APC) in HBV-, HCV- and NAFLD-related deaths from LC was highest in Central Latin America, while increases in ALD-related death from LC was highest in High-income North American region (Figure). Additionally, increases in HBV-, HCV-, ALD-related deaths from CLD were highest in Caribbean region while increases in NAFLD-related deaths from CLD was highest High-income North American region (Figure).
Conclusion: The burden of CLD and LC are driven by increases in NAFLD and ALD. There are also regional differences in burden and etiology of liver disease.

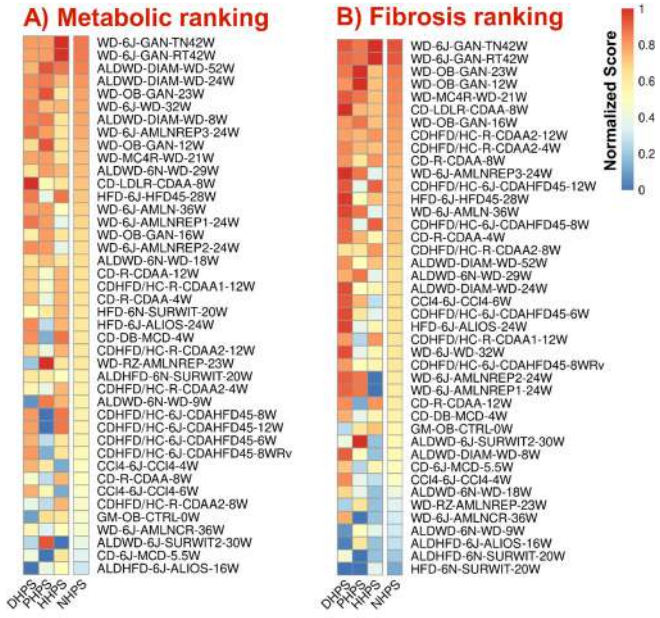
Background and aims: Non-alcoholic fatty liver disease (NAFLD) is recognized as a dysmetabolic state encompassing a wide range of liver diseases, including simple steatosis, steatohepatitis (NASH), cirrhosis, and hepatocellular carcinoma. The majority of preclinical NASH research is performed in rodents; nevertheless, the appropriate model recapitulating human disease is yet uncertain. To address this major unmet need, the LITMUS group did a wide-ranging retrospective review of commonly used murine models, comparing them to human NASH.
Method: We collated data/samples from 42 murine genetic/dietary NAFLD models (617 animals) and developed a complex bioinformatics pipeline providing an unbiassed ranking system (NASH Human Proximity Score, NHPS) that incorporates 1) metabolic phenotype; 2) centralized liver histology; 3) liver transcriptome benchmarked against human NASH (Accession: E-MTAB-9815; GSE130970; GSE135251). NHPS ranked the models based either on their metabolic significance (Fig. A) or ability to induce NASH-fibrosis (Fig. B), both considering a strong (phenotypic/histologic/transcriptomic) relevance to human NASH.
Results: In wild-type (WT) mice, the NHPS found that Western Diets (WD; high in cholesterol, refined carbohydrates, and fat), with/

without sugars in the drinking water, were the most similar to human NASH in terms of metabolic significance (induction of obesity and dyslipidaemia; Fig. A), and ability to induce histologically significant fibrosis (without compromising metabolic relevance; Fig. B). A plethora of choline-deficient (CD) models with varying nutrient (fat, cholesterol, methionine) compositions quickly induced NASH-fibrosis; however, body weight, metabolic profiling and transcriptomic data suggest relatively poor translatability to human NASH (especially in WT mice); these models should be used with caution only for specific purposes (e.g. to test anti-inflammatory or anti-fibrotic compounds). Across the diets investigated, WT rats and genetically altered (GA) models of obesity (e.g. ob/ob, MC4r KO) or hypercholesterolemia (e.g. LDLR KO) had the added benefit of aggravating liver damage and accelerating fibrosis progression while preserving metabolic traits.

Conclusion: Our findings give us a clear picture of how well the phenotype, liver histology, and liver transcriptome of common NAFLD models mimic human illness, and rank the proximity of their phenotype to human NASH. Overall, WD models rank best from a metabolic/transcriptomic standpoint; however, only a few models show substantial fibrosis (F2+), necessitating extended induction durations unless combined with GA backgrounds. The reverse translational value of human biomarkers of NASH progression is being investigated in prospective studies.

Funded by EU Horizon 2020 IMI2 and EFPIA, Grant Agreement 777377 (LITMUS).



NHPS: Weighted sum (1/3 each) of DHPS (DSEA Human Proximity Score – Sequencing data), PHPS (Phenotype Human Proximity Score), HHPS (Histology Human Proximity Score).

Efficacy and safety of finite 48-week treatment with the siRNA JNJ-3989 and the capsid assembly modulator (CAM-N) JNJ-6379 in HBeAg negative virologically suppressed (VS) chronic hepatitis B (CHB) patients: results from REEF-2 study

Kosh Agarwal[1], Maria Buti[2], Florian van Bömmel[3], Pietro Lampertico[4], Ewa Janczewska[5], Marc Bourliere[6], Thomas Vanwolleghem[7,8], Oliver Lenz[9], Thierry Verbinnen[9], Thomas Kakuda[9], Cristina Mayer[9], John Jerzorwski[9], Maria Beumont-Mauviel[9], Ronald Kalmeijer[9], Michael Biermer[9], Isabelle Lonjon-Domanec[9]. *[1]Institute of Liver Studies, King's College Hospital; [2]Hospital Universitario Valle de Hebrón; [3]University Hospital Leipzig; [4]Fondazione IRCCS Ca' Granda, Ospedale Maggiore Policlinico, University of Milan; [5]Medical University of Silesia; [6]Hôpital Saint Joseph; [7]Antwerp University Hospital (UZA); [8]Viral Hepatitis Research Group, Laboratory of Experimental Medicine and Pediatrics, University of Antwerp; [9]Janssen Research and Development*
Email: kosh.agarwal@nhs.net

Background and aims: JNJ-3989 is an siRNA designed to target all hepatitis B virus (HBV) RNAs, thus reducing synthesis of all HBV proteins. JNJ-6379 is a CAM-N that inhibits viral replication by inducing the formation of empty viral particles. The REEF-2 study assessed the efficacy and safety of JNJ-3989 200 mg SC Q4W, JNJ-6379 250 mg PO QD, and nucleos(t)ide analog (NA) PO QD in patients with HBeAg negative CHB.

Method: In this Phase 2b, double-blind, multicenter (EU only), placebo (PBO)-controlled study, non-cirrhotic HBeAg negative CHB patients with HBsAg >100 IU/ml and NA treatment for ≥2 years were randomized (2:1) to receive add-on JNJ-3989 + JNJ-6379 or PBO. All treatment including NA was discontinued after 48 weeks. The primary end point was the proportion of patients achieving HBsAg <0.05 IU/ml at follow-up week 24 without restarting NA treatment. Here, we report interim data at week 48 (end of treatment; EOT).

Results: 130 patients (67% male, 20% Asian, mean age 46 [23–65] years) were analyzed (85 active, 45 control). In the active and control arm at baseline (BL), 80% and 76% of patients had HBsAg levels ≥1,000 IU/ml (mean 3.4 [2.0–4.6] and 3.5 [2.0–4.8] $\log_{10}$ IU/ml) and mean duration of prior NA use was 8.4 (2.2–20.7) and 8.1 (2.2–17.4) years. At EOT, mean (SE) reductions in HBsAg from BL were −1.89 (0.060) $\log_{10}$ IU/ml in the active arm and −0.06 (0.012) $\log_{10}$ IU/ml in the control arm. In Asian (n = 15) and non-Asian patients (n = 61) in the active arm, HBsAg reductions were −2.05 (0.52) $\log_{10}$ IU/ml and −1.85 (0.52) $\log_{10}$ IU/ml, respectively. At EOT, the proportion of patients achieving HBsAg <100, <10, <1 IU/ml was 71.1%, 19.7%, and 2.6% in the active arm; and 2.4%, 0%, and 0% in the control arm; no patient in either arm achieved HBsAg seroclearance. Adverse events (AEs) were reported in 81.2% and 71.1% of patients in the active and control arms (grade 3/4 AEs were 15.3% and 4.4%). 7.1% of patients in the active arm had grade 3 eGFR events. After treatment initiation, eGFR reductions were seen in the active arm without further progression on continued treatment. Serious AEs were reported in 2 patients in the active arm and 1 patient in the control arm; none were considered related to study drug. Treatment discontinuation rates were 3.5% and 2.2% in the active and control arms; no AEs led to death.

Conclusion: JNJ-3989 + JNJ-6379 + NA showed greater reduction in HBsAg levels over 48 weeks compared to PBO + NA and was generally well tolerated and safe.

Microbial produced ethanol: an underestimated burden on the liver

Stijn Meijnikman[1], Mark Davids[2], Hilde Herrema[1], Omrum Aydin[1], Valentina Tremaroli[3], Joanne Verheij[1], Maurits De Brauw[4], Sven Francque[5], Christophe De Block[5], Fredrik Backhed[3], Victor Gerdes[1], Bert Groen[1], Max Nieuwdorp[1]. *[1]Amsterdam UMC, locatie AMC, Amsterdam, Netherlands; [2]Amsterdam UMC, locatie AMC, Vascular Medicine, Amsterdam, Netherlands; [3]Gothenburg University, Gothenburg, Sweden; [4]Spaarne Hospital Hoofddorp, Hoofddorp, Netherlands; [5]Antwerp University Hospital, Edegem, Belgium*
Email: a.s.meijnikman@amc.uva.nl

Background and aims: Endogenously produced ethanol has been suggested to play a significant role in the development of Non-Alcoholic Fatty Liver Disease (NAFLD). However, its role in human disease has never been demonstrated unequivocally. Here, we report on microbial endogenous ethanol production in individuals with and without NAFLD using four experiments in which we sampled portal vein blood, stimulated endogenous ethanol production, inhibited alcohol dehydrogenase (ADH) and eradicated ethanol producing bacteria via supplementation of broad-spectrum antibiotics.
Method: We designed and performed one prospective clinical study and one intervention study. In the first study, we enrolled 146 individuals from our bariatric surgery (BARIA cohort) and measured ethanol in fasting and 120 minutes after a mixed meal test (MMT). To study the burden of endogenously produced ethanol, we calculated difference between portal and peripheral plasma ethanol levels in a subset of individuals and validated in an external cohort. In the intervention study, 10 individuals with NAFLD and 10 healthy controls were infused with the selective ADH inhibitor 4-methylpyrazole and then underwent an MMT. In the NAFLD group, the MMT with 4-methylpryazol infusion was repeated after a week of supplementation with oral broad-spectrum antibiotics. Fecal shotgun metagenomics was performed in both studies.
Results: Endogenously produced ethanol was present in fasting samples at baseline with a profound increase observed 120 minutes after the MMT. Also, positive correlations were found between post prandial plasma ethanol and several (small intestinal) species belonging to the Lactic Acid Bacteria (LAB).
Portal vein ethanol concentrations increased in a dose dependent manner reaching mean levels in NAFL and NASH groups over 30 mmol/L. In the validation cohort, similar levels were observed. Portal vein ethanol positively correlated with LAB in the small intestine. Finally, in the intervention study, endogenously produced ethanol increased in all participants during the MMT, yet was significantly higher in the NAFLD group. Subsequently, depletion of intestinal microbiota following broad spectrum antibiotics resulted in near complete suppression of detectable ethanol during the MMT with 4-methylpyrazole, underscoring potential causality.
Conclusion: The human gut microbiome can produce large amounts of ethanol, which are clinically relevant in the pathogenesis of NAFLD. LAB abundance correlated significantly with high plasma ethanol concentrations in fasting portal vein blood and in postprandial venous blood.

Background and aims: NAFLD affects 55% of people with type 2 diabetes mellitus (T2DM), and glycaemic control predicts the severity of ballooning and fibrosis in NAFLD. Dietary interventions with low carbohydrates improve glycaemic control but the effect on NAFLD activity is unknown. We aimed to investigate the effect of a six-month low-carbohydrate high fat (LCHF) diet on NAFLD assessed by ≥2 points improvement in the NAFLD Activity Score (NAS) with at least 1 point improvement in either lobular inflammation or ballooning without worsening of fibrosis and on glycaemic control.
Method: We conducted a six-month randomised controlled diet trial in 185 people with T2DM. Participants were randomised 2:1 to LCHF or to a diet consisting of high carbohydrates and low fat (HCLF). Both diets were non-calorie-restricted. The LCHF diet consisted of maximum 20 energy percent (E%) carbohydrates, 50–60E% fats and 25–30E% proteins. The HCLF diet consisted of 50–60E% carbohydrates, 20–30E% fats and 20–25E% proteins. We performed liver biopsies and measured HbA1c (mmol/mol) at baseline and after six months. Biopsies were scored in a blinded matter according to the Non-alcoholic Steatohepatitis Clinical Research Network. The participants had ongoing dietitian consultations and compliance was reported continuously through an online food diary platform.
Results: Out of 185 randomised participants, 165 commenced the allocated intervention and were included in the analysis. At baseline the mean age was 56 (SD, 10) years, 58% were female, 88% had NAFLD, median NAS was 3 (1–5) and mean HbA1c was 56 (SD, 10) mmol/mol. After intervention we saw no significant difference between the groups in relation to improvement of ≥2 points in NAS ($p = 0.587$). However, more participants in the LCHF group improved NAS with ≥1 point compared to the HCLF group (70% versus 49%; $P = 0.028$), and fewer in the LCHF group experienced a worsening of NAS compared to the HCLF group (1% versus 23%; $P < 0.001$) (Figure). Participants in the LCHF group improved HbA1c with −9.5 versus −3.4 in the HCLF group ($p < 0.001$) and lost significantly more weight than in the HCLF group (−5.7 kg vs. −1.8 kg; $P < 0.001$). The self-reported macronutrient intake in LCHF versus HCLF throughout the intervention was 13/46E% carbohydrates, 61/29E% fats and 23/21E%.

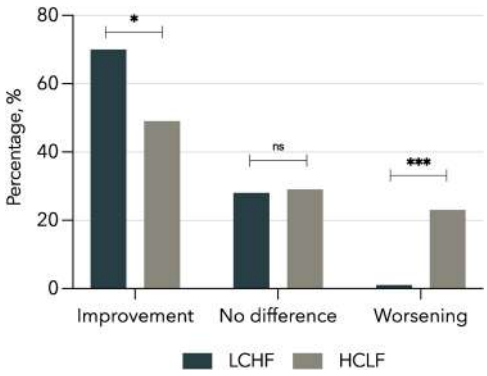

Figure: Change in NAS.

Conclusion: A six-month non-calorie-restricted LCHF diet improves NAS and HbA1c significantly more than a HCLF diet in people with T2DM.

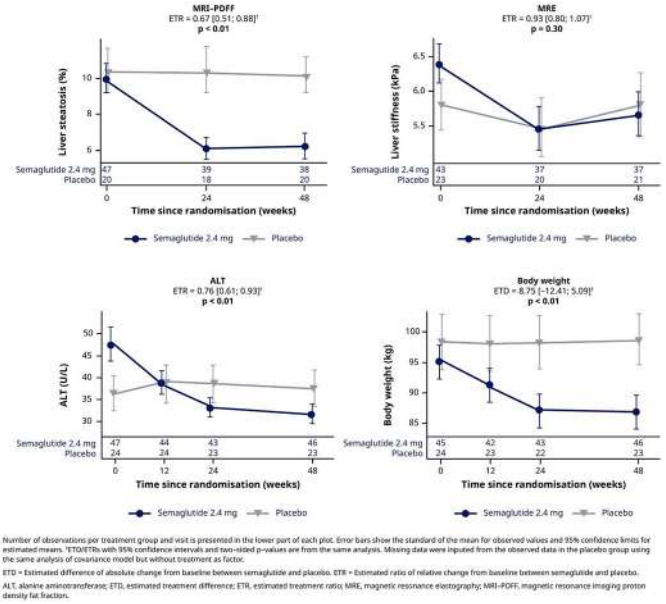
Background and aims: Patients with non-alcoholic steatohepatitis (NASH) and compensated cirrhosis (CC) are at high risk of liver-related and all-cause morbidity and mortality. In a previous placebo-controlled trial in patients with NASH without cirrhosis (NCT02970942), the glucagon-like peptide-1 receptor agonist semaglutide improved NASH resolution and associated metabolic parameters, and was well tolerated. We investigated the efficacy and safety of semaglutide in patients with NASH and CC.
Method: In a phase 2, randomised, placebo-controlled trial, adults with biopsy-confirmed NASH and CC, body mass index (BMI) ≥27 kg/m^2 and glycated haemoglobin (HbA_{1c}) ≤9.5% were randomised 2:1 to semaglutide 2.4 mg or placebo once weekly for 48 weeks. Histological parameters were assessed at baseline and week 48 by a single pathologist. The primary end point was the proportion of patients with ≥1 stage of liver fibrosis improvement without worsening of NASH after 48 weeks. Supportive secondary end points included NASH resolution, changes in: alanine- and aspartate-aminotransferase (ALT, AST); liver stiffness assessed by magnetic resonance elastography (MRE); liver fat content measured by magnetic resonance imaging proton density fat fraction (MRI-PDFF); cardiometabolic parameters; and exploratory biomarkers, and adverse events (AEs).
Results: Patients (N = 71) were mainly female (69%), with a mean age of 59.5 ± 8.0 years, BMI 34.9 ± 5.9 kg/m^2 and non-alcoholic fatty liver disease activity score 4.8 ± 1.0; 75% had type 2 diabetes. Baseline parameters were balanced between treatments. There was no difference between semaglutide and placebo for the primary end point (10.6% vs 29.2%; p = 0.09) or NASH resolution (34.0% vs 20.8%; p = 0.29). Compared with placebo, semaglutide reduced ALT (Figure), AST (estimated treatment ratio [ETR] 0.77; p < 0.01), MRI-PDFF but not MRE score (Figure), and pro-C3 levels (ETR 0.84; p = 0.03), and led to reductions in HbA_{1c} (estimated treatment difference −1.63; p < 0.01 for patients with diabetes) and body weight (Figure). Semaglutide also reduced triglycerides (ETR 0.83; p = 0.01) and very low-density lipoprotein cholesterol (ETR 0.83; p = 0.01). Similar proportions of semaglutide and placebo recipients reported AEs during the trial (89.4% vs 79.2%, of which 12.8% and 8.3%, respectively, were serious). Gastrointestinal AEs occurred in 76.6% of semaglutide recipients (vs 33.3% with placebo). Hepatic and renal function remained stable. There were no decompensating events or deaths.
Conclusion: Although the primary end point was not met, semaglutide 2.4 mg once weekly appeared safe, was well tolerated and improved cardiometabolic parameters and non-invasive markers of liver injury associated with fibrosis progression. Larger trials are needed to investigate whether semaglutide improves liver-related morbidity and mortality in patients with NASH and CC.



Number of observations per treatment group and visit is presented in the lower part of each plot. Error bars show the standard of the mean for observed values and 95% confidence limits for estimated means. †ETD/ETRs with 95% confidence intervals and two-sided p-values are from the same analysis. Missing data were imputed from the observed data in the placebo group using the same analysis of covariance model but without treatment as factor.
ETD = Estimated difference of absolute change from baseline between semaglutide and placebo. ETR = Estimated ratio of relative change from baseline between semaglutide and placebo.
ALT, alanine aminotransferase; ETD, estimated treatment difference; ETR, estimated treatment ratio; MRE, magnetic resonance elastography; MRI-PDFF, magnetic resonance imaging proton density fat fraction.

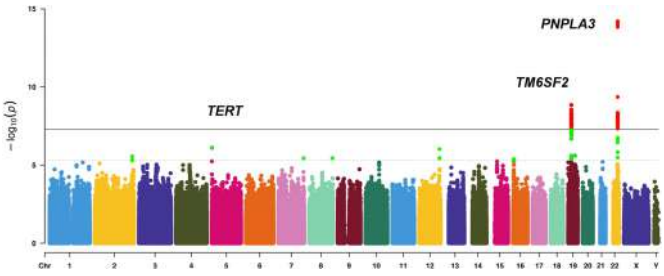
Background and aims: Hepatocellular carcinoma (HCC) often develops in patients with alcohol-related cirrhosis (ArC) at an annual risk of up to 2.9%. Some host genetic risk factors have been identified but do not account for the majority of the variance in occurrence. This study aimed to identify novel risk factors for the development of HCC in people with alcohol related cirrhosis.
Method: Patients with alcohol-related cirrhosis with HCC (cases: n = 1, 214) and without HCC (controls: n = 1, 866), recruited from Germany, Austria, Switzerland, Italy and the UK, were included in a two-stage GWAS utilizing a case-control design. A validation cohort of 1, 520 people misusing alcohol but with no evidence of liver disease was included to control for possible association effects of alcohol misuse *per se*. Genotyping was performed using the Infinium®Global Screening Array (GSA) (version 24v2, Illumina) and the OmniExpress Array (version 24v1-0a, Illumina).
Results: Associations with variants rs738409 in *PNPLA3* and rs58542926 in *TM6SF2* previously associated with HCC in patients with alcohol-related cirrhosis were confirmed at genome-wide significance. In addition, a novel locus rs2242652 in *TERT* (telomerase reverse transcriptase) attained genome-wide significant association in the combined meta-analysis with alcohol-related HCC at ($p = 6.41 \times 10^{-9}$, odds ratio (OR) = 0.61 (95%CI, 0.52–0.72). This protective association remained significant after correction for sex, age, BMI, type 2 diabetes, and ancestry. The minor alleles of variants rs2242652 ($p = 2.12 \times 10^{-44}$) and rs10069690 ($p = 4.08 \times 10^{-84}$) in *TERT* were associated with increased leukocyte telomere length.



Conclusion: This study identifies rs2242652 in *TERT* as a novel protective factor for HCC in patients with alcohol-related cirrhosis.

Background and aims: Necroptosis is a novel form of programmed cell death controlled through the molecules RIPK3 and MLKL. Recent studies showed that necroptosis and not apoptosis represents the dominant cell death pathway activated in non-alcoholic fatty liver disease (NAFLD). However, it is unknown how necroptosis and immune reactions are functionally related in the liver, if sublethal forms of necroptosis exist in vivo and how these molecular processes control the transition from chronic liver disease to hepatocellular carcinoma (HCC).
Method: We generated conditional genetic mouse models to activate necroptosis in hepatocytes and performed genetic sub-crossings for functional pathway dissection. We characterized liver inflammation through immunohistochemistry, biliary architecture through 3-D-Reconstruction of multi-slice immuno-fluorescence and HCC development through array-CGH-analysis. Immune-signatures ('Necroptome') were characterized by scRNA sequencing. Moreover, we developed a novel 2-photon-approach for live-imaging of necroptosis and the spatial and dynamic relation to immune cells in vivo. Mechanistic findings in mice were correlated with data from human NAFLD and HCC.
Results: We show for the first time that two alternative forms of necroptosis exist in the liver triggering distinct immunological response-programs licensed through the activation status of NF-kB. As such, pre-activation of NF-kB transforms hepatocytes into a sublethal state. In this "undead" state, the necroptosis machinery induces leakiness of cell membranes, allowing the release of NF-kB-dependent cytokines including CCL-20, IL-6 and MCP1. These functional alarmins promote activation of necroptosis-specific monocyte/macrophage subsets that in turn show a pro-carcinogenic and pro-fibrotic profile on single-cell level, ultimately promoting HCC development. In contrast, inhibition of distinct members of the NF-kB pathway (IKK-beta, NEMO, RelA) converts necroptosis into a rapidly lethal form of cell death. These rapidly dying hepatocytes do not release cytokines/alarmins upon their death, thus failing to trigger a reactive immune and stellate cell signature. Consequently, reprogramming towards this "hypo-reactive" necroptosis form prevents HCC development. In line, we identified areas of co-activation of NF-kB and the necroptosis machinery in human NAFLD biopsies and additionally could show that human patients with HCC featuring a transcriptional profile matching the newly discovered NF-kB/Necroptosis/Signature in mice had a specifically fatal clinical outcome.
Conclusion: Necroptosis can occur in two functionally distinct forms in the liver. Pharmacological reprogramming between these two alternative forms might represent a novel strategy to prevent the transition from chronic liver disease towards HCC development in high-risk NAFLD patients.

Background and aims: Bepirovirsen (BPV; GSK3228836) is an antisense oligonucleotide shown to induce a reduction in hepatitis B surface antigen (HBsAg), and in some cases transient HBsAg seroclearance, following 4 weeks (wks) treatment with a favourable safety profile in a phase 2a study in patients (pts) with chronic hepatitis B (CHB) infection. B-Clear is a phase 2b trial (NCT04449029) assessing the efficacy and safety of 12 or 24 wks BPV treatment in pts with CHB on-stable nucleos (t)ide analogue (NA) treatment or not on-NA therapy at study start. The study is ongoing; here we present interim results through the end of BPV treatment (EoT) for pts not on NA therapy.
Method: Multicentre, randomised, partial-blind (investigator unblinded), parallel-cohort study in pts with CHB. Pts required HBsAg >100 IU/ml, HBV DNA >2000 IU/ml and alanine aminotransferase <3× upper limit of normal. Pts were randomised (3:3:3:1) to 1 of 4 treatment arms, with treatment administered weekly with (w/) or without (w/o) loading doses (LD) on Days 4 and 11: 1. BPV 300 mg w/LD for 24 wks; 2. BPV 300 mg w/LD for 12 wks then 150 mg for 12 wks; 3. BPV 300 mg w/LD for 12 wks then placebo (PBO) for 12 wks; 4. PBO for 12 wks then BPV 300 mg w/o LD for 12 wks. Pts were stratified by baseline hepatitis B e antigen (HBeAg; positive/negative) and HBsAg level (≤3 or >3 log10 IU/ml). Primary end point: proportion of pts achieving HBsAg <lower limit of quantification (LLOQ) and HBV DNA <LLOQ sustained for 24 wks without rescue medication after planned BPV EoT. Secondary end points reported here: proportion of pts achieving HBsAg <LLOQ and HBV DNA <LLOQ by BPV EoT. Safety was assessed via adverse event (AE) monitoring.
Results: 230 pts (54% male, 57% Asian, 74% HBeAg negative, 19% HBsAg ≤3 log10 IU/ml) were included in the intent-to-treat

population (70, 68, 68 and 24 pts, respectively, in arms 1–4); 21 pts (9%) discontinued treatment. At EoT, 29%, 13%, 7% and 0% pts had HBsAg <LLOQ and HBV DNA <LLOQ in arms 1–4, respectively. HBsAg response data are shown in Figure. Overall, serious AEs (SAEs) were reported in 4% pts and treatment-related SAEs in 1% pts. No clinically meaningful differences in AEs across treatment arms.

Conclusion: 24 wks of 300 mg BPV resulted in HBsAg <LLOQ and HBV DNA <LLOQ in 29% of pts at EoT; the durability of this response is being assessed. There were no safety signals to preclude further development.

Background and aims: Approval of a drug therapy for NASH requires a very good safety/tolerability profile and acceptable therapeutic index. MAESTRO-NAFLD-1 (NCT04197479) is a randomized double-blind (DB) Phase 3 clinical trial of placebo (PBO) versus resmetirom (RES), a once-a-day oral selective thyroid hormone receptor β agonist, in >1100 patients with NAFLD with safety as the primary end point.
Method: Enrollment was Dec 2019 to Oct 2020 at 79 US sites. Requirements included 3 metabolic risk factors, fibroscan (FS) ≥5.5 kPa/CAP≥280 dBm, MRI-PDFF≥8%. Randomization was 1:1:1:1 to 3 DB arms, PBO, 80 or 100 mg RES (n = 972) or an 100 mg open label (OL) arm (n = 171). The primary objective was to evaluate the safety and tolerability of 80 or 100 mg RES versus PBO measured by the incidence of adverse events (AEs).
Results: At baseline the DB safety population (n = 969) was age 55.9 (11.8); female, 54.4%, white 88.6%; hispanic 34.7%; BMI 35.3 (6.0) type 2 diabetes 49%, hypertension 76.1%, dyslipidemia 87.9%; FS 7.4 (4.7) kPa. Discontinuations (22.5%) did not differ by treatment, most patient decision (pandemic related). DB compliance was impacted by COVID drug kit delays. AE withdrawals were 80 mg, 2.4%; 100 mg, 2.8%; PBO, 1.3%. The primary objective was met. TEAEs were 80 mg, 88.4%; 100 mg, 86.1%; PBO, 81.8%. TEAEs ≥grade 3 severity were 80 mg, 7.6%; 100 mg, 9.0%; PBO, 9.1%. AEs in excess of PBO were grade 1–2 AEs of diarrhea (80 mg, 23.5%; 100 mg, 31.2%; PBO, 13.8%) and nausea (80 mg, 11.9%; 100 mg, 18.2%; PBO, 7.9%), in the first few weeks. ALT increases ≥3XULN were 80 mg, 0.61%; 100 mg, 0.31%; PBO, 1.6%. There were no changes in body weight or HR. BP decreased by 2–3 mmHg in the RES arms. Key 2° end points were met (Table). Comparative mean reduction in FS VCTE was not significant; a responder analysis of FS and MRE showed significant reductions with RES treatment.
Conclusion: RES achieved the primary safety end point in this 52-week Phase 3 NAFLD clinical trial that identified patients by metabolic risk and non-invasive imaging. Key 2° end points were met including LDL-C, ApoB, triglycerides, MRI-PDFF, FS (CAP).

Reduction of intra-hepatic Z-AAT synthesis by fazirsiran decreases globule burden and improves histological measures of liver disease in adults with alpha-1 antitrypsin deficiency

Pavel Strnad[1], Mattias Mandorfer[2], Gourab Choudhury[3], Griffiths Bill[4], Christian Trautwein[1], Rohit Loomba[5], Romil Saxena[6], Thomas Schluep[7], Ting Chang[7], Min Yi[7], Bruce Given[7], James Hamilton[7], Javier San Martin[7], Jeffrey Teckman[8]. Email: pstrnad@ukaachen.de

Background and aims: Adults homozygous for PiZZ synthesize mutant alpha-1 antitrypsin (Z-AAT) that accumulates in hepatocytes leading to progressive liver disease and fibrosis. Fazirsiran, an investigational RNAi therapeutic, silences liver Z-AAT mRNA to reduce Z-AAT synthesis. This analysis assessed histological changes in patients (pts) with PiZZ AATD liver disease receiving fazirsiran in an ongoing, open-label, phase 2 study.
Method: Fazirsiran (200 mg [n = 12] or 100 mg [n = 4]) was administered subcutaneously on Day 1, Week (wk) 4 and then every 12 wks. The primary end point was change in liver Z AAT as measured by LC-MS/MS at Wk 24 or 48. Three pathologists blinded to subjects and time points assessed and adjudicated histological parameters including globule burden (periodic acid-Schiff with diastase [PAS +D] staining for extent of portal tract and periportal hepatocyte involvement and zonal location; total score of 0–9), globule size (scored by comparing % of total granules or size of largest globule to the size of a red blood cell; total score of 0–6), portal inflammation (score of 0–3), and METAVIR fibrosis (F0–F4).
Results: Fazirsiran reduced liver Z-AAT in all pts by a mean of 85% at Wk 24/48, with concomitant reductions in histological globule burden (mean score 7.4 at baseline and 2.3 at Wk 24/48). All 16 pts also showed reductions in globule size (mean score 3.0 at baseline and 1.0 at Wk 24/48). Removal of Z-AAT improved histological assessments of portal inflammation, a key feature of AATD liver disease; approximately two-thirds (8/13) of pts with a baseline score of ≥1 in portal inflammation showed improvement at Wk 24/48. In particular, portal inflammation on biopsy has been shown in previous observational studies to be strongly associated with fibrosis progression. Overall, 7/15 pts (7/12 subjects receiving 200 mg dose and 0/3 subjects receiving 100 mg dose) had a ≥1-point improvement in fibrosis. Fazirsiran was well tolerated, with no adverse events leading to study/drug discontinuation.
Conclusion: By reducing Z-AAT synthesis, fazirsiran improved histological features of AATD liver disease, including reductions in globule burden/size and severity of portal inflammation, leading to fibrosis regression.

Hepatitis C: Clinical aspects and therapy

OS001

Results of a ten year prospective observational study on acute hepatitis C in HCV-mono- and HIV/HCV-coinfected patients

Christiana Graf[1], Lara Fuhrmann[2,3], Lutz Thomas[4], Christoph Stephan[5], Gaby Knecht[4], Peter Gute[4], Markus Bickel[4], Kai-Henrik Peiffer[1], Fabian Finkelmeier[1], Georg Dultz[1], Nils Wetzstein[5], Natalie Filmann[6], Eva Herrmann[6], Stefan Zeuzem[1], Niko Beerenwinkel[2,3], Julia Dietz[1], Christoph Sarrazin[1,7]. *[1]Goethe University Hospital Frankfurt, Department of Internal Medicine I, Frankfurt, Germany; [2]ETH Zurich, Department of Biosystems Science and Engineering, Basel, Switzerland; [3]SIB Swiss Institute of Bioinformatics, Basel, Switzerland; [4]Infektiologikum, Frankfurt, Germany; [5]Goethe University Hospital, Department of Infectious Diseases, Frankfurt, Germany; [6]Goethe University Frankfurt, Institute of Biostatistics and Mathematical Modeling, Frankfurt, Germany; [7]St. Josefs-Hospital, Medizinische Klinik II, Wiesbaden, Germany*
Email: christiana.graf@kgu.de

Background and aims: Over the last two decades, a persistent epidemic of acute Hepatitis C virus (HCV) infections has been observed in HIV-positive men who have sex with men (MSM) in several metropolitan areas worldwide. In this study, epidemiological and clinical parameters as well as phylogenetic analyses were conducted to characterize HCV transmission among MSM.
Method: This prospective observational study analysed clinical and epidemiological parameters of patients with confirmed acute HCV infection between 2009 and 2019 from 3 centers in Frankfurt. NS5B population-based sequencing was performed at the time of diagnosis to determine HCV genotype (GT) and for phylogenetic analyses.
Results: A total of n = 161 patients diagnosed with acute HCV-infection were included in the study, of whom n = 140 (87%) were HIV-positive and n = 145 (90%) were MSM. We observed a different distribution of HCV genotypes over time. In the first eight years, HCV GT1a was most common (58–100%) but decreased to 30% in 2018. In contrast, the proportion of GT4d cases increased. While no GT4d cases were diagnosed in 2013, the proportion rose to 40% in 2019. There was a slight trend towards more GT3a cases in 2018 and 2019, while for GT1b and GT2 only individual cases were detected between 2009 and 2014. MSM were mainly infected with HCV GT1a (82%, 115/140) or GT4d (16%, 23/140 with sequencing data available). In contrast, HCV GT were almost equally distributed in non-MSM patients. Here, 36% were infected with HCV GT1a, 21% each with GT1b or GT3a and 16% had GT2. Phylogenetic analyses in NS5B showed a diverse sequence pattern in patients with HCV GT1b and GT3a. In contrast, HCV strains among MSM infected with HCV GT1a and 4d were more closely related. Based on the comparison of HCV GT or NS5B sequences, 24 patients (15%) were diagnosed with an HCV reinfection. The incidence rate in MSM for a first HCV infection declined in the period between 2017 and 2019 (3.6/1000PY) compared to the DAA era between 2013 and 2017 (6.8/1000 PY) and to the interferon era (2008–2013; 10.1/1000 PY). Conversely, the incidence of HCV reinfections among MSM increased slightly from 1.9/100PY to 2.8/100PY over time.
Conclusion: During the last 5 study years the prevalence of GT4 infections increased, while annual acute hepatitis C incidences decreased. HCV reinfection is an issue of major concern in HIV-positive MSM and may have implications for HCV elimination.

OS002

Multicenter prospective study for the use of shortened pre-emptive therapy with Glecaprevir/Pibrentasvir (G/P) and Ezetimibe in hepatitis C (HCV) seronegative non-liver solid organ transplant recipients of HCV viremic grafts

Bashar Aqel[1], Surakit Pungpapong[2], Adyr Moss[1], Rolland Dickson[1]. *[1]Mayo Clinic, Gastroenterology, Hepatology and Liver Transplant, Phoenix, United States; [2]Mayo Clinic, Jacksonville, United States*
Email: aqel.bashar@mayo.edu

Background and aims: Use of HCV viremic grafts has been associated with reduced waiting time and cost effectiveness analyses has been favorable. Preemptive treatment approach prevent delay in treatment initiation and will help eliminate risks of untreated HCV viremia. G/P is a highly effective direct acting antiviral agents with pangenotypic coverage and ezetimibe was found to help blocking the cholesterol receptor used by the HCV virus for cell entry.
Assess the efficacy and cost effectiveness of preemptive therapy with eight days of a combination of G/P and ezetimibe in recipients of non-liver HCV viremic solid organ transplant.
Method: This is a multicenter prospective, open label, internally funded study. Solid organ recipients who agreed to accept HCV viremic grafts were consented for the study. HCV pre-emptive therapy with G/P and ezetimibe was initiated upon call to the

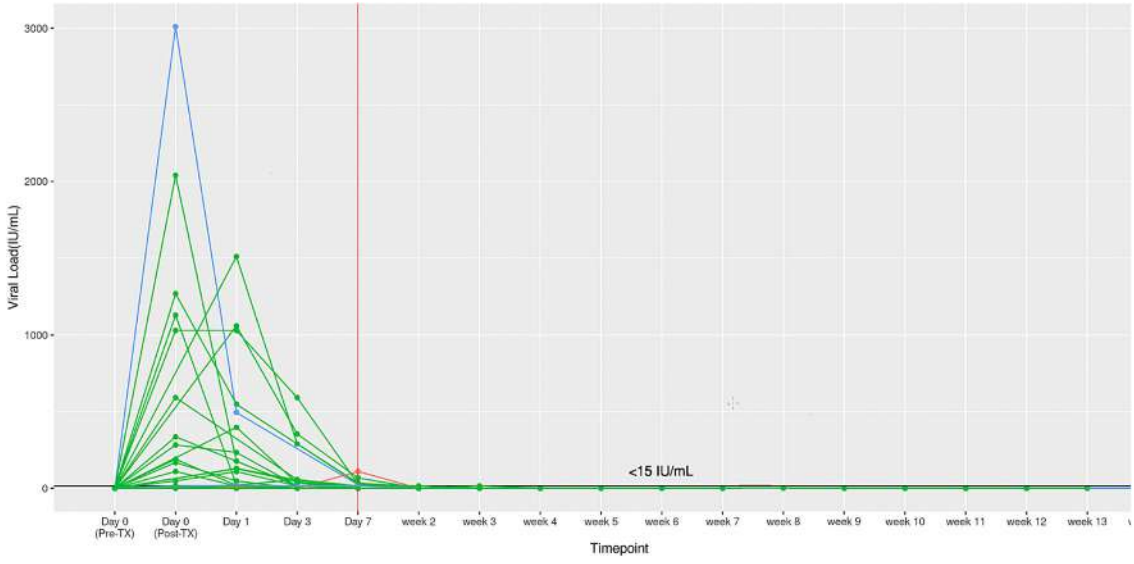

Figure: (abstract: OS002)

operative room. Combination therapy was continued for 7 days after transplant (total of 8 doses). HCV RNA was monitored up to 24 weeks post-transplant, and patients followed for 1 year to determine graft and patient survivals.
Results: 38 patients (32 kidney tx, 2 kidney/pancreas tx, 3 heart tx, 1 heart/kidney tx) have been enrolled to date. All patients completed treatment. Median age for patients was 60 years and 63% were males. Median time from list for HCV viremic grafts to tx was 32, 52, 71, and 151 days for heart, heart/kidney, kidney, and kidney/pancreas tx recipients respectively. Median donor age was 35 years. All donors had confirmed viremia. Transient viremia during the first 2 weeks post tx was detected in 28/38 (74%) patients (HCV RNA range 16–6870 IU/ml), and 12 patients had detectable viremia on post tx day 7 when treatment was completed (HCV RNA range of detectable but not measurable RNA-110 IU/ml). Four (4/38) patients continued to have detectable HCV RNA at week 2 post tx, and one of those patients remained detectable week 3 post tx. All patients achieved undetectable HCV RNA by week 4 post tx and all patients stayed negative 13 weeks post tx (SVR 12 of 100%) (Fig. 1). The cost of this preemptive approach was significantly lower when compared to the standard of care reactive treatment approach. Treatment was well tolerated, and all patients completed 8 days of combination therapy. One kidney transplant recipient died 65 days post-tx with acute subdural hematoma. This patient completed treatment per protocol and achieved viral clearance (undetectable HCV RNA at post tx week 8).
Conclusion: In the largest multicenter U.S. experience to date, G/P combined with ezetimibe was highly effective in preventing HCV infection in 100% of non-liver solid organ transplant recipients of HCV viremic grafts. Short-term graft and patient survivals are excellent. This approach appears to be cost effective and will potentially eliminate the risk of post-transplant complications from HCV transmission and enhance the use of HCV viremic grafts.

OS003
Effectiveness of voxilaprevir/velpatasvir/sofosbuvir in hepatitis C patients previously treated with direct-acting antiviral agents (DAA)

Christiana Graf[1], Julia Dietz[1], Beat Müllhaupt[2], Peter Buggisch[3], Jörn Schattenberg[4], Christoph Antoni[5], Stefan Mauss[6], Elena Durmashkina[7], Claus Niederau[8], Thomas Discher[9], Julian Schulze zur Wiesch[10], Tobias Müller[11], Thomas Berg[12], Christoph Neumann-Haefelin[13], Christoph Berg[14], Stefan Zeuzem[1], Christoph Sarrazin[1,7]. *[1]Goethe University Hospital, Department of Internal Medicine I, Frankfurt am Main, Germany; [2]University Hospital Zürich, Swiss-Hepato-Pancreato-Biliary Center and Department of Gastroenterology and Hepatology, Zürich, Switzerland; [3]Institute of Interdisziplinary Medicine IFI, Hamburg, Germany; [4]University Medical Center Mainz, I. Email: christiana.graf@kgu.de

Background and aims: Voxilaprevir/velpatasvir/sofosbuvir (VOX/VEL/SOF) is approved for HCV retreatment of direct-acting antiviral agents (DAA)-experienced patients. However, real-life data are still limited. The aim of the study was to analyse the effectiveness of VOX/VEL/SOF in a real-world setting.
Method: All consecutive patients with HCV retreated with VOX/VEL/SOF after DAA failure were enrolled in 153 centers in Germany, Austria, Switzerland and Belgium between May 2015 and November 2020. Sustained virological response (SVR) was defined as undetectable HCV RNA 4 (SVR 4) or 12 (SVR12) weeks after the end-of-treatment.
Results: A total of 416 patients were included: median age was 55 (21–84) years, 79% were male, median HCV RNA was 383, 000 (10–58, 300, 000) IU/ml. HCV genotype (GT) was 1 in 54% (1a in 26%, 1b in 28%), 2 in 1%, 3 in 39% and 4 in 6%. Patients received VOX/VEL/SOF for 12 weeks, ribavirin was added in 4% of treatment schedules. Overall, 365/416 (87.7%) patients by intention to treat analysis and 401/416 (96.4%) by per protocol analysis achieved SVR12, respectively. Genotype 3a ($p = 0.008$) and hepatocellular carcinoma ($p = 0.0034$) were the only predictors of a treatment failure. Treatment effectiveness was not significantly affected by the type of previous DAA regimen, by liver cirrhosis, HCV GT 1a and baseline HCV-RNA viral load. Virologic relapse was observed in 20 patients (10% GT1a, 15% GT1b, 75% in GT3a). The presence of resistance-associated substitutions within NS3, NS5A, and NS5B genes did not impact SVR12 ($p = 0.06$).
Conclusion: VOX/VEL/SOF is an effective retreatment for patients with HCV who have failed on a previous DAA course in a real-life setting. We identified HCV GT 3a and HCC as the main predictors of VOX/VEL/SOF failure.

OS004
Glecaprevir/pibrentasvir and sofosbuvir for 16 weeks without ribavirin is safe and highly effective retreatment for patients who have failed an NS5A inhibitor containing antiviral regimen

Edward J. Gane[1], Bridget Faire[2], Sherine Helmy[3], James Freeman[4]. *[1]University of Auckland, Grafton Campus, Liver Unit, Auckland, New Zealand; [2]New Zealand Liver Transplant Unit-Ward 71, Auckland, New Zealand; [3]Pharco Corporation, Cairo, Egypt; [4]GP2U, Australia*
Email: edgane@adhb.govt.nz

Background and aims: Oral DAA therapy has been available in New Zealand since mid-2016 for treatment of chronic hepatitis C. Over the last 5 years, more than 10,000 New Zealanders have been treated with NS5A inhibitor- based DAA therapy, of whom more than 300 have had virologic failure. Retreatment of patients with confirmed antiviral resistance requires a triple DAA combination of a polymerase, a protease and an NS5A inhibitor.
Method: In an open-labelled, ethics-approved study, 100 New Zealanders who had failed DAA therapy with confirmed NS5A resistance will be retreated with glecaprevir/pibrentasvir (GLE/PIB) from Feb 2019) plus sofosbuvir for 16 weeks. Patients with decompensated cirrhosis or hepatocellular carcinoma or post-transplant are excluded.
Results: To-date, 57 patients have been enrolled in the study. Median age was 56 years (38–80), 78% were male and 44% had established cirrhosis. Thirty-five patients had previously failed GLE/PIB, 19 failed ombitasvir, paritaprevir, dasabuvir, and ritonavir (PrOD) and 1 each failed grazoprevir/elbasvir (GRZ/ELB), ledipasvir/sofosbuvir (LDV/SOF) and sofosbuvir/velpatasvir (SOF/VEL). Six patients had failed multiple regimens. Most frequently detected NS5A resistance-associated substitutions (RASs) were Y93H (57%), A30 K (26%), Q30 K/H (26%, M28 T/F/V (11%). Multiple NS5A RASs were detected in 39% patients. Resistance profiles were similar in PrOD and GLE/PIB failures.
One patient died from opioid overdose during treatment. There were no other SAEs or AE-related treatment discontinuations. Two other patients stopped treatment within 4 weeks because of psychosocial issues, one of whom has started retreatment.
45 patients have completed therapy and 37 have reached the SVR12 timepoint, of whom 36 (98%) are cured (complete SVR results will be available in early 2022). The only treatment failure to-date was a 53-year-old noncirrhotic female, previously treated with PrOD.

Conclusion: Glecaprevir/pibrentasvir plus sofosbuvir for 16 weeks is a safe and highly effective retreatment regimen for patients who have previously failed GLE/PIB and other DAA regimens regardless or cirrhosis status, or NS5A RAS profile. There is no indication for adding ribavirin.

OS005

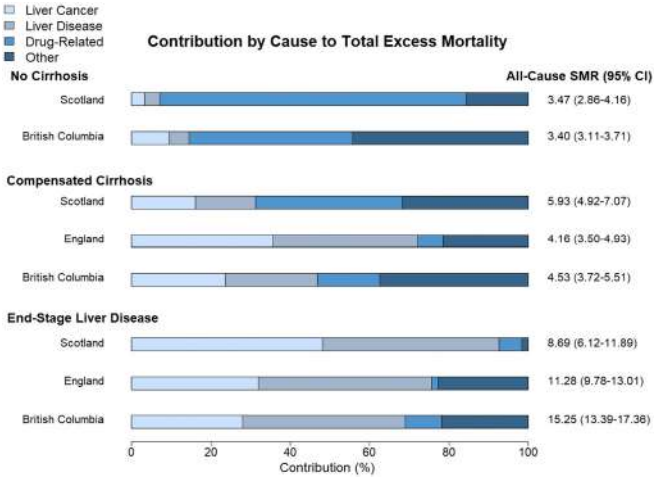
Excess mortality risk among hepatitis C patients after being "cured" in the interferon-free era: results from three population-based cohorts

Victoria Hamill[1,2], Stanley Wong[3], Jennifer Benselin[4,5], Mel Krajden[3,6], Peter Hayes[7], David Mutimer[8], Amanda Yu[3], John Dillon[9], Will Gelson[10], Hector Velasquez[3,11], Philip Johnson[12], Stephen Barclay[13], Maria Alvarez[3], Hidenori Toyoda[14], Kosh Agarwal[15], Andrew Fraser[16,17], Sofia Bartlett[3,11], Mark Aldersley[18], Andrew Bathgate[7], Mawuena Binka[3,11], Paul Richardson[19], Joanne Morling[4,5,20], Stephen Ryder[4], Douglas Macdonald[21], Sharon Hutchinson[1,2], Eleanor Barnes[22], Neil Guha[4,5], William Irving[4,5], Naveed Janjua[3,11,23], Hamish Innes[1,2,20]. *[1]Glasgow Caledonian University, School of Health and Life Sciences, Glasgow, United Kingdom; [2]Public Health Scotland, Glasgow, United Kingdom; [3]British Columbia Centre for Disease Control, Vancouver, British Columbia, Canada; [4]Nottingham University Hospitals NHS Trust and the University of Nottingham, NIHR Nottingham Biomedical Research Centre, Nottingham, United Kingdom; [5]University of Nottingham, School of Medicine, Nottingham Digestive Diseases Centre, Nottingham, United Kingdom; [6]The University of British Columbia, Department of Pathology and Laboratory Medicine, Vancouver, British Columbia, Canada; [7]Royal Infirmary of Edinburgh, Edinburgh, United Kingdom; [8]Queen Elizabeth Hospital Birmingham, Liver and Hepatobiliary Unit, Birmingham, United Kingdom; [9]University of Dundee, School of Medicine, Division of Molecular and Clinical Medicine, Dundee, United Kingdom; [10]Cambridge University Hospitals NHS Foundation Trust, Cambridge Liver Unit, Cambridge, United Kingdom; [11]University of British Columbia, School of Population and Public Health, Vancouver, British Columbia, Canada; [12]University of Liverpool, Department of Molecular and Clinical Cancer Medicine, Liverpool, United Kingdom; [13]Glasgow Royal Infirmary, Glasgow, United Kingdom; [14]Ogaki Municipal Hospital, Department of Gastroenterology, Ogaki, Japan; [15]King's College Hospital NHS Foundation Trust, Institute of Liver Studies, London, United Kingdom; [16]Aberdeen Royal Infirmary, Aberdeen, United Kingdom; [17]Queen Elizabeth University Hospital, Glasgow, United Kingdom; [18]St James's University Hospital, Leeds Liver Unit, Leeds, United Kingdom; [19]Royal Liverpool and Broadgreen University Hospitals NHS Trust, Liverpool, United Kingdom; [20]University of Nottingham, Lifespan and Population Health, Nottingham, United Kingdom; [21]Royal Free London NHS Foundation Trust, Gastroenterology and Hepatology, London, United Kingdom; [22]University of Oxford, Nuffield Department of Medicine and the Oxford NIHR Biomedical Research Centre, Oxford, United Kingdom; [23]St Paul's Hospital Vancouver, Centre for Health Evaluation and Outcome Sciences, British Columbia, Canada*
Email: victoria.hamill@gcu.ac.uk

Background and aims: Although the number of people living with a hepatitis C sustained viral response (SVR) has increased dramatically, mortality rates in this patient group remain poorly understood. Here, our goal was to assess excess mortality after SVR achievement in the interferon (IFN)-free era.

Method: We performed data analysis on patients achieving SVR in the IFN-free era (2014–2018/19) from three population-based cohorts in Scotland (SC), England (EN), and British Columbia (BC). Patients were divided into three disease stage groups: no cirrhosis (SC and BC only); compensated cirrhosis; and end stage liver disease (ESLD). Age-standardised mortality rates were calculated to take account of different age/sex structures between cohorts and disease stage groups. Further, we calculated standardised mortality ratios (SMRs) to compare the frequency of mortality in SVR patients to the general population (GP). We also quantified the proportion of excess death attributable to: a) death from liver cancer; b) death from liver disease unrelated to cancer; c) and death from drug-related causes. Finally, Poisson regression was used to identify factors associated with excess mortality.

Results: Our analysis included 20, 031 patients, of which 1, 402 (7%) died during follow-up. Mean follow-up duration was 2.2–3.9 years, and mean age ranged from 46.3 (SC) to 56.7 (BC). Mortality rates varied considerably according to disease stage. For example, the age-standardised mortality rate ranged from 12 to 23, 27–38, and 62–118 deaths per 1000 person-years in non-cirrhosis, compensated cirrhosis and ESLD patients, respectively. SMRs indicated that all-cause mortality was 3.4–3.5 times higher than the GP in non-cirrhosis patients, 4.2–5.9 times higher in compensated cirrhosis patients, and 8.7–15.3 times higher in ESLD patients. For non-cirrhosis patients, drug-related causes were responsible for the greatest proportion of excess death (77% SC; 41% BC). Conversely, for cirrhosis patients, liver-related causes were the key driver, responsible for 30–95% of excess deaths. In the regression analysis, younger age, drug use and comorbidities were associated with greater excess mortality (see Figure).



Conclusion: In the largest study performed to-date, we show that individuals achieving SVR in the interferon-free era have a considerably higher mortality risk than the GP, driven mainly by drug-related mortality (in non-cirrhosis patients) and liver-related causes (in cirrhosis patients).

Impact of direct-acting antiviral treatment for hepatitis C on cardiovascular diseases and extrahepatic cancers

Laurent Lam[1], Helene Fontaine[2], Nathanaël Lapidus[1,2], Celine Dorival[1], Jonathan Bellet[1], Dominique Larrey[3], Pierre Nahon[2,4], Alpha Diallo[5], Carole Cagnot[5], Clovis Lusivka-Nzinga[1], François Teoule[1], Gilles Hejblum[1], Marc Bourliere[6,7], Stanislas Pol[2,8], Fabrice Carrat[1,2]. *[1]Sorbonne Université, INSERM, Institut Pierre Louis d'Épidémiologie et de Santé Publique, IPLESP, Paris, France; [2]Assistance Publique-Hôpitaux de Paris, France; [3]Hôpital Saint Eloi and IBR, INSERM, Montpellier, France; [4]Inserm, UMR-1162, "Génomique fonctionnelle des tumeurs solides", Paris, France; [5]ANRS, Emerging Infectious Diseases, Paris, France; [6]Hôpital Saint Joseph, Marseille, France; [7]INSERM, UMR 1252 IRD SESSTIM, Aix Marseille Université, Marseille, France; [8]Université de Paris, Paris, France*
Email: laurentlam@hotmail.fr

Background and aims: The impact of direct-acting antivirals (DAAs) on extrahepatic complications in chronic hepatitis C (CHC) patients remains poorly described. We estimated the association of DAAs with cardiovascular events and extrahepatic cancers.

Method: The prospective ANRS CO22 HEPATHER cohort was enriched with individual data until December 2018 from the French National Health Insurance Database (SNDS), which contains medical information regarding ambulatory care and hospital admissions. CHC patients were enrolled between August 2012 and December 2015 in 32 French hepatology centers. A total of 8148 CHC adults were selected. Cardiovascular events (stroke, acute coronary syndrome, pulmonary embolism, heart failure, arrhythmias and conduction disorders [ACD], peripheral arterial disease [PAD]) and cancers (colorectal, bladder, prostate, kidney, lung, pancreas, thyroid, head/neck, breast) were derived from the SNDS. Associations between DAAs and extrahepatic events were estimated using marginal structural models, with adjustments for clinical confounders and medications.

Outcomes	Adjusted hazard ratios associated with DAAs (95% Confidence Interval)
Total population (n = 8148)	
Acute stroke	1.30 (0.82, 2.08)
Acute coronary syndrome	1.00 (0.63, 1.60)
Acute pulmonary embolism	2.10 (0.64, 6.85)
Acute heart failure	1.15 (0.74, 1.78)
Arrhythmias and conduction disorders	1.46 (1.04, 2.04)
Peripheral arterial disease	0.54 (0.33, 0.89)
Major cardiovascular events	1.03 (0.81, 1.31)
Any cardiovascular event	1.10 (0.90, 1.36)
Any extrahepatic solid cancer	1.23 (0.50, 3.03)
Patients with advanced fibrosis (n = 3586)	
Acute stroke	0.58 (0.29, 1.18)
Acute coronary syndrome	0.59 (0.29, 1.19)
Acute pulmonary embolism	0.79 (0.16, 3.97)
Acute heart failure	0.47 (0.27, 0.81)
Arrhythmias and conduction disorders	1.02 (0.57, 1.84)
Peripheral arterial disease	0.36 (0.17, 0.73)
Major cardiovascular events	0.50 (0.36, 0.71)
Any cardiovascular events	0.58 (0.42, 0.79)
Any extrahepatic solid cancer[c]	0.39 (0.09, 1.71)

Results: Analyses of 12 905 person-years (PY) of no DAA exposure and 22 326 PY following DAA exposure showed a reduced risk of PAD after DAAs (HR, 0.54; 95% CI, 0.33 to 0.89), a beneficial effect of DAAs on overall cardiovascular outcomes in patients with advanced fibrosis (aHR, 0.58; 95% CI, 0.42 to 0.79), and an increased risk of ACD (hazard ratio [HR], 1.46; 95% CI, 1.04 to 2.04) predominant after the first year following DAA initiation. There was no association between DAAs and extrahepatic cancer (HR, 1.23; 95% CI, 0.50 to 3.03).
Conclusion: DAAs were associated with a decreased risk of cardiovascular outcomes in patients with advanced fibrosis, a decreased risk of PAD regardless of the fibrosis stage, and an increased risk of ACD, supporting long-term cardiac monitoring after DAA therapy. DAAs were not associated with extrahepatic cancer development or reduction.

Cirrhosis and its complications: Other clinical complications except ACLF and critical illness

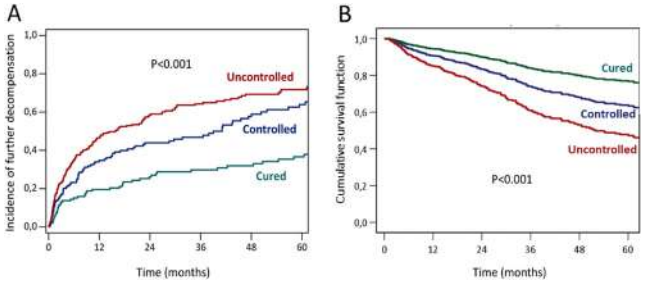
Etiological cure prevents further decompensation and mortality in cirrhotic patients with ascites as the single first decompensating event

Marta Tonon[1], Lorenz Balcar[2,3], Georg Semmler[2,3], Valeria Calvino[1], Bernhard Scheiner[2,3], Simone Incicco[1], Rafael Paternostro[2,3], Carmine Gabriele Gambino[1], David JM Bauer[2,3], Antonio Accetta[1], Lukas Hartl[2,3], Alessandra Brocca[1], Mathias Jachs[2,3], Michael Trauner[2,3], Mattias Mandorfer[2,3], Paolo Angeli[1], Thomas Reiberger[2,3], Salvatore Piano[1]. *[1]University of Padua, Department of Medicine, Padova, Italy; [2]Medical University of Vienna, Division of Gastroenterology and Hepatology, Department of Internal Medicine III, Vienna, Austria; [3]Medical University of Vienna, Vienna Hepatic Hemodynamic Laboratory, Division of Gastroenterology and Hepatology, Department of Internal Medicine III, Vienna, Austria*
Email: salvatorepiano@gmail.com

Background and aims: Etiologic treatment reduces the risk of decompensation and mortality in compensated cirrhosis. However, in the setting of decompensated cirrhosis the impact of etiologic treatment is less predictable, in particular in patients with ascites, who remain at high risk of developing further decompensating events and death. The aim of the study was to evaluate the impact of etiological treatment in decompensated patients with cirrhosis and ascites as the single index decompensating event. The end points were the occurrence of further decompensation (i.e. refractory ascites, spontaneous bacterial peritonitis [SBP], hepatorenal syndrome [HRS-AKI], variceal bleeding [VB] and hepatic encephalopathy [HE]) and mortality.
Method: Cirrhotic patients with ascites as single first decompensation event at the University Hospital of Padova or the Vienna General Hospital between 2003–2021 were included and followed until death, liver transplantation or September 2021. The etiology was considered as "cured" in case of removal of the primary etiological factor (e.g. HCV: virological cure, HBV: virological suppression, ALD: alcohol abstinence) and as "controlled" in case of partial removal of etiologic factor (e.g. HBV: partial suppression of HBV-DNA, ALD: mostly abstinent but with drinking episodes).
Results: We included 622 patients (mean age: 57 ± 11 years, male 68%, mean MELD 15 ± 6), the most common etiology were ALD (59%) and HCV (23%). Etiology was "cured" in 146 patients (24%), "controlled" in 170 (27%) and uncontrolled in 306 (49%). During a median follow-up of 33months, 350 patients (56%) developed further decompensation (33%refractory ascites, 29% HE, 17% SBP, 13% HRS-AKI, 9% VB). The incidence of further decompensation at 5 years was significantly lower in patients with "cured" vs "controlled" vs uncontrolled etiology (38% vs 64% vs 72%, respectively; $p < 0.001$; Fig. 1A). In multivariable analysis (adjusted for age, varices, etiology, Child Pugh class, creatinine and sodium), "cured" (aHR = 0.52; $p < 0.001$) and "controlled" etiology (aHR = 0.60; $p < 0.001$) were both independently associated with a lower risk of further decompensation. Considering response to etiological treatment as time-dependent covariates, 5-year cumulative incidence of survival was significantly higher in patients with cured vs controlled vs uncontrolled etiology (83% vs 58% vs40%, respectively; $p < 0.001$; Fig. 1B). In multivariable analysis, etiological cure (aHR = 0.35, $p < 0.001$) and controlled etiology (aHR = 0.61, $p = 0.003$) were independently associated with lower mortality.



Conclusion: In cirrhotic patients with ascites as single first decompensating event, the cure or control of etiology of liver disease reduces the risk of further decompensations and mortality.

Email: doctor.ashokchoudhury@gmail.com

Background and aims: Decompensated chronic liver disease (DCLD) is associated with poor outcomes, but no global study has addressed this after hospitalization. We prospectively evaluated non-elective hospitalized patients with DCLD to determine disease profile, predictors of readmission and 30 days mortality post discharge following index hospital admission under "***C***hronic ***L***iver disease ***E***volution ***A***nd ***R***egistry for ***E***vents and ***D***ecompensation (CLEARED) consortium.

Method: Data were prospectively collected from 49 centres from 6 continents of non-elective admissions in DCLD patients with or without cirrhosis, aged ≥18 years. We performed an interim analysis to predict readmission and mortality within 30 days following index hospital discharge. World Bank data were used to stratify countries according to income.

Results: 1383 patients, mean age 54.97 ± 13.55 years; 64% male; diverse ethnicity [White 39%, Asian 30%, Hispanic 10%, Black 9%] were analyzed. Alcohol was the most common etiology (46%), followed by NASH (23%), HBV (13%) and HCV (11%). Admissions were almost exclusively for liver related complications i.e. GI bleed (30%), HE (34%), AKI (33%), and anasarca (24%). Mean admission CTP was 10 (5–14) and MELD-Na 23 (6–40). Only 11% were listed for transplant. 51% had hospitalization in previous six months. 24% were infected at admission and another 13% developed infections subsequently. During hospitalization, organ failures were: AKI 46%; as brain 16%, circulatory 14%, and respiratory 13%; 25% needed ICU admission. Median hospital stay was 7 days (1–140) and 11% lost to follow-up after discharge. 33% were readmitted, 3% were transplanted while 26% of patients died within 30 days. The most significant independent factors predicting readmission within 30 days were being in low/lower middle income country ($p < 0.0001$), a high discharge MELD-Na ($p = 0.0005$), and hospitalization ≤6 M ($p = 0.006$). The most significant independent predictors of 30-day-mortality post index discharge were age, discharge MELD-Na ($p < 0.0001$ for both), and various organ failures during index admission ($p < 0.01$).

Conclusion: The clinical outcomes of patients with DCLD following index hospital admission vary widely around the world. Mortality within 30 days post discharge is largely dependent on patient and disease factors. Readmission post discharge, however, is variable across continents and inversely correlates socio-economic status. Global characterization of patients at high risk of readmission should include further study of socio-economic factors in addition to severity of liver disease.

OS009

Dyserythropoiesis is underrecognized and contributes to severe anemia in liver cirrhosis

Chhagan Bihari[1], Sumit Garg[1], Shiv Kumar Sarin[2]. [1]*Institute of Liver and Biliary Sciences, Pathology and Hepatology, Delhi, India;* [2]*Institute of Liver and Biliary Sciences, Hepatology, Delhi, India*
Email: shivsarin@gmail.com

Background and aims: Moderate to severe anemia is one of the common complication in liver cirrhosis and is often multifactorial. Contribution of dyserythropoiesis (DE) in cirrhosis related anemia is often neglected and has not been studied. We aimed to investigate the prevalence, severity and mechanisms of dyserythropoiesis in cirrhosis patients.
Method: We studied the bone marrows (BM) of cirrhosis patients (n = 517), who underwent a BM aspiration/biopsy between Jan 2014–Dec 2018, for investigation of anemia, hypersplenism or other clinical indications. Cases of haematological or non-hematological neoplasias, chronic kidney disease, chronic or acute drug injury, acute and chronic hepatitis and granulomatous pathology were excluded. Morphological analysis of BM aspirate, biopsies, erythroid colony assessment were done. A >5% dyserythropoiesis in erythroid lineage was considered and categorized as mild: 5–10%; moderate: 10–15% and marked: >15%.
Results: A 68/517 (13.2%) cirrhosis patients had dyserythropoiesis and none from control group. Of them 44% had mild; 35.4% moderate and 20.6% marked dyserythropoiesis in the BM. Cirrhosis patients with DE had significantly lower hemoglobin than those without DE (7.6 ± 1.4 gm/dl vs 8.9 ± 1.9 gm/dl, p < 0.001), but comparable serum iron (83.7 ± 42 vs 90.2 ± 46.6 mcg/dl, p = 0.997); total iron binding capacity (243.2 ± 85.1 vs 231 ± 87.2 mcg/dl, p = 0.291); and transferrin saturation (50.9 ± 27.9 vs 55.6 ± 30.8 %, p = 0.206) and serum folate (16 ± 3.8 vs 15.8 ± 4.4 ng/ml) levels. The former however, had higher vitamin B12 (2339.2 ± 1406 vs 1842 ± 1411.9 pg/ml, p = 0.010) levels. Further, other confounding factors for anemia like lactate dehydrogenase (p = 0.494), reticulocyte count (p = 0.808), thyroid stimulating hormone (p = 0.208), hepcidin (p = 0.16), erythropoietin (p = 0.23), and spleen size (p = 0.310) were comparable. Grades of dyserythropoiesis were associated with Child's score (p = 0.003) with marked dyserythropoiesis being noted in Child C. Dyserythropoiesis was mainly associated with alcohol and non-alcoholic steatohepatitis (51/68, 75%) as compared to viral, autoimmune and other etiologies. BM examination showed fewer erythroid colonies (8 vs. 10.7, p < 0.001) and proerythroblasts (7 vs. 17.9, p < 0.001) in the erythroid colonies of patients with DE. The DE was significantly related with low GATA.1 (7.7 ± 4.3 vs 13.6 ± 7.8; p = 0.001) non-nuclear localization of HSP70 (p = 0.04) and excess erythroferrone (23.4 ± 7 vs 14.2 ± 5.2, p < 0.001) as compared to no-DE.
Conclusion: Approximately 13.2% patients with cirrhosis with severe anemia show dyserythropoiesis. Standard hematological and iron studies fail to identify it and bone marrow examination is merited. Alternations in the erythroid colonies, HSP70 localization and diminished GATA.1 in BM are associated with dyserythropoiesis.

OS010

Effect of recruitement and selection policies on the volume of outcome of patients transplanted with ACLF-3

Baptiste Michard[1], Thierry Artzner[1], Pietro Addeo[1], Philippe Bachellier[1], Camille Besch[1], Vincent Castelain[1], Raphael Clere-Jehl[1], Mathilde Deridder[1], Max Guillot[1], Jean-Étienne Herbrecht[1], Ralf Janssen-Langenstein[1], Maleka Schenck[1], Francis Schneider[1], François Faitot[1]. [1]*Hopitaux Universitaires de Strasbourg*
Email: baptiste.michard@chru-strasbourg.fr

Background and aims: Liver transplantation (LT) for critically ill cirrhotic patients is a debated issue, which raises complex medical, surgical and ethical challenges. In particular, it is crucial to achieve high post-LT survival in order to justify allocating livers to these patients, especially given the current organ shortage. To date, there is no granular data concerning the 3-year post-LT outcome of ACLF-3 patients.
Method: This study describes the three-year post-LT survival of a single center granular cohort of patients with ACLF-3 at the time of LT and compares it to the post-LT survival of all the patients who were transplanted without ACLF-3 in the same center between 2007 and 2018. Over this period of time, two policies were gradually implemented in this center: (i) developing a network of peripheral centers that transferred critically ill cirrhotic patients for LT assessment and (ii) increasing use of the transplantation for ACLF-3 model (TAM) score criteria to identify the optimal transplantability window.
Results: A total of 828 first time single LTs were performed over the study period. 91 patients had ACLF-3 at the time of LT. The overall three-year survival of ACLF-3 patients was 66% vs 82% (p < 0.001) for the rest of the cohort. Over the study period, both the number of

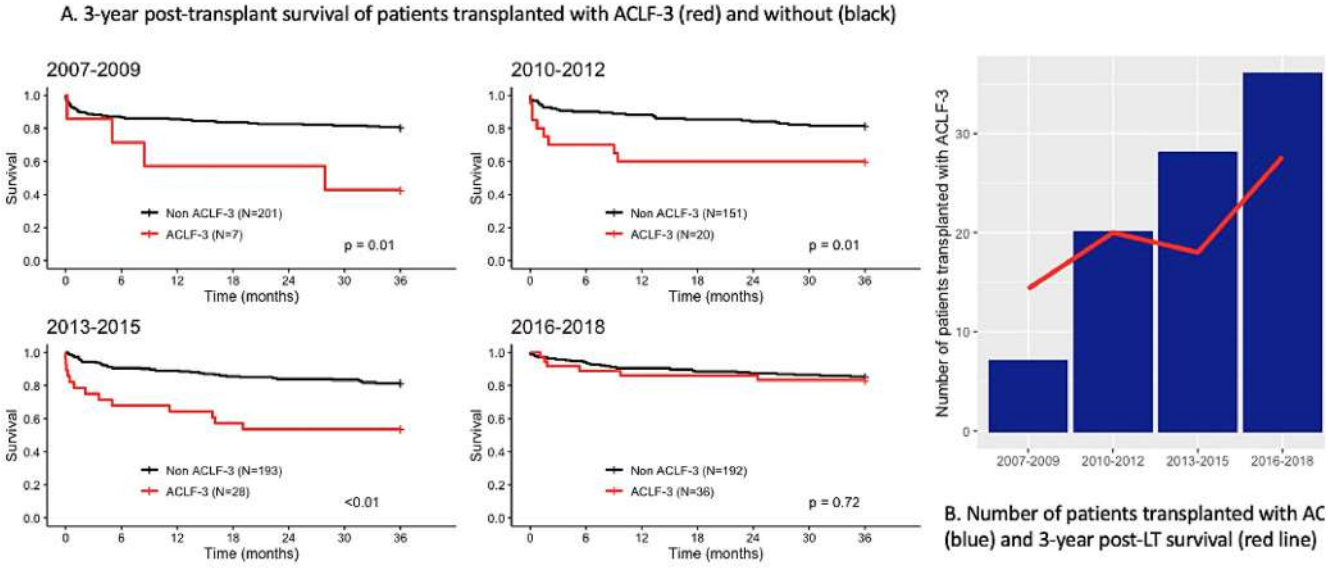

Figure: (abstract: OS010)

patients transplanted with ACLF-3 and their 3-year post-LT survival increased over time: 2007–2009: 7 patients, 43% survival; 2010–2012: 20 patients, 60% survival; 2013–2015: 28 patients, 54% survival; 2016–2018: 36 patients, 83% survival (no significant difference in survival between the ACLF-3 and the non ACLF-3 group in the last period). This increase in the number of patients transplanted and in their post-LT three-year survival was not observed in the general population of patients transplanted without ACLF-3 (cf. Figure). A total of 12 ACLF-3 patients were transplanted with TAM scores>2. However, in the last period (2016–2018), in which both the number of patients transplanted with ACLF-3 and the post-LT survival were the highest, no patient was transplanted with a TAM score>2.

Conclusion: This study, which originates from the largest single center cohort of patients transplanted with ACLF-3, illustrates how gradually building a network of peripheral centers to refer critically ill cirrhotic patients to an expert ICU and LT center can lead to a dramatic increase in the number of patients transplanted with ACLF-3. It also shows that there is a learning curve when transplanting patients with ACLF-3 and that the implementation of the TAM score to help identify the optimal transplantability window at the time of organ proposal contributes to optimizing post-LT outcomes. The combination of these strategies can help centers increase the number of patients transplanted with ACLF-3 while reaching post-LT outcomes for these patients that are similar to those of non ACLF-3 patients.

Real-world evidence on long-term albumin treatment in patients with decompensated liver cirrhosis in Italy

Wim Laleman[1], Jonel Trebicka[2], Alastair O'Brien[3], Paolo Caraceni[4], Sandra Santos[5], Tatiana Vilchez[6], Kyle Rodney[7], Sofia Schweiger[8], Paolo Angeli[9]. *[1]University Hospitals Leuven, Department of Gastroenterology and Hepatology, Section of Liver and Biliopancreatic Disorders, Leuven, Belgium; [2]Goethe University Hospital Frankfurt, Translational Hepatology Department of Internal Medicine, Frankfurt, Germany; [3]University College London, Institute for Liver and Digestive Health, London, United Kingdom; [4]University of Bologna, Department of Medical and Surgical Science, Bologna, Italy; [5]CSL Behring, Lisbon, Portugal; [6]CSL Behring, Barcelona, Spain; [7]Adivo Associates LLC, California, United States; [8]Adivo Associates LLC, Buenos Aires, Argentina; [9]University of Padova, Department of Medicine, Unit of Internal Medicine and Hepatology, Padova, Italy*
Email: paolo.angeli54@gmail.com

Background and aims: Human albumin plays an important role in the management of patients with decompensated liver cirrhosis. Guidelines recommend short-term albumin in specific acute conditions, but clinical trial data have also shown benefits of long-term albumin (LTA) treatment. This study aimed to analyse real-world data on LTA treatment in patients with cirrhosis across Italy.
Method: Data from an independent audit platform was collected on patients with cirrhosis and ascites who received non-LTA, defined as standard medical treatment with diuretics and albumin only for acute indications, or LTA, with infusions at weekly intervals for ≥6 months. Audits were performed between 2018 and 2020, using institutional data and callbacks with healthcare professionals in Italy from 43 locations (hospitals, pharmacies and health units). Retrospective analysis was conducted on patient demographics, treatment dose and regimen, complication rates and hospitalisation outcomes.
Results: Data were captured for 6660 patients (non-LTA: 4305; LTA: 2355). Main etiologies of cirrhosis were alcoholic (33%), viral (29%) non-alcoholic steatohepatitis (30%) and other (7%). In LTA patients, the mean (range) treatment duration was 14 (6–36) months and initial dose was 87 (10–280) g/week, followed by 37 (10–60) g/week. The need for paracentesis (3.1 vs 6.2 per patient per year) and the incidence of refractory ascites (0.57 vs 0.71 per patient per year) were lower in LTA than in non-LTA patients. A lower incidence (episodes per patient per year) of other major complications was also reported in LTA patients: spontaneous bacterial peritonitis (0.19 vs 0.09), hepatorenal syndrome (0.28 vs 0.16) and hepatic encephalopathy (0.40 vs 0.31). Hospitalisations were 2.40 and 2.85 per patient per year in LTA and non-LTA groups, respectively. Differences were maintained when comparing patients within age groups (≤39, 40–59, ≥60 years).
Conclusion: These real-word data captured through an audit methodology indicate that Italian hepatologists consider LTA a valuable approach for the medical management of decompensated cirrhosis, as LTA is currently prescribed in a vast proportion of patients with ascites. Although the present study does not allow the comparison of the two groups, the lower incidence of paracentesis and complications observed in patients receiving LTA is consistent with the benefits documented by the ANSWER trial. Considering this, the cost-effectiveness of LTA and potential for reducing the economic burden upon healthcare systems should be assessed.

OS012

Impact of cirrhotic cardiomyopathy and severity of liver cirrhosis on the development of acute kidney injury

Simona Bota[1], Marcel Razpotnik[1], Philipp Wimmer[2], Michael Hackl[2], Gerald Lesnik[3], Hannes Alber[2], Markus Peck-Radosavljevic[1].
[1]Klinikum Klagenfurt am Wörthersee, Department of Internal Medicine and Gastroenterology (IMuG) and Emergency Medicine (ZAE), Klagenfurt, Austria; [2]Klinikum Klagenfurt am Wörthersee, Department of Internal Medicine and Cardiology (IMuK), Klagenfurt, Austria; [3]Klinikum Klagenfurt am Wörthersee, Institut for diagnostic and interventional Radiology, Klagenfurt, Austria
Email: bota_simona1982@yahoo.com

Background and aim: New criteria of cirrhotic cardiomyopathy (CCM) were published from a multidisciplinary consortium (Izzy et al. Hepatology 2019 Nov 11. doi: 10.1002/hep.31034) and define systolic dysfunction of the left ventricle as ejection fraction (EF) ≤50% and/or global longitudinal strain (GLS) <–18%, while the diastolic dysfunction is diagnosed when three of the following conditions are present: average E/e' >14, peak tricuspid regurgitation velocity >2.8 m/s, septal e'<7 cm/s, left atrial volume index >34 ml/m^2.
Our **aim** was to assess the influence of CCM, severity and etiology of liver cirrhosis on the development of acute kidney injury.
Method: Our prospective study included consecutive patients with liver cirrhosis without structural heart disease, arterial hypertension, HCC outside Milan criteria, portal vein thrombosis, presence of TIPS and with optimal acoustic echocardiography window. The patients were evaluated between 12/2018–11/2021 in our in- and out-patient Department. Conventional and speckle-tracking echocardiography (Vendor GE, EchoPAC PC software) were performed by a single investigator (EACVI TTE certified).
Acute kidney injury (AKIN) was defined according to the International Ascites Club as increase to serum creatinine of 0.3 mg/dL in <48 h or 50% increase in serum creatinine from baseline value within ≤3months.
The follow-up was performed until the patient was last seen or death.
Results: 412 cirrhotic patients were evaluated during the study period and 133 fulfilled the inclusion criteria and were included in the final analysis. The mean age of patients was 57.1 ± 10.2 years (60.1% males), 70.1% with alcoholic etiology and 48.1% with Child-Pugh A liver cirrhosis.
The median follow-up was 21 (0.5–36) months. Acute kidney injury was diagnosed in 26/133 (19.5%) of patients, while CCM (systolic and/or diastolic dysfunction) was present on 15% of patients.
The presence of acute kidney injury was correlated in univariate analysis with presence of CCM, Child-Pugh score, MELD score, alcoholic etiology of liver cirrhosis and prothrombin time (Table).
In multivariate logistic regression analysis only CCM and alcoholic etiology remained significantly associated with AKIN: CCM -OR = 13.6

(95% CI: 3.8–54.0), p = 0.0001 and alcoholic etiology-OR = 5.3 (95% CI: 1.1–26.3), p = 0.03.

	Spearman r correlation coefficient
Age	r = 0.089, p = 0.30
Male gender	r = 0.052, p = 0.54
BMI	r = 0.103, p = 0.23
Alcoholic etiology	**r = 0.186, p = 0.03**
Spleen size	r = 0.082, p = 0.34
Presence of CCM	**r = 0.323, p = 0.0001**
Child-Pugh score	**r = 0.259, p = 0.002**
MELD score	**r = 0.237, p = 0.005**
Presence of portal hypertension	r = 0.107, p = 0.21
Albumin	r = –0.169, p = 0.06
Platelet count	r = 0.037, p = 0.67
Prothrombin time	**r = –0.197, p = 0.02**

Conclusion: The presence of CCM is a strong predictor of acute kidney injury development among cirrhotic patients.

Non-invasive assessment of liver disease except NAFLD

OS013

Association of long term methotrexate therapy with liver fibrosis markers: a multi-centre prospective case-control study

Edmond Atallah[1,2], Jane Grove[1,2], Colin Crooks[1,2], Esther Burden-teh[3], Ruth Murphy[4], Sulleman Moreea[5], Abhishek Abhishek[6], Kelsey Jordan[7], Aftab Ala[8], David Hutchinson[9], Richard Aspinall[10], Guruprasad Aithal[1,2]. *[1]University of Nottingham, Nottingham Digestive Diseases Centre, School of Medicine, Nottingham, United Kingdom; [2]Nottingham University Hospitals NHS Trust and the University of Nottingham, National Institute for Health Research (NIHR) Nottingham Biomedical Research Centre, Nottingham, United Kingdom; [3]University of Nottingham, Centre of Evidence Based Dermatology, School of Medicine, Nottingham, United Kingdom; [4]Sheffield Dermatology Research, University of Sheffield, Sheffield, United Kingdom; [5]Bradford Teaching Hospitals NHS Foundation Trust, Bradford, United Kingdom; [6]Nottingham University Hospitals NHS Trust Queen's Medical Centre Campus, United Kingdom; [7]Brighton and Sussex University Hospitals NHS Trust, Brighton, United Kingdom; [8]Royal Surrey County Hospital, Surrey, United Kingdom; [9]Royal Cornwall Hospitals NHS Trust, Cornwall, United Kingdom; [10]Portsmouth Hospitals University NHS Trust, Portsmouth*
Email: edmond.atallah@nottingham.ac.uk

Background and aims: Incidence of acute drug-induced liver injury due to methotrexate (MTX) reduces significantly after the first year of treatment. However, decompensated cirrhosis attributed to MTX accounts for 0.07% of patients listed/transplanted in the USA. We evaluated the risk of long-term MTX therapy on liver fibrosis prospectively in a case-control study.

Method: Between 2014–2021, adult patients diagnosed with Rheumatoid Arthritis (RA) or Psoriasis (PS) were recruited prospectively from six UK sites. Patients on MTX for ≥6 months were defined as cases, whereas those with RA or PS for ≥2 years who never received MTX were controls. All patients underwent full liver profile, enhanced liver fibrosis (ELF) markers, and transient elastography (TE). Multivariate analysis was performed using logistic regression and results were presented as adjusted odds ratio (OR) and 95% confidence interval.

Results: Of 999 patients included (mean age 60.8 ± 12 years, 622 females (62.3%)), 976 had valid TE values; 149 (15.3%) had liver stiffness ≥7.9 KPa. Of 892 with available ELF, 262 had ELF score ≥9.8 (29.4%). Age and BMI were independently associated with elevated liver stiffness and ELF. Diabetes was associated with significant fibrosis defined by liver stiffness ≥7.9 KPa, OR = 3.21 (1.96–5.21), p < 0.001. But, neither MTX cumulative dose nor duration of exposure was associated with elevated liver stiffness [OR = 1.02 (0.93–1.12) and 1.00 (0.99–1.0), respectively] and ELF score [OR = 1.06 (1.0–1.12) and 1.00 (0.99–1.0), respectively]. Regular use of non-steroidal anti-inflammatory drugs was associated with ELF score ≥9.8, OR = 1.78 (1.22–2.60), p = 0.003.

Conclusion: Lack of association of MTX cumulative dose and duration with liver fibrosis in RA or PS indicates that the risk of liver fibrosis due to MTX itself might have been overestimated. The degree of inflammation in RA and PS may confound ELF as a marker to detect fibrosis.

Table: Demographic and phenotypic features for cases and controls

Characteristics	MTX group (n = 876)	Control group (n = 123)	p
Age (years), mean (SD)	61.6 (11.6)	55.6 (13.5)	**<0.001**
Female, n (%)	560 (63.9)	62 (50.4)	**<0.01**
Diagnosis, n (%)		55 (44.7)	**<0.001**
RA	615 (70.2)	67 (54.5)	
PS	241 (27.5)	1 (0.8)	
Both	20 (2.3)		
Type 2 Diabetes	100 (11.5)	21 (17.1)	**NS**
Hyperlipidaemia	225 (25.9)	28 (22.8)	**NS**
BMI (kg/m^2), mean (SD)	29.9 (6.7)	30.9 (7.5)	**NS**
Alcohol >14 units/week, n (%)	83 (9.5)	25 (20.3)	**<0.001**
Fibrosis markers			
TE groups, n (%)	731 (85.5)	96 (79.3)	**0.08**
Low <7.9	124 (14.5)	25 (20.7)	
High ≥ 7.9			
ELF groups, n (%)	562 (71.4)	68 (64.8)	**NS**
Low risk <9.8	202 (25.7)	34 (32.4)	
Moderate risk (≥9.8 to <11.3)	23 (2.9)	3 (2.9)	
High risk ≥11.3			

NS: Not significant.

Background and aims: Only a few patients with compensated cirrhosis who underwent esophagogastroduodenoscopy (EGD) screening for varices were found to have varices needing treatment (VNT). Our study aimed to identify a novel machine learning-based model (ML EGD) for ruling out VNT and avoiding unnecessary EGD in patients with compensated cirrhosis.
Method: A total of 2794 patients from China, Singapore and India were enrolled. Of them, 1283 patients in a real-world cohort from one university hospital, 966 in a multicenter cohort (test cohort 1) from 14 university hospitals, and 545 in an international cohort (test cohort 2) from Singapore and India were included, respectively. For the real-world cohort, patients were shuffled and sampled randomly into training and validation cohort with a ratio of 9:1. In the training cohort, a light gradient boosting machine algorithm was used to develop the pre-model to detect VNT based on clinical data. A shapley value method was used to evaluate the importance of included variables according to pre-model. ML EGD was furthermore developed based on the most related variables to detect VNT using light gradient boosting machine algorithm. Then, we validated it in the validation cohort and tested it in the two external test cohorts.
Results: The main etiology of cirrhosis was hepatitis B infection in the training (68.02%), validation cohort (68.99%) and test cohort 1 (79.19%) and the main etiology in test cohort 2 was hepatitis C infection (47.16%). Liver stiffness, platelet count and total bilirubin were evaluated as the most related variables to detect VNT to develop ML EGD. By receiver operator characteristic curve, the most accurate cut-off to rule out patients with VNT was chosen as a ML EGD below 0.50 with a negative predictive value of 96.4%. In the training cohort, a ML EGD below 0.50 could spare 607 (52.6%) unnecessary EGD with a missed VNT rate of 3.6%. In the validation cohort, test cohort 1 and test cohort 2, a ML EGD score below 0.50 could spare 75 (58.1%), 506 (52.4%), 224 (41.1%) EGD with a missed VNT rate of 1.4%, 2.8%, and 3.1%, respectively. Comparing with Baveno VI criteria, ML EGD improved the proportion of avoided EGD (training cohort, 52.6% vs 29.4%; validation cohort, 58.1% vs 44.2%; test cohort 1, 52.4% vs 26.5%; test cohort 2, 41.1% vs 21.1%).
Conclusion: We developed a robust machine learning-based model, named ML EGD, with excellent performance to exclude VNT in patients with compensated cirrhosis.

Email: a.stockdale@liverpool.ac.uk

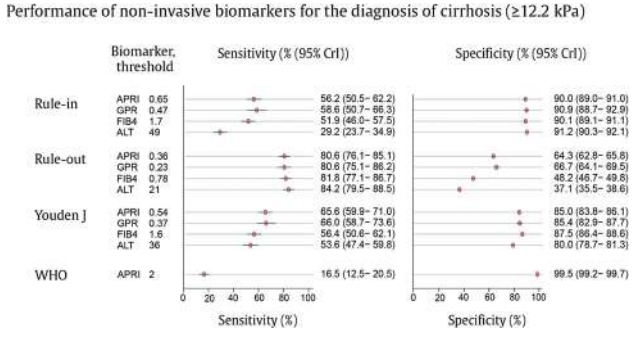
Background and aims: In sub-Saharan Africa, hepatitis B is the principal cause of liver disease, and associated mortality is rising.

Low-cost non-invasive biomarkers of liver fibrosis are needed to identify patients at risk of HBV-related mortality who therefore require antiviral treatment. We evaluated the performance of the biomarkers APRI (AST to platelet ratio index), FIB-4 and GPR (GGT to platelet ratio) in an individual patient data (IPD) meta-analysis.

Method: We included data from HEPSANET, a network comprised of 12 cohorts of HBsAg-positive individuals in 8 sub-Saharan African countries. We used transient elastography as a reference test for cirrhosis (≥12.2 kPa) and significant fibrosis (≥7.9 kPa). We excluded patients who were pregnant, had hepatitis C, D, or HIV co-infection, were on hepatitis B therapy or had acute hepatitis. Upper limits of normal were 40 U/L for AST/AST and 61 U/L for GGT. We fitted a bivariate Bayesian IPD model with patient-level covariates and study-level random effects.

Results: We included 3549 patients. Median age was 33 years (IQR 28–41) and 60% were male. The prevalence of significant fibrosis and cirrhosis among included cohorts was 18% and 7% respectively. APRI and GPR had the best discriminant performance (area under curve 0.81 and 0.82) relative to FIB-4 (0.77) or ALT alone (0.70) for cirrhosis. The World Health Organization (WHO) threshold of APRI>2.0 was associated with sensitivity of 16.5% (95% credible interval 12.5–20.5) and specificity of 99.5% (99.2–99.7) for cirrhosis. At rule-in thresholds for cirrhosis APRI (cut-off 0.65) had sensitivity of 56.2% and specificity of 90.0%; GPR (cut-off 0.47) had sensitivity of 58.6% and specificity 90.9%. At rule out-thresholds for cirrhosis APRI (0.33) had sensitivity and specificity of 80.6% and 64.3%; GPR (0.23) had sensitivity 80.6% and specificity of 66.7% (Figure). The subset of asymptomatic patients who were diagnosed with HBV through routine screening had a mean cirrhosis prevalence of 2.5%, and APRI (cut-off 0.65) had a positive predictive value (PPV) of 13.2% and negative predictive value (NPV) of 98.8%. Among patients diagnosed with HBV due to suspected liver disease, cirrhosis prevalence was 27%; with APRI cut-off 0.65, PPV was 59.6% and NPV 84.5%.

Conclusion: APRI at the WHO-recommended threshold of 2.0 has a poor sensitivity for the diagnosis of cirrhosis in sub-Saharan Africa; WHO guidelines should be revised for the WHO African region to reflect these findings. APRI and GPR had equivalent diagnostic performance and performed best at ruling out cirrhosis but were less good at correctly identifying cases. Programs need to be aware of the significant trade-offs between under- and over-diagnosis of liver cirrhosis when implementing low-cost fibrosis markers in hepatitis B programs in sub-Saharan Africa.



OS016

Prediction of ten-year risk of severe liver disease in the general population using commonly available biomarkers

Hannes Hagström[1], Jacinth Yan[2], Mats Talbäck[2], Anna Andreasson[3], Göran Walldius[2], Matteo Bottai[2], Niklas Hammar[2]. *[1]Karolinska Institutet; [2]Karolinska Institutet, Sweden; [3]Stockholm University, Sweden*
Email: hannes.hagstrom@ki.se

Background and aims: Estimating risk for severe liver disease, including cirrhosis, in the general population is complicated in part due to the rarity of this outcome. Existing prediction tools are suboptimal and there is a need for improvement. Here, we aimed to identify subgroups of persons in the general population with high risks for development of severe liver disease using commonly available biomarkers.

Method: We used laboratory and clinical data on 126, 925 individuals aged 35–79, in Stockholm, Sweden, with clinical examinations between 1985 and 1996. No individuals had known chronic liver disease, a drug- or alcohol use disorder at baseline. Nationwide registries were used to ascertain ten-year cumulative incidence of severe liver disease, a composite of diagnoses corresponding to cirrhosis or its complications. Candidate biomarkers were selected based on if they meaningfully improved prediction of severe liver disease in addition to the established FIB-4 score. They were then categorized and combined, creating subgroups with different risk profiles.

Results: During a follow-up of average 9.3 years, we ascertained 630 incident cases of severe liver disease (0.5%). On top of the FIB-4 score we identified age, impaired glucose, and gamma-glutamyl transferase (gGT) to meaningfully improve a classification of risk. 24 risk groups were created, with a cumulative incidence of severe liver disease at ten years ranging from 0.2% (age 35–65, low FIB-4, no impaired glucose and normal gGT) to 32.1% (age 35–65, high FIB-4, impaired glucose and high gGT). A heatmap of these risk groups was created (Figure 1).

Cumulative incidence of severe liver disease at ten years			FIB-4 Low	FIB-4 Intermediate	FIB-4 High
gGT high	Impaired glucose	age ≥66	13.0	13.7	29.1
		age 35-65	2.6	10.7	32.1
	No Impaired glucose	age ≥66	3.6	0.0	22.7
		age 35-65	2.2	7.4	25.4
gGT normal	Impaired glucose	age ≥66	1.3	2.8	12.5
		age 35-65	0.6	1.0	6.0
	No Impaired glucose	age ≥66	0.6	0.7	2.5
		age 35-65	0.2	0.4	5.5

Figure 1: Heatmap of subgroups with differing risk for severe liver disease at ten years, in percent.

Conclusion: Estimates of risk of severe liver disease in the general population using the FIB-4 score can be substantially improved by adding age and biomarkers commonly available in the primary care setting.

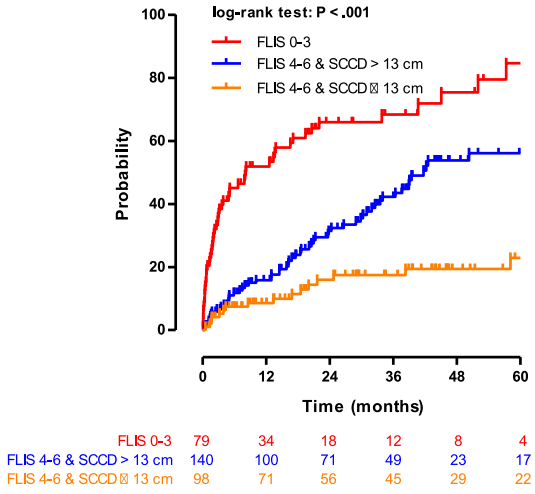
OS017

Gadoxetic acid-enhanced MRI-derived Functional Liver Imaging Score (FLIS) and spleen diameter provide complementary information for risk stratification in ACLD

Nina Bastati[1], Lucian Beer[1], Ahmed Ba-Ssalamah[1], Sarah Poetter-Lang[1], Raphael Ambros[1], Antonia Kristic[1], David Lauber[1], Lorenz Balcar[1], Katharina Pomej[2], Teresa Binter[2,3], Benedikt Simbrunner[2,3], Georg Semmler[2,3], Yesim Bican[1], Jacqueline C. Hodge[1], Thomas Wrba[4], Michael Trauner[2], Thomas Reiberger[2,3], Mattias Mandorfer[2,3]. *[1]Department of Biomedical Imaging and Image-Guided Therapy, Medical University of Vienna, Vienna, Austria; [2]Division of Gastroenterology and Hepatology, Department of Internal Medicine III, Medical University of Vienna, Vienna, Austria; [3]Vienna Hepatic Hemodynamic Lab, Division of Gastroenterology and Hepatology, Department of Internal Medicine III, Medical University of Vienna, Vienna, Austria; [4]IT-Systems and Communications, Medical University of Vienna, Vienna, Austria*
Email: mattias.mandorfer@meduniwien.ac.at

Background and aims: The Functional Liver Imaging Score (FLIS) derived from gadoxetic acid-enhanced MRI (GA-MRI) correlates with hepatic function in chronic liver disease (CLD) patients. Splenic metrics, i.e., volume and craniocaudal diameter (SCCD) are markers of portal hypertension, a key driver of disease progression.

We aimed to investigate the prognostic utility of FLIS and SCCD for hepatic decompensation and transplant-free mortality in CLD.
Method: Three hundred ninety-seven CLD patients undergoing GA-MRI were included. The FLIS was calculated by summing the points (0–2 each) assigned to three hepatobiliary phase features: hepatic enhancement, biliary excretion, and portal vein signal intensity. Patients were stratified into 3 clinical groups according to FIB-4 and presence/history of decompensation: non-advanced CLD (non-ACLD), compensated ACLD (cACLD), and decompensated ACLD (dACLD). The associations between SCCD/FLIS and decompensation/transplant-free mortality were investigated using Cox regression analysis and log-rank test.
Results: We observed a strong correlation between spleen volume and SCCD (Spearman's rho: 0.887; $p < 0.001$), and thus, the simple measure SCCD was used for further analyses. The inter-reader (intraclass coefficient, ICC: 0.982; n = 241) and intra-reader (ICC: 0.997; n = 41) agreement for the SCCD were excellent. Median SCCD showed stepwise increases from non-ACLD (11.8 cm), cACLD (13.3 cm), to dACLD (15.2 cm; $p < 0.001$).
Since non-ACLD patients are at negligible risk of decompensation/liver-related death, we abstained from analysing direct end points in this subgroup. In patients with cACLD, SCCD predicted decompensation (adjusted-hazard-ratio, [aHR]: 1.1, 95% confidence interval [95% CI]: 1.02–1.18; $p = 0.014$) in an analysis adjusted for MELD and albumin; dichotomizing SSCD resulted in an aHR of 2.51 (95%CI: 1.22–5.21, $p = 0.01$) for those with a SCCD >13 cm. In patients with ACLD (i.e., cACLD/dACLD combined), FLIS (0–3 vs. 4–6 points) was a risk factor for transplant-free mortality (aHR: 2.64, 95%CI: 1.61–4.01, $p < 0.001$), even after adjusting for age, MELD, and albumin. Of note, FLIS (0–3 vs. 4–6 points; aHR: 1.74, 95%CI: 1.18–2.58, $p = 0.005$) and SCCD (>13 vs. ≤13 cm; aHR: 2.16, 95%CI: 1.44–3.24, $p < 0.001$) were independently predictive of the composite end point of decompensation/transplant-free mortality, even after adjusting for the previously mentioned prognostic indicators. Grouping patients according to FLIS/SCCD accurately stratified the risk of decompensation/transplant-free mortality (Figure).



Conclusion: The FLIS and SCCD are simple GA-MRI-based imaging markers providing complementary information for risk stratification in patients with advanced chronic liver disease.
N.B. and L.B. contributed equally.

OS018

ADAPT, a score incorporating PRO-C3, for the early detection of liver fibrosis in a large population-based study

Ann T. Ma[1,2,3], Guillem Pera[3,4], Martina Perez[1,2,3,5], Mette Juul Nielsen[6], Morten Karsdal[6], Diana Leeming[6], Carmen Expósito[4], Alba Martínez-Escudé[4,7], Isabel Graupera[1,2,3], Maja Thiele[8,9], Aleksander Krag[8,9], Núria Fabrellas[2,3,5], Llorenç Caballeria[3,4], Pere Ginès[1,2,3,5]. *[1]Liver Unit, Hospital Clínic de Barcelona, Barcelona, Spain; [2]Institut d'Investigacions Biomèdiques August Pi i Sunyer (IDIBAPS), Barcelona, Spain; [3]Centro de Investigavción Biomédica en Red de Enfermedades Hepática y Digestivas (CIBEREHD), Madrid, Spain; [4]Unitat de Suport a la Recerca (USR) Metropolitana Nord, Fundació Institut Universitari d'Investigació en Atenció Primària Jordi Gol i Gurina (IDIAP Jordi Gol), Mataró, Spain; [5]Facultat de Medicina-Universitat de Barcelona, Barcelona, Spain; [6]Nordic Bioscience, Herlev, Denmark; [7]Centre d'Atenció Primària La Llagosta, La Llagosta, Spain; [8]Department of Gastroenterology and Hepatology, Odense University Hospital, Denmark; [9]Department of Clinical Research, Faculty of Health Sciences, University of Southern Denmark, Odense, Denmark*
Email: pgines@clinic.cat

Background and aims: Non-invasive screening of liver fibrosis in the general population has become an important target in order to identify liver disease early and avoid its progression. Novel biomarkers of extracellular matrix formation, including PRO-C3, a marker of type III collagen formation, have emerged as accurate predictors of advanced fibrosis in NAFLD and alcohol-related liver disease. A composite score known as ADAPT, that includes PRO-C3, age, platelet count, and diabetes, has recently been validated in both these patient populations, but its effectiveness to screen for liver fibrosis in asymptomatic subjects in the general population is unknown.
Method: This study was performed in a large population-based cohort of randomly selected subjects aged 18–75 in the Barcelona metropolitan area without known liver disease (mean age 54, 43% male, 10% with type 2 diabetes, 28% with metabolic syndrome, 9% with at-risk alcohol consumption). Serum PRO-C3 levels were measured by enzyme-linked immunosorbent assay in 2670 subjects. Liver fibrosis was estimated by measuring liver stiffness with transient elastography (TE). Significant fibrosis was defined as a TE ≥9.2 kPa based on previous data supporting that this cut-off had the best diagnostic accuracy for fibrosis ≥F2 on liver biopsy (Clin. Gastroenterol. Hepatol. 2018 PMID 29452268).
Results: The prevalence of significant fibrosis was 3.1% (83/2670). The median level of PRO-C3 was higher in subjects with significant fibrosis compared to those without (14 vs. 12 ng/ml, $p < 0.001$). The ADAPT score predicted significant fibrosis with moderate accuracy (AUROC 0.76; 95% CI 0.71–0.82), higher than scores frequently used to identify fibrosis in the general population, such as FIB-4 or APRI, and similar to NAFLD Fibrosis Score (NFS). Fatty liver index (FLI) exhibited the highest discriminative ability (AUROC 0.87; 95% CI 0.84–0.91; Figure 1). Amongst subjects with metabolic/alcohol risk factors and a high FLI≥60, the sequential use of ADAPT using the best cut-off of 6.1 had an excellent negative predictive value for significant fibrosis (Se 51%, Sp 82%, PPV 20%, NPV 95%).

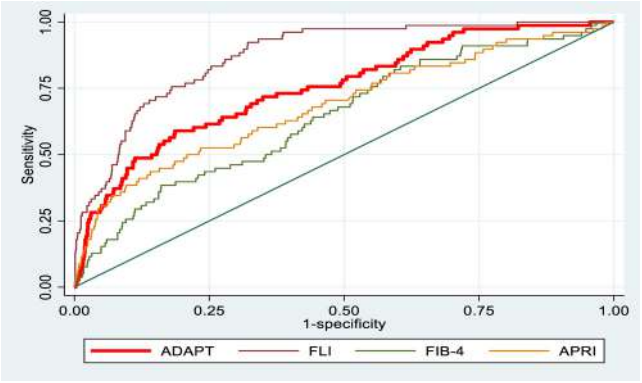


Figure: ROC curves of non-invasive fibrosis scores for prediction of significant fibrosis.

Conclusion: In this population-based study, the ADAPT composite score that includes PRO-C3 offers superior predictive accuracy for the diagnosis of significant liver fibrosis as compared to other recommended screening tools such as FIB-4 and APRI. The individual components of ADAPT are easily accessible clinical parameters and as such could be used as a tool for the early detection of liver fibrosis in the general population, particularly in a sequential-type approach.

Immune-mediated and cholestatic: Experimental and pathophysiology

OS019

Novel anti-cholestatic treatment strategies by combining inhibition of the Apical sodium-dependent bile acid transporter with stimulation of urinary bile salt excretion or lowering bile salt synthesis

Roni Kunst[1,2], Esther Vogels[1], Isabelle Bolt[1], Ronald Oude-Elferink[1,2], Stan van de Graaf[1,2]. [1]*Tytgat Institute for Liver and Intestinal Research, Department of Gastroenterology and Hepatology;* [2]*Amsterdam Gastroenterology Endocrinology Metabolism, Amsterdam, Netherlands*
Email: r.f.kunst@amsterdamumc.nl

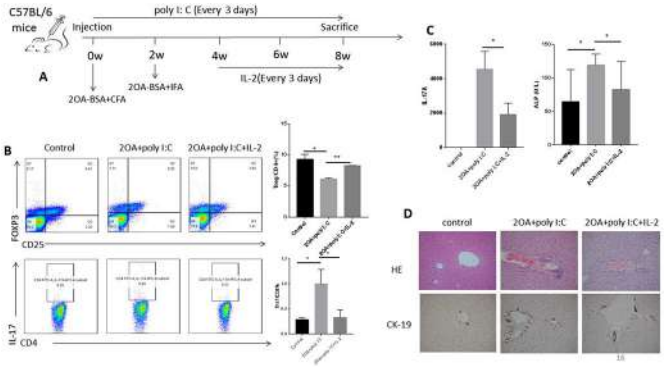
Background and aims: The apical sodium-dependent bile acid transporter (ASBT) is primarily expressed in the small intestine and kidney, where it prevents bile salts from being excreted in respectively feces and urine. Intestine-restricted drugs that inhibit ASBT are currently clinically explored to reduce toxic accumulation of bile acids during cholestasis. Intestine-restricted ASBT inhibitors (ASBTi) may be less effective in severe cholestasis and also yield gastrointestinal side-effects in case of high bile salt load in the colon. Here, we test two ASBT-targeting treatment strategies in pre-clinical models with cholestasis-induced liver injury. First, systemic ASBT inhibition, to increase renal bile acid excretion and second a combination treatment with obeticholic acid (OCA) to limit bile salt synthesis and reduce colonic bile acid load.
Method: Systemic ASBT inhibition was tested by performing a bile duct ligation (BDL) in adult ASBT knock-out (KO) mice (129P2/OlaHsd background, Jackson) and wild-type littermates to induce severe cholestasis. In our second strategy, BDL was performed in adult wild-type C57Bl/6 mice after 2 days oral gavage pre-treatment with OCA and ASBTi. In a different model, wild-type C57Bl/6 mice were fed a 0.1% 3, 5-diethoxycarbonyl-1, 4-dihydrocollidine (DDC) diet while receiving daily treatment with either placebo, OCA, ASBTi or both (OCA + ASBTi). After sacrifice, liver injury was determined by plasma liver enzymes, RT-qPCR and liver histology, while HPLC analysis was used to quantify bile salt concentrations in plasma, liver, small intestine and feces.
Results: ASBT KO mice had reduced liver necrosis, reduced bilirubin and alkaline phosphatase (ALP) levels compared to wild-type mice after BDL. ASBT KO mice also showed a trend to reduced bile salt pool size, and increased urinary bile salt excretion. OCA + ASBTi treatment reduced the total bile salt pool size before cholestasis-onset and resulted in reduced bilirubin, ALP and a ~60% reduction in liver necrosis compared to placebo control in a BDL model. Besides, OCA + ASBTi treatment decreased fecal bile salt excretion compared to monotherapy with ASBTi.
Conclusion: Systemic ASBT inhibition effectively reduces BDL-induced liver damage. Combined OCA + ASBTi treatment lowers the bile salt pool size and improves liver health after BDL-induced cholestasis, while it also shows therapeutic potential by reducing fecal bile salt excretion.

OS020

Low-dose IL-2 alleviates drug-induced primary biliary cholangitis in mice by improving Treg and Th17 balance

Zilong Wang[1], Bo Feng[1], Yandi Xie[1], Rui Jin[1], Zhicheng Liu[1]. [1]*Peking University Hepatology Institute, Beijing, China*
Email: fengbo@pkuph.edu.cn

Background and aims: The imbalance of regulatory T (Treg) and T helper 17 (Th17) cells correlates with increased risk of autoimmune diseases. Their imbalance was also reported in primary biliary cholangitis (PBC) patients. Previous studies have suggested that low-dose IL-2 can alleviate disease severity through modulating $CD4^+$T cell subsets in patients with autoimmune diseases. However, the efficacy of low-dose IL-2 in PBC remains unexplored. Hence, the present study aimed to examine effects of low-dose IL-2 in PBC mouse models.
Method: PBC was induced in female C57BL/6 mice by two immunizations with 2-nonynoic acid (2OA-BSA) at two-week intervals. Besides, polyinosinic polycytidylic acid (poly I:C) was injected i.p. every three days. The control group was injected with PBS instead of 2OA-BSA and poly I:C. PBC mice were divided into the treated and untreated groups, and low-dose IL-2 was injected s.c. every three days after four weeks from modeling in the treated group (Fig. A)and the untreated group was replaced with saline. The serum was isolated from blood sampled by eyeball extirpating for biochemical detection. Th17 and Tregs were analyzed by flow cytometry, and the related cytokines were analyzed by ELISA. Liver histopathology was examined by HandE and immunohistochemical staining. The experimental data were analyzed by SPSS 24.0 software. $P < 0.05$ indicated statistical significance.
Results: Eight weeks after modeling, the serum AMA was positive and the ALP was significantly increased in PBC mice compared with control group. The pathology showed lymphocyte infiltration in the portal area, and damage and reactive proliferation of small bile duct, and $CD4^+$ and $CD8^+$ T cells were infiltrated around the bile duct. Flow cytometric examination of spleen cells revealed recovery of reduced Tregs and increased Th17 after low-dose IL-2 treatment (Treg/CD4%:9.26 ± 0.50 vs 6.10 ± 0.14 vs 8.24 ± 0.04; Th17/CD4%: 0.29 ± 0.20 vs 1.00 ± 0.17 vs 0.33 ± 0.09) ($p < 0.05$) (Fig. B). Low-dose IL-2 treatment inhibited IL-17A levels (0 vs 4549 ± 597.5 vs 1928 ± 387) ($p < 0.05$) and improved serum biochemical index (ALP: 119.1 ± 6.20 vs 82.36 ± 12.6 U/L) (Fig. C). Histopathological examination of liver revealed the improvement of portal area inflammation and reactive bile duct hyperplasia and damage after low-dose IL-2 treatment (Fig. D).



Conclusion: The PBC mouse model was successfully induced by the combination of 2OA-BSA and poly I:C and it can model human disease early status. Low-dose IL-2 inhibited PBC by augmenting Treg and decreasing Th17 numbers, which paly important role in the pathogenesis of the PBC. The improvement of biochemical indexes and liver histopathology, suggesting that low-dose IL-2 treatment may be considered as novel therapy for PBC in the future.

OS021

Cholangiocytes cleave surface CD100 from biliary infiltrating T cells and mediate pathogenic Th17 differentiation

Xiaojun Jiang[1,2,3], Kari Otterdal[2], Brian K. Chung[1,2,3], Christopher Maucourant[4], Christine Zimmer[4], Sverre Holm[2], Daniel Geanon[4], Annika Bergquist[5], Tom Hemming Karlsen[1,3], Niklas Björkström[4], Espen Melum[1,2,3,6,7]. *[1]Norwegian PSC Research Center, Oslo University Hospital Rikshospitalet, 0424 Oslo, Norway; [2]Research Institute of Internal Medicine, Oslo University Hospital Rikshospitalet, 0424 Oslo, Norway; [3]Institute of Clinical Medicine, University of Oslo, 0318 Oslo, Norway; [4]Center for Infectious Medicine, Department of Medicine Huddinge, Karolinska Institutet, Karolinska University Hospital, 141 52 Stockholm, Sweden; [5]Department of Gastroenterology and Hepatology, Karolinska University Hospital Huddinge, Karolinska Institutet, 171 77 Stockholm, Sweden; [6]Section of Gastroenterology, Department of Transplantation Medicine, Division of Surgery, Inflammatory Diseases and Transplantation, Oslo University Hospital Rikshospitalet, 0424 Oslo, Norway; [7]Hybrid Technology Hub-Centre of Excellence, Institute of Basic Medical Sciences, Faculty of Medicine, University of Oslo, 0317 Oslo, Norway.*

Background and aims: Chronic inflammation surrounding bile ducts contributes to the disease pathogenesis of most cholangiopathies, but the mechanism enabling pathogenic immune cells to adapt and survive in the biliary environment remains largely unknown. We have recently reported a variant of CD100 to be the causal mutation for a familial form of primary sclerosing cholangitis (PSC). Herein, we investigate how CD100 participates in the biliary local inflammation and its relevance to the differentiation of pathogenic immune cells.
Method: CD100 expression was assessed by spatial transcriptomics (10x Genomics) and *in situ* immunohistochemistry (IHC) in explanted livers of patients with PSC (n = 4–6) and other cholangiopathies (Ctrl, n = 4–5). Soluble CD100 (sCD100) was measured by ELISA in paired serum, plasma, and bile samples (n = 11–19). Biliary infiltrating immune cells were collected from endoscopic retrograde cholangiopancreatography brush samples (Ctrl, n = 6; PSC, n = 6) and surface expression of CD100 was evaluated by flow cytometry. To model pathogenic interactions between immune cells and cholangiocytes, splenic cells isolated from C57BL/6 wild-type (WT) and CD100 mutated mice were co-cultured with small or large cholangiocytes. Altered gene expression was assessed with RNA sequencing of purified cell subsets after co-culture.
Results: Spatial transcriptomics revealed *SEMA4D/CD100* RNA expression in all examined livers and demonstrated the localization in *KRT19*$^{+}$ bile duct regions (Ctrl, 7–40%; PSC, 11–94%). In contrast, CD100 protein expression measured by IHC was nearly undetectable in diseased periductal areas of the PSC livers. Moreover, surface expression of CD100 on biliary infiltrating immune cells was reduced and accompanied by increased sCD100 in plasma and bile from PSC patients, suggesting that CD100 is cleaved from the surface of immune cells in regions adjacent to the bile ducts. In co-culture experiments, we observed that activated immune cells adhered to cholangiocytes and correlated with the death of large but not small cholangiocytes. T cells were dominant (49.9–64.4%) in the adherent immune population and lost their surface CD100 expression. RNA sequencing data showed increased *Adamts4* in co-cultured cholangiocytes which appeared to cleave CD100. Genes involved in anti-apoptosis and T-helper 17 (Th17) differentiation were enriched in adherent T cells and further upregulated in T cells with mutated CD100.
Conclusion: Cholangiocytes induce cleavage of CD100 on biliary infiltrating T cells that facilitates persistent inflammation and local Th17 differentiation. These findings highlight a novel pathway in the liver with cholangiocyte-driven Th17 cell differentiation that is associated with CD100 cytoplasmic signaling. Targeting this pathogenic pathway serves as an attractive target for mitigating bile duct inflammation in PSC.

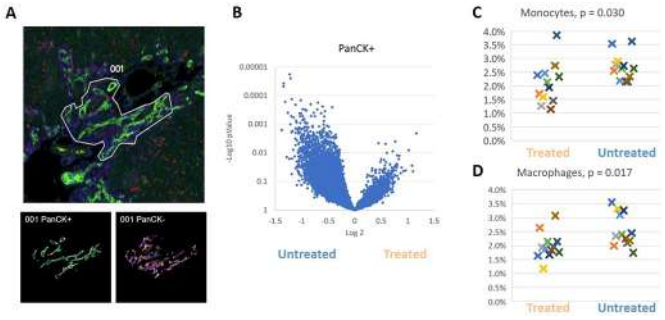
OS022

Novel approach combining whole liver single-cell RNA sequencing and spatial gene profiling using Nanostring GEOMX enables identification of specific cell sub-populations and pathways regulated by CCL24

Michal Segal-Salto[1], Raanan Greenman[1], Arnon Aharon[2], Ophir Hay[3], Amnon Peled[3], Adi Mor[4]. *[1]Chemomab Therapeutics Ltd., RandD, Tel Aviv, Israel; [2]Chemomab Therapeutics Ltd., Clinical, Tel Aviv, Israel; [3]Hadassah Hebrew University Hospital, Genetic Therapy Institute, Jerusalem, Israel; [4]Chemomab Therapeutics Ltd., Tel-Aviv, Israel*
Email: michal@chemomab.com

Background and aims: CCL24 (Eotaxin-2) is a chemokine that regulates profibrotic and proinflammatory activities through the CCR3 receptor. We previously demonstrated that CM-101, a CCL24 blocking antibody, improves liver inflammation, fibrosis and cholangitis in the Mdr2 knockout (Mdr2 -/-) mouse model. Characterization of CCL24 expression in relation to the different cell populations in Mdr2-/- mice and its inhibition effect on cholangiocytes and immune response was studied using two gene expression methods.
Method: Identification of cell population, including immune cells and CCL24 expressing cells in livers of Mdr2-/- mice was done by scRNA seq from whole liver. NanoString's technology was utilized for gene expression studies, focusing on the bile-duct injury sites. In this system segmenting of cholangiocytes (Pan-CK+) and immune cells (Pan-CK–) cells was done in liver sections from Mdr2-/-mice non-treated or treated with CM-101.
Results: Mdr2-/- mice treated with CM-101 resulted in reductions in: serum ALP, liver inflammation, liver peribiliary collagen deposition and cholangiocytes proliferation. Using whole liver scRNA seq we demonstrated that CCL24 is expressed in macrophage cells. This analysis identified a few specific disease relevant immune sub-populations, however it is missing crucial information that relates to cell localization. To overcome this, we used NanoString to characterize the alternations in peribiliary transcriptome following CM-101 treatment. Spatial profiling separated cholangiocytes (PanCK+) and non-cholangiocytes (PanCK–) peribiliary cells, distinguishing cholastatic, proinflammatory and profibrotic effects. Gene set enrichment analysis showed reduction in proliferation and senescence pathways in PanCK+ cells, whereas PanCK- cells showed reduction in ECM remodeling pathways and increased metabolic pathways. Cell deconvolution of the heterogeneous PanCK- population revealed alternation in the peribiliary immune cells, marked by reduction in macrophages and monocytes following treatment with CM-101.

Conclusion: Augmenting whole liver scRNA seq with spatial transcriptome analysis, is a novel approach to identify cell populations and pathways specific to the damaged peribiliary area. Using this approach we demonstrated that CCL24 regulates cholestatic, inflammatory and fibrotic liver damage, and its underling mechanisms. Understanding the underling mechanisms of CCL24 blockade and its ability to prevent liver injury in animal supports its role in PSC and its potential beneficial effect for PSC patients.



OS023

T regulatory cells promote bile duct regeneration through modulating ductular reaction in a model of cholestatic liver injury

Naruhiro Kimura[1,2,3], Gareth Hardisty[1], Atsunori Tsuchiya[3], Shuji Terai[3], David Withers[2], Wei-Yu Lu[1,2]. [1]*University of Edinburgh, Centre for Inflammation Research, Edinburgh, United Kingdom;* [2]*University of Birmingham, Institute of Immunology and Immunotherapy, Birmingham, United Kingdom;* [3]*Niigata University, Division of Gastroenterology and Hepatology, Niigata, Japan*
Email: w.y.lu@ed.ac.uk

Background and aims: Reduced regulatory T cells (Tregs) and increased bile duct senescence are observed in primary sclerosing cholangitis (PSC) patients, with the degree of cholangiocyte senescence linking to disease severity and prognosis. Cholangiocytes can act as facultative liver progenitor cells through ductular reaction during extensive liver damage, whether this process is impaired during PSC remains to be investigated. The role of Tregs in modulating tissue resident progenitor cells have been shown in multiple organs, but this remains unclear in the context of liver regeneration. We aim to use transgenic murine models to investigate the cause of reduced Tregs in the liver and whether the lack of Tregs in the liver affect bile duct regeneration and senescence.
Method: Foxp3^{GFP}DTR transgenic mice were used to reduce Tregs number in a dose dependant manner. 50% of Tregs were depleted to avoid triggering systematic autoimmunity whilst cholestatic liver injury was induced by the feeding of 3, 5-diethoxycarbonyl-1, 4-dyhydrocollidine (DDC) diet and compared to the control group with intact Tregs population. We generated the Foxp3^{GFPCreERT}tdTom^{loxSTOPlox} mice to investigate Tregs stability. Tamoxifen was injected intraperitoneally to induce tdTom expression in Foxp3 Tregs and cell fate was investigated after DDC diet to determine Tregs stability. CD4 T-cells were isolated and co-cultured with intrahepatic cholangiocytes organoids to confirm the effect of CD4 T-cells on cholangiocytes.
Results: Mice with reduced Tregs have a lower tolerance to the feeding of DDC diet, with rapid weight loss and two times higher periportal fibrosis than the control group. Histological findings showed that the reduction in Tregs decrease the magnitude of Ck19^{+} ductular reaction by 30%. A two-fold increase in Ck19+p21+ senescing cholangiocytes was observed in the group with reduced Tregs after DDC induced liver injury. Transcriptional analysis of liver tissue revealed downregulation of *Yap1*, *Sox9* and *Ctgf*, suggesting the Yap pathway is affected following Tregs reduction. This is further confirmed with immunohistochemistry showing a two-fold reduction in the number of Yap and Sox9 expressing Ck19+ cholangiocytes. The Foxp3 fate mapping experiments showed that the labelled Tregs population reduces Foxp3 expression after DDC diet indicating that the stability of Tregs decreases during liver injury.
Conclusion: Our results demonstrated that the role of Tregs in promoting bile duct regeneration by modulating ductular reaction through the Hippo-Yap pathway. Furthermore, the observation that Foxp3 Tregs become unstable in an injured microenvironment in mice may explain the lack of Tregs seen in PSC patients. These show the potential of using Tregs to promote liver regeneration but also highlights the stability of Tregs should be taken into consideration when designing cell based Tregs therapy.

Deep learning for automatic diagnosis and morphologic characterisation of malignant biliary strictures using digital cholangioscopy: a pilot study

Miguel Mascarenhas[1], João Afonso[1], Tiago Ribeiro[1], Ana Santos[1], Hélder Cardoso[1], João Pedro Sousa Ferreira[2], Filipe Vilas-Boas[1], Pedro Pereira[1], Guilherme Macedo[1]. [1]*Centro Hospitalar Universitário de São João, Department of Gastroenterology, Porto, Portugal;* [2]*Faculdade de Engenharia da Universidade do Porto, Department of Mechanical Engineering, Porto, Portugal*
Email: miguelmascarenhassaraiva@gmail.com

Background and aims: Patients with indeterminate biliary strictures (BS) pose a significant diagnostic challenge. Digital cholangioscopy (DC) has enabled morphologic characterization as well as the performance of visually guided biopsies. However, the diagnostic yield of DC remains suboptimal, and the visual characterization of these lesions has significant interobserver variability. Recently, the development of artificial intelligence (AI) algorithms, particularly convolutional neural networks (CNNs) for interpretation of endoscopic images has generated intense interest. We aimed to develop a CNN-based system for simultaneous automatic detection of malignant BS in D-SOC images and identification of three morphologic features: nodules (NN), papillary projections (PP) and tumor vessels (TV).
Method: We developed and validated a CNN based on DC images (Spyglass DS II, Boston Scientific, USA). Each frame was labeled as normal/benign finding or as a malignant lesion if definite histologic evidence of biliary malignancy was available. Moreover, we evaluated the performance of the CNN for the detection of morphologic features associated with histology-proved biliary malignancy: NN, PP, and TV. The image dataset was split for constitution of training and validation datasets. The performance of the CNN was measured by calculating the accuracy, area under the curve (AUC), sensitivity, specificity, positive and negative predictive values (PPV and NPV, respectively).
Results: We included 23 595 images from 125 patients (20719 of malignant BS and 2876 of normal or benign findings). The model had a sensitivity of 98.9%, a specificity of 97.7% and an overall accuracy of 98.7%. The AUC was 1.00.
Additionally, the model comprised 2876 images of NN, 1675 images showing PP, and 4153 images of YV. The accuracy for the automatic detection of each of these features was, respectively, 96.9%, 96.1%, and 91.5%.
Conclusion: We developed a combined CNN for automatic detection of malignant BS as well as the automatic identification of morphologic features associated with increased probability of malignancy. The application of AI models to DC may increase its diagnostic yield for patients with indeterminate BS. Furthermore, accurate real-time automatic identification of features associated with increased probability of malignancy may help to guide biopsies, thus increasing their rentability.

Table 1: Performance metrics of the combined convolutional neural network

	Malignant strictures (vs. normal/benign findings)	NN (vs normal/other findings)	PP (vs normal/ other findings)	TV (vs normal/ other findings)
Sensitivity	98.9%	96.1%	98.2%	85.7%
Specificity	97.7%	98.9%	94.8%	100%
PPV	99.7%	99.5%	91.7%	100%
NPV	92.8%	91.4%	98.9%	82.5%
Accuracy	98.7%	96.9%	96.1%	91.5%
AUC	0.987	1.000	1.000	1.00

Abbreviations; PPV-positive predictive value; NPV-negative predictive value; AUC-area under the curve.

Non-invasive assessment/treatment and liver related outcomes in NAFLD/ALD

OS025

Non-invasive fibrosis scores as prognostic biomarkers of liver events, cardiovascular events and all-cause mortality in people with obesity and/or type 2 diabetes in the UK: a longitudinal cohort study

Tarp[3], Kamlesh Khunti[4]. *[1]Translational and Clinical Research Institute, Faculty of Medical Sciences, Newcastle University, Newcastle Upon Tyne, United Kingdom; [2]Newcastle NIHR Biomedical Research Centre, Newcastle Upon Tyne Hospitals NHS Trust, Newcastle Upon Tyne, United Kingdom; [3]Novo Nordisk A/S, Søborg, Denmark; [4]Diabetes Research Centre, University of Leicester, Leicester General Hospital, Leicester, United Kingdom*

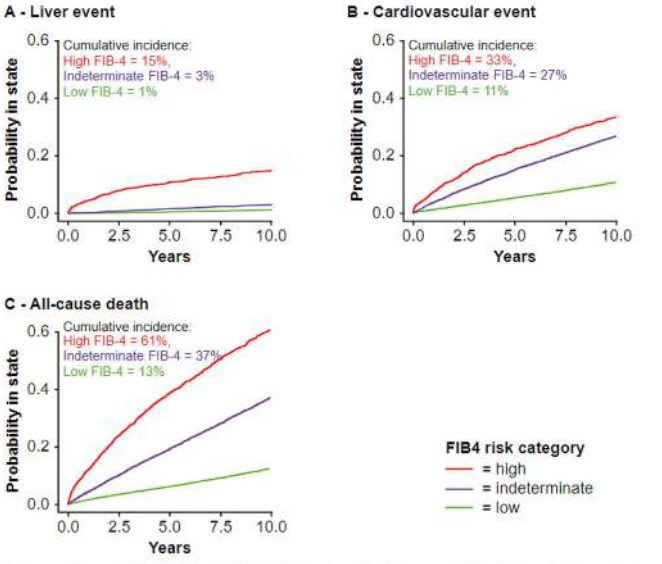
Email: quentin.anstee@ncl.ac.uk

Background and aims: Progression of non-alcoholic steatohepatitis to cirrhosis may lead to life-threatening liver-related complications, increased liver-specific and all-cause mortality and cardiovascular (CV) disease. An important predictor of severe outcomes is biopsy-confirmed liver fibrosis, but biopsies are not scalable outside of specialist practice. This real-world study investigated the prognostic utility of six non-invasive fibrosis scores on clinical outcomes in patients with obesity and/or type 2 diabetes (T2D) seen in routine general practice.

Method: In a longitudinal cohort design, patients ≥18 years with obesity and/or T2D, ≥1 fibrosis score calculable from the UK Clinical Practice Research Datalink (CPRD) after 1 January 2001, no alcohol-related disorders and/or other chronic liver diseases in Hospital Episodes Statistics (HES) and/or no prescriptions of drugs inducing liver disease in CPRD were included. Patients were followed from inclusion date until time of first clinical outcome event (liver-related hospitalisation or death [liver event], CV hospitalisation or death [CV event] or all-cause death) recorded in HES or Office for National Statistics Death Registration, database migration, 10 years' follow-up or 1 January 2020, whichever came first. Fibrosis-4 Index (FIB4), the score of focus, was categorised as low (<1.30), indeterminate (1.30–2.67) or high (>2.67) risk. Cumulative incidence functions were calculated and hazard ratios (HRs) estimated using Cox proportional hazards models with calendar time as underlying timescale.

Results: In total, 44 481 eligible patients (46% male, median age 58.8 years) had measures available for FIB4 calculation. There were 979 liver events, of which ascites (n = 412), cirrhosis (n = 201) and gastro-oesophageal varices (n = 160) were most common. The risk of an incident liver event was highest in the first years after FIB4 measurement in the high FIB4 group and relatively constant over time in the other two groups (Figure). The incidences of a liver event, CV event and death in the high FIB4 group were 15%, 33% and 61%, respectively. Patients in the indeterminate and high FIB4 groups were at greater risk of liver events vs the low-risk group (HR 2.81 [95% confidence interval 2.43, 3.26] and 18.42 [15.67, 21.65], respectively). An increased risk was also seen for CV events and all-cause mortality in these groups. HRs remained higher for the high vs low FIB4 group after adjustment for sex and age. For the other scores, risk of an outcome event was also elevated for patients with a high vs low score.

Cumulative incidence plots for liver events, cardiovascular events and mortality according to Fibrosis-4 Index (FIB4) in the population with obesity and/or type 2 diabetes



Percentage risks are for 10 years' follow-up. Event risks plotted as Aalen-Johansen cumulative incidence functions, with all-cause mortality included as a competing risk factor in plots of liver and cardiovascular events.

Conclusion: In this real-world population of patients with obesity and/or T2D, and no other clinically recognised liver disease, the risk of a clinical event was significantly higher in patients with high vs low FIB4 score, highlighting the prognostic potential of FIB4 (and other non-invasive fibrosis scores) in this population.

Email: hhegmar@gmail.com

Background and aims: Prognosis in chronic liver disease is heterogenous, and fibrosis stage is the best predictor of liver-related events. Liver stiffness measurement (LSM) by Vibration-Controlled Transient Elastography (VCTE) is a non-invasive biomarker of fibrosis. It is uncertain if LSM can predict risk for future liver-related events. The aim was to investigate the prognostic ability of LSM.

Method: This was a Swedish multi-center cohort study including patients (n = 13, 170) with chronic liver disease who underwent LSM by VCTE between 2008 and 2019. Exclusion criteria were an unreliable LSM, congestive heart failure, and decompensated cirrhosis at baseline. Liver-related events were ascertained from Swedish national health registers. In patients without baseline cirrhosis, we investigated progression to "severe liver disease," defined as a diagnosis of cirrhosis, decompensated cirrhosis or hepatocellular carcinoma (HCC). In patients with baseline cirrhosis, we investigated progression to decompensation or HCC. Incidence rates and cumulative incidence at two and five years were calculated. Cox regression was used to evaluate the rate of outcomes for categories of LSM values.

Results: Patients (median age 46 years, 59% men) had a median LSM of 5.9 (interquartile range 4.6–8.0) kPa. Etiologies consisted of hepatitis C (n = 6849, 52.0%), hepatitis B (n = 3497, 26.6%), alcohol-related liver disease (n = 211, 1.6%), autoimmune liver disease (n = 624, 4.7%), non-alcoholic fatty liver disease (n = 699, 5.3%) and other or uncertain etiologies (n = 1290, 9.8%). Patients without baseline cirrhosis (n = 11, 883) had 333 (2.8%) events of severe liver disease during a median follow-up time of 2.9 years. Patients with cirrhosis at baseline (n = 1287) had 206 (16.0%) events of decompensation or HCC. In patients without cirrhosis, a LSM of 12–15 kPa was associated with a 42-fold higher rate of severe liver disease than a LSM of <6 kPa (Figure A). In patients with cirrhosis, a LSM >30 kPa was associated with a 5.4-fold higher rate of decompensation compared to a LSM of 15–17 kPa (Figure B). Incidence rates per 1000 person-years in severe liver disease ranged from 2.1 (95%CI 1.6–2.8) to 88.9 (95%CI 73.2–107.9) for LSM <6 kPa and 12–15 kPa, respectively. Incidence rates per 1000 person-years in decompensated cirrhosis ranged from 18.2 (95% CI 10.3–32.0) to 109.6 (95%CI 88.9–135.1) for LSM 15–17 kPa and >30 kPa, respectively. In patients without cirrhosis, the cumulative incidence at two years ranged from 0.4 (0.3–0.6)% to 19.1 (15.1–23-5)%, and at five years from 1.1 (0.8–1.6)% to 32.9 (26.9–38.9)%, respectively.

Conclusion: Increased LSM by VCTE is associated with higher rates of progression to cirrhosis and decompensation in a dose-response manner. The results can be used to guide follow-up and treatment decisions.

Medicine and Human Genetics, Philadelphia, United States
Email: craig.teerlink@va.gov

Background and aims: FIB-4 is a clinically relevant marker to track fibrosis in patients with chronic liver disease including NAFLD/NASH. Here, we first defined Fib-4 trajectory by linear slope of serial FIB-4 measurements as a measure of fibrosis progression, then examined its correlation with liver-related complications and genetic associations with a non-invasive ALT-based proxy NAFLD phenotype recently defined among participants in the VA's Million Veteran Program (MVP) with available clinical and genetic data (Serper et al, PLOS ONE 2020).
Method: Individual FIB-4 slopes were estimated via linear regression for MVP participants with greater than 4 outpatient FIB-4 values who met criteria for proxy NAFLD phenotype based on previously validated algorithm for chronic ALT elevation without other known causes of chronic liver disease. Linear models were constructed excluding outliers at >2 Cook's distances from predicted. Patients whose initial FIB-4 values exceeded the 90% percentile (baseline advanced fibrosis) were assigned slopes equivalent to the 99th percentile of the sample. The AUROCs for the coefficient of FIB-4 slope for predicting development of cirrhosis, hepatocellular carcinoma, ascites and death were generated. MFIB4 was then used as a quantitative phenotype in a genome-wide association analysis using REGENIE software. Variants were restricted to MAF >0.01 and INFO >0.30. Three distinct racial/ethnic groups were defined for the cohort (European, African, and Hispanic ancestry) and analyzed separately; a trans-ancestry meta-analysis was performed with METAL software.
Results: FIB-4 slopes were obtained from 61, 689 subjects (10, 594 African, 46, 137 European, and 4, 958 Hispanic ancestry subjects). AUROC of FIB-4 slope for prediction of cirrhosis, hepatocellular carcinoma or ascites were 0.75–0.76. Among European ancestry subjects, FIB-4 slope was associated with 6 genome-wide significant loci (p value $<5 \times 10^{-8}$) including 3 with previously known associations to NAFLD and hepatic fibrosis (GCKR, HSD17B13, and PNPLA3). The GWAS of African and Hispanic ancestry did not return any significant results, however, the trans-ancestry meta-analysis identified an additional signal.
Conclusion: Fibrosis progression based on FIB-4 trajectory correlated with clinically meaningful complications of liver disease progression, as well as known markers of cirrhosis among patients with non-invasive ALT-based NAFLD phenotype. Further work is ongoing to define the use of FIB-4 trajectory and genetic risk factors as predictors for long term outcome of chronic liver disease.

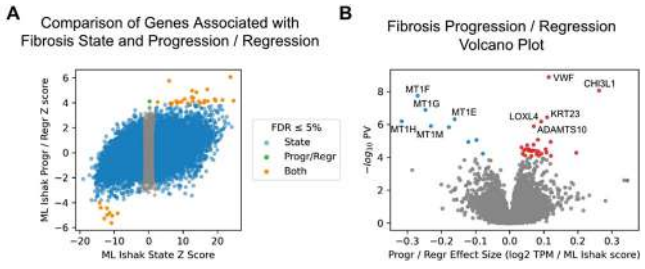
Machine learned histological fibrosis score empowers characterization of baseline gene signatures associated with fibrosis progression or regression in a NASH F3/F4 clinical trial

Michael D. Bereket[1], Francesco Paolo Casale[1], Lorn Kategaya[1], Anna Shcherbina[1], Navpreet Ranu[1], Alicia Lee[1], Kelly Haston[1], Rohit Loomba[2], Arun Sanyal[3], Stephen Harrison[4], Zobair Younossi[5], Catherine Jia[6], David Lopez[6], Li Li[6], Robert Myers[6], David Breckinridge[6], Andrew Billin[6], Ellen Berg[1], Santhosh Satapati[1], Eilon Sharon[1], Theofanis Karaletsos[1], Daphne Koller[1], Matthew Albert[1]. *[1]Insitro, South San Francisco, United States; [2]University of California San Diego, La Jolla, United States; [3]Virginia Commonwealth University, Richmond, United States; [4]University of Oxford, United Kingdom; [5]Inova Fairfax Medical Campus, Fairfax, United States; [6]Gilead Sciences, Inc., Foster City, United States*
Email: research_operations@insitro.com

Background and aims: We characterized disease severity with a machine learning (ML) analysis of liver biopsy images, and used it to identify baseline gene signatures that are predictive of fibrosis progression or regression in NASH.
Method: Bulk RNA-seq, HandE stained biopsy images, and pathologist Ishak fibrosis scores are curated from screening and week 48 visits in the STELLAR 3 and STELLAR 4 clinical trials (n = 1097 patients with all end points). A continuous score for fibrosis was extracted using convolutional neural networks (CNN) trained to predict pathologist scores from HandE-stained biopsies (Casale et al, EASL 2020). We identify genes associated with fibrosis state by testing for associations between baseline expression and baseline fibrosis scores, controlling for age and sex. Fibrosis progression/regression genes are identified by testing for associations between baseline expression and the difference between baseline and followup fibrosis scores after controlling for both ML and pathologist baseline fibrosis scores, age, sex, and treatment.
Results: The continuous ML fibrosis scores are highly correlated with pathologist Ishak scores (correlation = 0.88). Variation of the ML fibrosis score within Ishak scores exhibits similar transcriptomic associations as variation in Ishak scores (correlation of z scores = 0.88), suggesting that the ML score identifies intra-score variability consistent with pathologist assessed fibrosis. We identify 12, 862 genes associated with ML fibrosis state (likely driven in part by changes in cell type composition) and 37 genes associated with ML fibrosis progression/regression (A, B). Using the same covariates, analysis of the ML score identifies a superset of the progression/regression genes identified with the pathologist score (37 vs 3 genes). Notably, the progression/regression-associated genes are not the top state-associated genes. Progression associated genes include expected extracellular matrix and cytoskeletal function-related genes. Lipid metabolism genes identified include the progression associated gene AKR1B10 (involved in hepatic carcinogenesis) and the regression associated gene AKR1D1 (involved in resistance to oxidative stress). Other regression associated genes identified include metallothionein genes, involved in the protection against oxidative stress, and CLEC4M, a liver sinusoidal endothelial cell-specific gene.
Conclusion: ML assessment of liver biopsies and the statistical inference framework introduced herein produced insights on baseline gene expression signatures that are predictive of and potential drivers for NASH fibrosis progression or regression.



Genes associated with fibrosis state and progression / regression. A) Scatter plot of z scores from differential expression analysis of ML fibrosis state and progression / regression. B) ML fibrosis progression / regression differential expression volcano plot.

OS029

Fibroscan-AST (FAST) score predicts liver-related outcomes in 1683 HIV-infected patients at risk for NAFLD

Giada Sebastiani[1,2], Jovana Milic[3], Dana Kablawi[1], Claudia Gioe'[4], Al Shaima Al Hinai[2], Bertrand Lebouche[5], Amine Benmassaoud[1], Marc Deschenes[1], Antonio Cascio[4], Giovanni Mazzola[4], Giovanni Guaraldi[3]. *[1]McGill University Health Centre Glen Site (MUHC), Medicine, Montréal, Canada; [2]McGill University, Division of Experimental Medicine, Montréal, Canada; [3]University of Modena and Reggio Emilia, Modena, Italy; [4]Università degli Studi di Palermo, Health Promotion Sciences and Mother and Child Care "Giuseppe D'Alessandro", Palermo, Italy; [5]McGill University Health Centre Glen Site (MUHC), Family Medicine, Montréal, Canada*
Email: giada.sebastiani@mcgill.ca

Background and aims: Non-alcoholic fatty liver disease (NAFLD) affects 35% of people living with HIV (PWH) in absence of viral

hepatitis coinfection. About 15% of these PWH have also significant liver fibrosis. Natural history studies employing accurate non-invasive tools are lacking. The FibroScan-AST (FAST) score was developed to identify patients with histologic NASH with advanced fibrosis and elevated NAFLD activity score (NAS) associated with higher risk of end-stage liver disease. We estimated prevalence and evolution of severe NAFLD defined by FAST score in a large multicenter cohort of PWH.

Method: FibroScan was performed in consecutive PWH without viral hepatitis coinfection from three prospective cohorts in Canada and Italy (LIVEHIV in Montreal; liver pathologies in HIV in Palermo; Modena HIV metabolic clinic) as part of a routine screening program for NAFLD. We compared prevalence of FAST>0.35 (90% sensitivity and 50% specificity for NASH with ≥F2 fibrosis and NAS≥4) and FAST≥0.67 (50% sensitivity, 90% specificity). Incidence of liver-related outcomes (ascites, encephalopathy, variceal bleeding, hepatocellular carcinoma) and extra-hepatic events (cancer, cardiovascular disease) was evaluated by survival analysis.

Results: We included 1683 PWH (mean age 50.1 years, HIV duration 15.5 years, BMI 25.3 Kg/m^2; 74.5% male, diabetes prevalence 32%). Prevalence of FAST>0.35 and FAST≥0.67 was 8.1% and 1.5%, respectively. At baseline, on multivariable logistic regression higher BMI (adjusted odds ratio [aOR] 1.15, 95% CI 1.10–1.20), longer duration of HIV infection (aOR 1.05, 95% CI 1.02–1.07), lower CD4 cell count (aOR 0.99, 95% CI 0.99–0.99) and male sex (2.11, 95% CI 1.22–3.65) were associated with FAST >0.35. During a median follow-up period of 3.5 years, incidence of liver-related and extra-hepatic outcomes was 7% and 11.5%, respectively. Incidence of liver-related outcomes significantly increased according to FAST score category (see Figure). There was no difference in extra-hepatic events by FAST score category. On multivariable Cox regression analysis, FAST score >0.35 was an independent predictor of liver-related outcomes (adjusted hazard ratio 4.44, 95% CI 1.66–11.9) after adjusting for sex, BMI, diabetes, duration of HIV infection, protease inhibitors exposure and CD4 cell count.

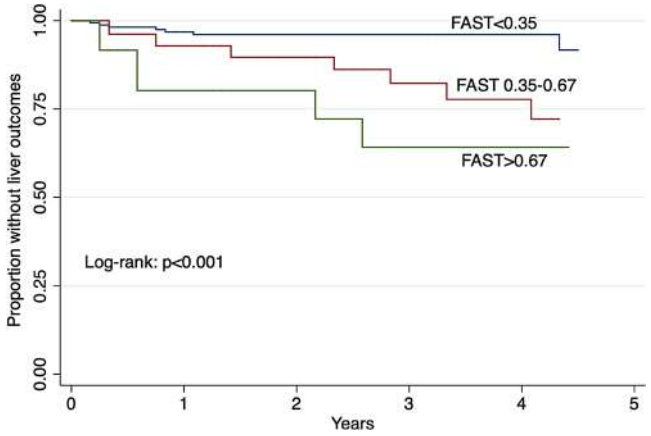


Figure: Survival curves for incidence of liver-related outcomes by FAST score category.

Conclusion: A significant proportion of PWH without viral hepatitis coinfection are at risk for severe NAFLD. FAST score predicts liver-related in this population. Non-invasive testing can help risk stratification and management in this population at risk for NASH and associated liver-fibrosis.

OS030

Impact of resmetirom-mediated reductions in liver volume and steatosis compared with placebo on the quantification of fibrosis using second harmonic generation in a serial liver biopsy study

Dean Tai[1], Mustafa Bashir[2], Rebecca Taub[3], Yayun Ren[1], Elaine Chng[4], Stephen Harrison[5]. *[1]Histoindex, Research; [2]Duke University, Radiology; [3]Madrigal Pharmaceuticals, RandD, Conshohocken, United States; [4]Histoindex, [5]Pinnacle, Clinical Research*
Email: rebeccataub@yahoo.com

Background and aims: Resmetirom (MGL-3196) is a liver-directed, orally active selective thyroid hormone receptor-β agonist that reduces steatosis by MRI-PDFF (−43% (80 mg); −53% (100 mg), Phase 3) and liver volume (LV) −20% (Phase 2 serial liver biopsy

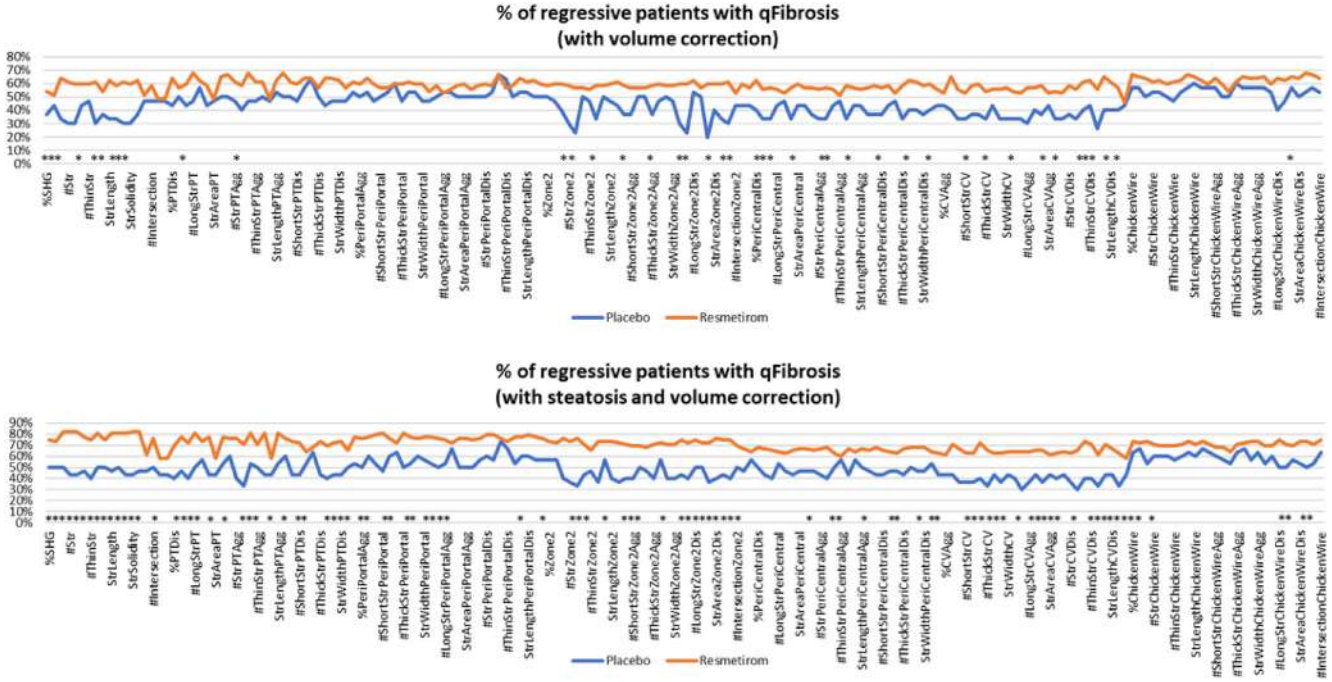

Figure: (abstract: OS030)

study) that were elevated at baseline. Assessment of histological features that stage NASH fibrosis may be impacted in the setting of decreased steatosis and LV following therapeutic intervention. Artificial intelligence (AI)-based algorithms such as qFibrosis can incorporate normalization procedures to account for steatosis area and LV reduction, thereby improving the detection of fibrosis changes. The aim of this analysis is to quantify and correct fibrosis changes related to resmetirom-mediated steatosis and LV changes that are not captured by NASH-CRN scoring system.

Method: Fibrosis was estimated as a continuous variable using second harmonic generation (SHG) (qFibrosis)/two photon excited fluorescence of 102 paired biopsy samples from MGL-3196-05, a 36-week randomized double-blind, placebo-controlled resmetirom phase 2 serial liver biopsy study. qFibrosis (normalized by tissue area) was subsequently corrected for steatosis (tissue area-steatosis area), or LV reduction determined by PDFF (volume/average volume raw parameter based on all samples). In the final model, steatosis and LV were both corrected prior to assessment of qFibrosis. Relative changes in 184 fibrosis parameters were determined as (P) progressing (≥10%), (R) regressing (<10%) or (N) no change.

Results: In normal qFibrosis without correction, resmetirom treatment resulted in a significant reduction in fibrosis (≥1-point reduction) in F3 patients compared to placebo. With LV correction, 45/184 regression parameters demonstrated significant changes after resmetirom treatment (top panel). When steatosis and LV correction factors were combined, 111/184 ($p < 0.05$) regression parameters were reduced significantly with resmetirom (bottom panel). Fibrosis regression was observed in all regions (portal, per-portal, zone 2, peri-central, central). Progression patterns were different from regression and also significantly impacted by correction.

Conclusion: Quantification of changes in NASH fibrosis are impacted by therapeutic interventions that reduce LV. Correcting the AI-based algorithm of qFibrosis for LV and steatosis reveals the significant impact of resmetirom across treated patients in this phase 2 study, regardless of NASH fibrosis stage.

Alcoholic liver disease

OS031

Survival and liver recompensation after declined for early liver transplantation for severe alcohol-associated hepatitis

Christine Hsu[1], Ethan Weinberg[2], Gene Im[3], William Davis[1], Jimin Ko[4], Stephanie Rutledge[3], Matthew Dukewich[2], Mohamed Shoreibah[5], Mahmoud Aryan[5], Aidan Vosooghi[6], Michael R. Lucey[7], John Rice[7], Norah Terrault[8], Brian Lee[6]. *[1]Medstar Georgetown University Hospital, Medicine, District of Columbia, United States; [2]University of Pennsylvania, Medicine, Philadelphia, United States; [3]Mount Sinai, Medicine, New York, United States; [4]Georgetown University School of Medicine, Medicine, District of Columbia, United States; [5]University of Alabama at Birmingham, Medicine, Birmingham, United States; [6]University of Southern California, Medicine, Los Angeles, United States; [7]University of Wisconsin, Medicine, Madison, United States; [8]University of Southern California, Medicine, Los Angeles, United States*
Email: cch87@georgetown.edu

Background and aims: Early liver transplantation (LT) for alcohol-associated hepatitis (AH) is controversial in part because some patients may recover, and obviate the need for LT. We aimed to (i) determine factors associated with survival and liver recompensation among patients with severe AH declined for early LT; (ii) delineate the trajectory of recompensation and MELD recovery among survivors.

Method: In this retrospective, multi-center study among 5 American Consortium of Early Liver Transplantation for Alcohol-Associated Hepatitis (ACCELERATE-AH) sites, we randomly sampled 134 patients who were evaluated and then declined for early LT for severe AH between 2012 and 2021. All had MELD>20 and less than 6 months of abstinence at LT evaluation. Recompensation was defined as MELD<15 without evidence of variceal bleeding, or ascites requiring diuretics, or overt hepatic encephalopathy requiring medication. Analyses were adjusted for center clustering.

Results: Among 134 patients (median age 49 [IQR 39–57]; 57% male; median abstinence time 36 [IQR 14–70] days; median MELD-Na 33 [IQR 28–38]), the most common reasons for LT decline were: psychosocial (62%), clinical improvement (16%), medical co-morbidities (9%), and financial/insurance (4%). Probability of 3-month, 6-month, and 1-year survival was 58%, 55%, and 48%. Probability of 3-month, 6-month, and 1-year recompensation was 4%, 4%, and 6%. In multivariable analysis, lower MELD-Na (aOR 0.8; $p = 0.01$) and absence of grade 3 or 4 hepatic encephalopathy (aOR 0.02; $p = 0.004$) were associated with 3-month survival. In multivariable analysis, lower MELD-Na (aOR 0.9; $p < 0.001$), married/stable partner (OR 2.0; $p = 0.001$), and private (aOR 3.4; $p = 0.01$) or Medicare (aOR 4.7; $p = 0.002$) vs. Medicaid (reference) insurance were associated with 6-month survival. Among patients declined due to clinical improvement during LT evaluation, 93% were alive at 6 months, but only 15% were recompensated. Among survivors, median MELD at 1-month, 3-months, 6-months, and 1-year were: 28 (IQR 22–38), 26 (IQR 19–33), 15 (IQR 12–23), and 12 (IQR 8–18).

Conclusion: Liver recompensation is very rare among patients with severe AH declined for early LT. Lower MELD was predictive of short- and long-term survival, and marital and insurance status emerged as strong predictors of long-term survival. The distinction between survival and liver recompensation after LT evaluation for severe AH would benefit from further attention.

OS032

Role of macrophage-derived MLKL in alcohol-associated liver disease

Xiaoqin Wu[1], Xiude Fan[1], Megan McMullen[1], Tatsunori Miyata[1], Adam Kim[1], Vai Pathak[1], Jianguo Wu[1], Nicole Welch[1], Jaividhya Dasarathy[2], Srinivasan Dasarathy[1], Laura Nagy[1]. *[1]Cleveland Clinic; [2]Case Western Reserve University, Department of Family Medicine, Metro Health Medical Center*
Email: nagyl3@ccf.org

Background and aims: Mixed Lineage Kinase Domain like Pseudokinase (MLKL), a key downstream effector of necroptosis, also has non-necroptotic functions in regulating intracellular and extracellular vesicle trafficking that disrupts the balance between cell death and survival, critical for regulating liver injury and inflammation in alcohol-associated liver disease (ALD). Previously, we observed that *Mlkl*$^{-/-}$ mice were partially protected from ethanol-induced injury. Immunohistochemical staining of liver biopsies from patients with alcohol-associated hepatitis (AH) revealed that phospho-MLKL was localized to both hepatocytes and mononuclear immune cells. Moreover, MLKL co-localized with macrophage marker F4/80 in liver of ethanol-fed mice. Given the important contribution of macrophages to the pathogenesis of ALD, we hypothesized that macrophage-derived MLKL has a potential role in ethanol-induced injury.

Method: Primary mouse Kupffer cells (mKCs) isolated from *Mlkl*$^{-/-}$ and wild type (WT) mice and peripheral monocytes from healthy controls (HC) and patients with AH, treated or not with an inhibitor of MLKL, were used in phagocytosis assays. Bone marrow transplants between *Mlkl*$^{-/-}$ mice and littermates were conducted to distinguish the role of myeloid vs non-myeloid MLKL in the Gao-binge murine model of ALD.

Results: Challenge of macrophages with lipopolysaccharide (LPS) induced STAT1-mediated expression and phosphorylation of MLKL, as well as translocation and oligomerization of MLKL to intracellular compartments including phagosomes and lysosomes, but not the plasma membrane. LPS enhanced uptake and degradation of pHrodo

red E.coli bioparticles by mKCs, whilst ethanol impaired this phagocytic process. Pharmacological or genetic inhibition of MLKL suppressed phagocytic capability of mKCs both at baseline or in response to LPS with/without ethanol, as well as peripheral monocytes isolated from both HC and patients with AH. Additionally, *in vivo* study showed that *Mlkl* deficiency in non-myeloid cells (WT→*Mlkl*$^{-/-}$) had no effect on Gao-binge ethanol-induced injury; in contrast, ethanol-induced hepatic injury, steatosis and inflammation were exacerbated in *Mlkl*$^{-/-}$→WT chimeric mice. *Mlkl*$^{-/-}$→WT mice also had elevated numbers of hepatic macrophages, monocytes and neutrophils in response to ethanol. Flow cytometry analysis of non-parenchymal cells demonstrated that *Mlkl* deficiency in myeloid cells suppressed Gao-binge-triggered F4/80^{+} macrophage death via necrosis/necroptosis. Furthermore, *Mlkl* deficiency in myeloid cells exacerbated ethanol-mediated bacterial burden in livers, likely through inhibiting expression of phagocytic receptors.

Conclusion: Together, these data indicate that macrophage-derived MLKL restricts ethanol-induced liver inflammation and injury by regulating hepatic innate cell homeostasis and phagocytosis of macrophage.

OS033

Baseline plasma metabolic phenotype of patients with severe alcoholic hepatitis and its association with outcome

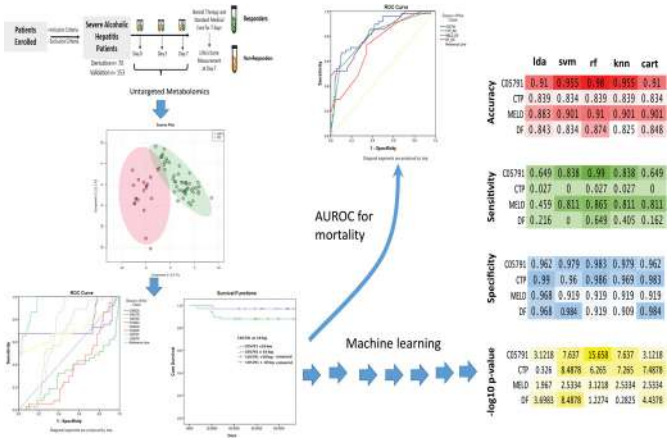
Manisha Yadav[1], Gaurav Tripathi[1], Nupur Sharma[1], Babu Mathew[1], Vasundhra Bindal[1], Jaswinder Maras[1], Shiv Kumar Sarin[2]. [1]*Institute of Liver and Biliary Sciences, Molecular and Cellular Medicine, New Delhi, India;* [2]*Institute of Liver and Biliary Sciences, Hepatology, New Delhi, India*
Email: jassi2param@gmail.com

Background and aims: Severe alcoholic hepatitis (SAH) has a high mortality and corticosteroid therapy is effective in reducing 28-day mortality in only about 60% of patients. There are reliable clinical indicators predicting steroid non-response after 7 days of therapy (Lille score >0.45).

Method: Plasma metabolic phenotype was studied using ultra-high-performance liquid chromatography and high-resolution mass spectrometry to identify corticosteroid non-responders at baseline. Altogether, 223 SAH patients were included, 70 in derivative [50 responders (R) and 20 non-responders (NR)] and 153 in validation cohort [136 R, 17 NR]. Temporal change in the metabolic profile and Weighted Metabolome Correlation Network Analysis (WMCNA) were performed and correlated to disease severity.

Results: Of the 713 annotated features (metabolomic/biochemical/spectral databases), 8 plasma metabolites significantly discriminated non-responders; most importantly high urobilinogen (13-fold), cholesterol sulfate (6.9-fold), AMP (4.7-fold), N-Formimino-L-glutamate (4.3-fold), tryptophan (4.7 folds), and low 4-imidazoleacetate (10 fold), urocanic acid (2.2 fold) and thymine (2.4 fold) levels. Additionally, plasma urobilinogen, AMP, and cholesterol sulfate discriminated non-survivors ($p < 0.01$). Temporal change in metabolite expression was higher in responders ($p < 0.05$). WMCNA identified metabolite modules and linked pathways specific to NR and mortality with disease severity ($r > 0.7$; $P < 0.01$). In validation cohort, baseline plasma urobilinogen (C05791) showed high reliability [AUC = 0.94, 0.91–0.97] for predicting non-response with hazard-ratio of 1.5 (1.2–1.6) for mortality prediction. C05791 at 10 log (arbitrary units) cut-off reliably segregated non-survivors (p value <0.01, log-rank test) and showed 98% accuracy, 99% sensitivity and 98% specificity using Random Forest-based Machine-Learning model.

Conclusion: Plasma metabolome signatures can predict pre-therapy steroid response and disease outcome in patients with SAH. Baseline plasma urobilinogen levels should be used for determining corticosteroid response.



OS034

Il-1beta Signal Inhibition in acute alcoholic hepatitis: a multicentre, randomised, double-blind, placebo-controlled phase 2 trial of canakinumab therapy (ISAIAH)

Email: nvergis@imperial.ac.uk

Background and aims: Short-term mortality in acute alcohol-related hepatitis (AAH) patients is high and available therapy does not result in durable benefit. A role for IL-1beta has been demonstrated in the pathogenesis of alcohol-induced steatohepatitis in mice. This study explored the safety and potential benefits of canakinumab (CAN), a monoclonal antibody targeting IL-1beta, for patients with AAH in a double-blind placebo (PBO)-controlled randomised trial.

Method: Patients with biopsy-confirmed AAH and discriminant function ≥32 but MELD ≤27 were randomly allocated 1:1 to receive either CAN 3 mg/kg or PBO once in 4 weeks. Liver biopsies were taken before and 28 days after treatment. The primary end point was histological improvement at 28 days compared to baseline, adjudicated by 3 independent histopathologists who were blinded to treatment allocation. Key secondary end points were the proportions of Lille responders; changes in MELD; and death within 90 days. Adverse events, including infections, were compared between groups.

Results: Fifty-seven patients were randomised: 29 CAN vs 28 PBO. Two patients were withdrawn with negative biopsy results; 1 did not receive allocated intervention due to an adverse event and a further 6 did not attend for second biopsy. Data were therefore available for 48 patients for primary end point analysis. In CAN-treated patients, 14/

24 (58.3%) demonstrated histological improvement compared to 10/24 (41.7%) PBO-treated patients, a difference of 16.7% (p = 0.248). Regression models did not identify significant improvement of CAN-therapy on prognostic scores of liver function such as Lille model or MELD. Four of the 55 AAH patients (7.3%) in the intention-to-treat analysis died within 90 days: 2 in each group. There were 20 vs 29 serious adverse events occurring in 10 vs 10 patients (CAN vs PBO). There were no safety signals: of the 49 serious adverse events, 6 were infectious complications of which 1/20 (5%) occurred in CAN-treated and 5/29 (17%) occurred in PBO-treated patients. In exploratory analyses after adjustment for baseline prognostic factors, CAN therapy was associated with overall histological improvement (p = 0.04), improvement in mononuclear cell infiltrate (p = 0.06), and reduction in serum AST (p = 0.02).

Conclusion: CAN therapy in AAH demonstrated a good safety profile but did not alter biochemical or clinical outcomes compared to PBO. After adjustment for baseline prognostic factors, CAN was associated with histological improvements that did not translate into improved prognostic scores of liver function nor survival.

Outcome	Canakinumab	Placebo	P
Histological Improvement (%)	58.3	41.7	0.25
Lille response (% Lille score<0.45)	22.2	25.0	0.8
Day 28 median MELD change	−5.07	−6.50	0.14
Day 28 median GAHS change	−2	−2	0.69
SAEs (n)	20	29	-
Infection SAEs (n)	1	5	0.38

OS035

Probiotic LGG-derived exosome-like nanoparticles inhibit ALD through intestinal FXR activation in mice: role of miR194 and bile acids

Wenke Feng[1], Mengwei Jiang[1], Fengyuan Li[1], Craig J. McClain[1], Lihua Zhang[1], Jiyeon Lee[1]. [1]*University of Louisville, Medicine, Louisville, United States*
Email: wenke.feng@louisville.edu

Background and aims: Patients with alcohol-associated liver disease (ALD) often exhibit excessive bile acid (BA) accumulation and steatosis. Farnesoid X receptor (FXR)-fibroblast growth factor 15/19 (FGF15/19) signaling plays a critical role in hepatic lipid and BA metabolism. In this study, we aimed to investigate whether alcohol exposure reduced BA-mediated intestinal FXR activation and increased intestinal miR194 expression that suppressed *Fxr* mRNA expression, and whether *Lactobacillus rhamnosus* GG-derived exosome-like nanoparticles (LDNPs) attenuated ALD through regulation of intestinal miR194-FXR-FGF15 signaling in mice.

Method: C57BL/6, global Fgf15 knockout ($Fgf15^{-/-}$), and intestinal epithelial cell-specific *Fxr* knockout ($Fxr^{\Delta IEC}$) mice were administered the NIAAA binge-on-chronic model alcohol exposure protocol. Probiotic strain *Lactobacillus rhamnosus* GG was cultured and LDNPs were isolated from the culture supernatant.

Results: Alcohol feeding increased intestinal miR194 expression, which suppressed intestine *Fxr* and subsequently *Fgf15* expression, resulting in a reduced circulation FGF15 protein level. Gut microbiota-mediated BA transformation was dysregulated by alcohol leading to the decreased ligand-mediated FXR activation. Reduced FXR-FGF15 signaling resulted in an increase in hepatic BA synthesis and lipogenesis and liver injury. Importantly, three-day oral administration of LDNPs suppressed hepatic BA synthesis and lipogenesis and protected the liver from alcohol-induced injury. We further showed that LDNP treatment decreased intestinal miR194 and increased FXR-FGF15 signaling. miR194 suppressing intestinal *Fxr* mRNA expression was further confirmed in in Caco-2 cells and mouse enteroid. miR194 mimic decreased, and miR194 inhibitor increased, *Fxr* mRNA expression. Fecal and serum FXR activity was decreased by alcohol and restored by LDNP treatment. Importantly, the beneficial effects of LDNP were eliminated in intestinal $Fxr^{\Delta IEC}$ and $Fgf15^{-/-}$ mice.

Conclusion: Our results demonstrate that increased intestinal miR194 suppresses *Fxr* expression resulting in a defective FXR-FGF15 gut-liver signaling in ALD. LDNP treatment inhibits alcohol-induced liver injury by suppressing intestinal miR194 and improving BA profile that lead to an activated FXR-FGF15 signaling to suppress BA *de novo* synthesis and lipogenesis during ALD development.

Does screening for liver fibrosis change alcohol consumption, diet, and exercise? A prospective cohort study on the consequences of screening in 2, 764 individuals

Maria Kjærgaard[1,2], Katrine Prier Lindvig[1,2], Johanne Kragh Hansen[1], Simon Langkjær Sørensen[1], Stine Johansen[1,2], Katrine Thorhauge[1,2], Peter Andersen[1], Isabel Graupera[3], Pere Ginès[3], Aleksander Krag[1,2], Maja Thiele[1,2]. [1]*Odense University Hospital, Department of Gastroenterology and Hepatology, Odense, Denmark;* [2]*University of Southern Denmark, Institute of Clinical Research, Odense, Denmark;* [3]*Hospital Clínic de Barcelona, Institut D'investigacions Biomédiques August Pi I Sunyer (IDIBAPS), Barcelona, Spain*
Email: maria.kjaergaard@rsyd.dk

Background and aims: There is a growing interest in screening for liver fibrosis, and a belief that early disease detection will lead to lifestyle changes in screening-positive individuals. However, this assumption is not based in evidence. We therefore evaluated self-reported lifestyle changes after screening for liver fibrosis.

Method: Prospective study of participants from the general population at risk of alcohol related (ALD) or non-alcoholic fatty liver disease (NAFLD). All were screened with transient elastography (TE) and all participants, independently on TE, were given information on recommended lifestyle changes. We considered TE ≥8 kPa as screening positive. All participants received an online questionnaire on lifestyle changes one week and six months after the screening visit.

Results: We included 2, 764 participants, 1, 273 at risk of ALD and 1, 491 at risk of NAFLD. Median age was 58 years (52–64), 54% were male, and 268 (10%) had an elevated TE ≥8 kPa. Response rate was high, at 89% after one week and 85% after six months. After one week, half of the ALD group (50%) reported abstinence, or a decrease in alcohol consumption, while only 0.8% reported an increase in alcohol consumption. Screening sustained its effect on alcohol consumption after six months (figure), with a reported median alcohol intake decreasing 8 units/week in the ALD group. Screening-positive subjects disclosed more pronounced reductions in alcohol intake than screening negatives (decreased 13 vs 6 units/week), and a positive screening test predicted alcohol abstinence (odds ratio 2.9, 95% CI 1.8–4.7). We observed the same pattern for diet and exercise: After one week, 26% of all respondents reported that they consumed less food and/or more healthy food, increasing to 34% after six months. This was most pronounced in the at-risk of NAFLD group (Figure), where a positive screening test predicted improved diet (OR 1.8, 1.3–2.4). Both groups reported comparable improvements in exercise (figure). In the NAFLD group, 23% reported a weight loss exceeding 3 kg after six months, and a positive screening test predicted a weight loss above 3 kg (OR 3.5, 1.2–10.5).

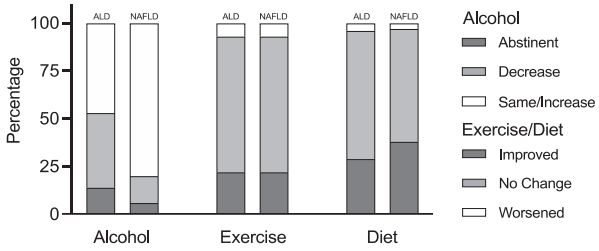

Figure: Lifestyle changes after 6 months.

Conclusion: After being screened for liver fibrosis, participants report improved lifestyle, with both acute and sustained changes in alcohol consumption, diet, exercise, and weight loss. The changes are most pronounced in participants with elevated liver stiffness, but not limited to this.

Fibrosis

Peroxidasin deficiency re-programs macrophages toward pro-fibrolysis function and promotes collagen resolution in liver

Mozhdeh Sojoodi[1], Derek J. Erstad[1], Stephen Barrett[1], Shadi Salloum[2], Shijia Zhu[3], Tongqi Qian[3], Eric Gale[4], Veronica Clavijo Jordan[4], Yongtao Wang[1], Shen Li[1], Michael Lanuti[1], Peter Caravan[4], Yujin Hoshida[3], Raymond Chung[2], Gautam Bhave[5], Georg Lauer[2], Bryan C. Fuchs[1], Kenneth K. Tanabe[1]. *[1]Massachusetts General Hospital, Surgery, Boston, United States; [2]Massachusetts General Hospital, Gastroenterology, Boston, United States; [3]University of Texas Southwestern Medical Center, Internal Medicine, United States; [4]Massachusetts General Hospital, Radiology, Boston, United States; [5]Vanderbilt University Medical Center, Division of Nephrology and Hypertension, United States*
Email: msojoodi@mgh.harvard.edu

Background and aims: Non-alcoholic liver disease (NAFLD) is stimulated by excessive fat deposition in hepatocytes. During NAFLD, inflammation and activation of tissue repair mechanisms replaces necrotic tissue with extracellular matrix (ECM), which are stabilized into a complex fibrotic scar and creates fibrosis. Peroxidasin (PXDN) is a peroxidase enzyme that is known to stabilize ECM proteins through cross-linking of collagen molecules. In this project, we aim to investigate the expression and function of PXDN during the development of liver fibrosis.
Method: *Pxdn*$^{-/-}$ and *Pxdn*$^{+/+}$ mice were fed with a choline-deficient L-amino acid-defined high-fat diet (CDAHFD) for 16 weeks to create a NAFLD-HCC preclinical model. Liver histology, collagen content, flow cytometry, immunostaining of immune cells, RNA-seq, and liver function tests were analyzed. *In vivo* imaging of liver reactive oxygen species (ROS) was performed using a redox-active iron complex, Fe-PyC3A.
Results: Genome-wide expression analysis of liver tissue and differential gene expression (DGE) combined with Gene Ontology (GO) analysis identified significant upregulation of genes associated with hypoxia and TNFα signaling pathways already in *Pxdn*$^{-/-}$ sham livers (without injury). Using Fe-PyC3A as an MRI contrast agent, we detected a higher content of ROS in *Pxdn*$^{-/-}$ livers (healthy) that could activate hypoxia-related molecular pathways. In addition, we observed an upregulation of genes involved in the innate immune response, leukocyte activation, and chemotaxis. After 16 weeks of CDAHFD, gross analysis of collected liver showed no HCC nodule formation in *Pxdn*$^{-/-}$ mice while 60% of the WT mice had HCC tumors. Collagen staining showed less collagen accumulation in *Pxdn*$^{-/-}$ mice. Flow cytometry of macrophages showed *Pxdn*$^{-/-}$ mice had increased pro-healing M2 macrophages recruitment in early- and mid-stage NAFLD (4 weeks and 8 weeks on CDAHFD) compared to WT controls. In addition, we observed a significant decrease in the number of CD3^{+} T cells and CD8^{+} cytotoxic T cells in the late-stage of NAFLD in *Pxdn KO* mice. DGE analysis revealed that IL-12 is highly expressed in *Pxdn*$^{-/-}$ injured livers. Additionally, multiple other T cell-related molecules such as IL-10, IL-6, CCL2, IL-7, and CD4 were elevated in *Pxdn*$^{-/-}$ injured liver. Elevation of these cytokines is an indicator for higher recruitment of pro-healing and anti-HCC macrophage to the site of injury.
Conclusion: Our findings demonstrate that PXDN deficiency is associated with the induction of the hypoxia and TNFα signaling pathways and the recruitment of pro-healing and anti-HCC macrophages to the liver. This results in significantly decreased collagen stabilization during liver fibrosis and accelerates fibrosis reversal. In addition, recruited macrophages-controlled T cell response and inhibited HCC formation in *Pxdn*$^{-/-}$ mice.

OS038

Targeting the liver circadian clock by REV-ERB-alpha activation improves liver fibrosis by circadian gating of TGF-beta signaling

Email: mukherji@unistra.fr

Background and aims: Liver fibrosis is the key risk factor for hepatocellular carcinoma, a leading cause of cancer death worldwide. Approved anti-fibrotic therapies are absent and most compounds in clinical development have limited anti-fibrotic efficacy. The circadian clock (CC) is a major regulator of liver metabolism, but its role in the pathogenesis of liver fibrosis and as a potential therapeutic target is unknown.
Method: We utilized liver specific CC-mutant mice to establish the molecular relationship between the CC-oscillator and TGF-beta signaling under physiological conditions. Moreover, we profiled the circadian gene expression pattern in patient-derived models for NASH and fibrotic liver disease including primary human hepatocytes, human myofibroblasts, spheroids and a human liver chimeric mouse model for diet-induced fibrotic liver disease. Furthermore, we performed functional studies using small molecules targeting CC components.
Results: Here we show that the physiological liver CC-oscillator is temporally restricting (gating) TGF-beta signaling and that this regulation is lost in metabolic liver disease progressing to fibrosis. The loss of TGF-beta signaling regulation leads to constitutive expression of genes driving fibrosis in patients. Mechanistic studies in primary human hepatocytes and myofibroblasts revealed a reciprocal relationship between increased TGF-beta-driven fibrotic-signaling and the CC, which we confirmed in patient-derived liver spheroids and in two mouse models for NASH-driven fibrosis. Remarkably, a pharmacological restoration of REV-ERB-alpha activity markedly inhibited fibrosis in a human liver chimeric NASH mouse model in vivo and spheroids generated from patients with liver fibrosis.
Conclusion: We discovered that the perturbation of the liver CC plays a key role in the pathogenesis of liver fibrosis. Furthermore, our in vivo and ex vivo studies in patient-derived models suggest that targeting REV-ERB-alpha is an effective approach for treatment of liver fibrosis-an important and rising global unmet medical need.

Background and aims: Understanding the embryonic development of Hepatic stellate cells (HSCs) and their activation is fundamental to develop new therapeutic strategies. We developed a protocol to differentiate iPSCs to HSCs by sequential addition of growth factors. We hypothesis that the differentiation protocol may be an excellent tool for drug discovery. By performing a time course proteomic characterization, we envision to understand the protein dynamics across differentiation and identify transcription factors involved in the maintenance HSC phenotype and cell activation.
Method: MS proteomics was performed in 4 independent differentiations of iPSC to HSCs and primary human HSCs. Seven staggerer mice (RORA−/−) and their wildtype littermates were treated with CCl4 during 4 weeks. Fourteen mice were treated with CCl4 and 7 were treated with the RORA agonist SR1078. qPCR, immunofluorescence and immunohistochemistry assays were used as validation. RORA expression was evaluated in a cohort of 25 patients with alcohol and metabolic associated chronic liver disease.
Results: Proteomic results indicated that iPSC-HSC differentiation occurred in three stages: undifferentiated phase (Day 0 to 4), intermediate fetal stage (Day 6 to 8) and final maturation stage (Day 10 to 12). Developmental markers of fetal HSC, such as VIM, ALCAM, FBLN1 and DCN were sequentially expressed and followed by mature HSC markers, indicating the recapitulation of the embryonic development in vitro. Pathway analysis of iPSC-HSCs and primary HSCs revealed RORA as an important transcription factor in HSC phenotype and commitment. Experimentally, we first evaluated the effect of RORA on HSC development. iPSC-HSC across differentiation were treated with SR1078, which increased the expression of HSC phenotype and quiescence markers such as RELN, PCDH7, LRAT and LHX2. Next, we evaluated the role of RORA on HSC activation by treating iPSC-HSCs, which decreased the expression of ACTA2 and increased the expression of quiescent markers (LRAT and LHX2). *In vivo* studies with the staggerer mice, showed an increased fibrotic content by Sirius Red staining and an increased gene expression of fibrogenic markers such as ACTA2, collagens and MMPs in the mutant group. In addition, SR1078 treatment of CCl4 mice showed a reduction of collagen deposition and aSMA staining, together with a reduced expression of fibrogenic markers. In patients, expression of RORA correlated negatively with fibrogenic markers and MELD Score. These results suggest that RORA plays a role in the progression of liver fibrosis.
Conclusion: The present study demonstrates that the differentiation protocol is a new and reliable tool for the study of HSC biology and the discovery of new antifibrogenic targets. Moreover, we identify RORA as a targetable transcription factor to mitigate liver fibrosis.

Stellate cell dynamics in progression and regression of hepatic fibrosis

Laura Almale del Barrio[1], Emma A.H. Scott[1], Frederik Adam Bjerre[1], Mike Terkelsen[1,2], Kim Ravnskjaer[1,2]. [1]*University of Southern Denmark, Department of Biochemistry and Molecular Biology, Odense, Denmark;* [2]*University of Southern Denmark, Center for Functional Genomics and Tissue Plasticity (ATLAS), Odense, Denmark*
Email: ravnskjaer@bmb.sdu.dk

Background and aims: Non-alcoholic steatohepatitis (NASH) is a metabolic liver disease characterized by hepatic lipid accumulation, chronic inflammation and fibrosis, in which fibrogenic myofibroblasts are central players. These scar-forming cells are derived mainly from activated hepatic stellate cells (HSCs). NASH and cirrhosis were traditionally considered irreversible conditions, but clinical studies have demonstrated that they can be reversed. HSC inactivation seems to be a key mechanism, but the inactivation process is poorly understood. This prompted us to characterize HSC dynamics at single-cell resolution during the induction and regression of NASH-associated fibrosis *in vivo*.
Method: Lrat-cre/mCherry knock-in mice were fed a western diet (WD) combined with carbon tetrachloride (CCl_4) for eight weeks (treated) or chow diet (untreated). Regression of liver disease was studied four weeks after WD/CCl_4 cessation (reversal). RNA-sequencing, single-cell RNA-sequencing and immunohistochemistry/immunofluorescence were performed to investigate HSC activation and inactivation.
Results: NASH regression led to profound changes at histological, whole-liver transcriptional, and single-cell levels. We annotated 14 discrete hepatic populations including activated and quiescent HSCs in our single-cell data set obtained from treated, reversal, and untreated mice. We next performed gene expression distribution analyses of cells within and across treatment groups to stratify the HSC population. We here identified HSC subpopulations relating to NASH regression; potentially inactivated HSCs and HSCs that had reverted towards a more quiescent state. Additionally, using single-cell gene regulatory network analysis we determined specific gene-regulatory networks for the aforementioned HSC subpopulations.
Conclusion: Our results broaden our understanding of HSC transitions in the liver during induction and regression of NASH, and suggest new molecular mechanisms that could mediate the HSC inactivation and reversion during NASH resolution.

Machine learning methods for detailed characterization of TGF-beta-induced signatures in a large iPSC-derived hepatic stellate cell cohort

Panagiotis Stanitsas[1], Kara Marie Liu[1], Lorn Kategaya[1], Kelly Haston[1], Alicia Lee[1], Shahin Mohammadi[1], Haoyang Zheng[1], Francesco Paolo Casale[1], Navpreet Ranu[1], Ahmed Sandakli[1], Pooja Prasad[1], Owen Chen[1], Anne Baldwin[1], Albert Kim[1], Eilon Sharon[1], Ajamete Kaykas[1], Daphne Koller[1], Matthew Albert[1]. [1]*Insitro, South San Fransisco, United States*
Email: research_operations@insitro.com

Background and aims: Activation of hepatic stellate cells (HSCs) by TGF-beta plays a central role in fibrotic changes related to Non-Alcoholic Steatohepatitis (NASH). We aimed to establish a screenable *in vitro* system for identification of anti-fibrotic targets in activated HSCs. This required the development of a novel machine learning (ML) framework which was used to characterize a large cohort of control and NASH induced pluripotent stem cell-derived HSCs (iHSCs).
Method: We differentiated iHSCs from 56 iPSC lines and characterized them using high content imaging and single cell (sc) RNA-seq analysis. For ML image analysis, we derived a novel deep learning method that was tasked with producing informative featurizations of segmented cell images, followed by covariate correction.

Transcriptomic datasets were featurized using a state-of-the-art archetypal analysis based framework. Using each of our transcriptomic and imaging datasets separately, and viewing pHSCs as ground truth, we quantified three quality metrics for iHSCs: (i) predictiveness of TGF-beta response in an ML classifier trained on pHSCs; (ii) separation between TGF-beta and DMSO in an unsupervised ML model; (iii) similarity of the overall cell state distribution between iHSCs and pHSCs.

Results: The established ML framework provided informative featurizations of our cellular assays and allowed for the correction of experimental artifacts. We showed robustness of TGF-beta-induced ML phenotype in pHSCs both in imaging and transcriptomics (mean AUC 0.96 for out-of-line assessment in imaging, Figure 1A; mean AUC 0.98 in transcriptomics, data not shown). Interpretation of learned ML phenotypes revealed insights into the TGF-beta responsiveness of pHSCs. This allowed us to utilize multi-parametric criteria to evaluate the cohort of iHSCs. We observed a strong correlation between transcriptomic and imaging characterizations used for the ranking of iHSC lines (spearman = 0.66, p = 8.7 * 10^{-5}, Figure 1B).

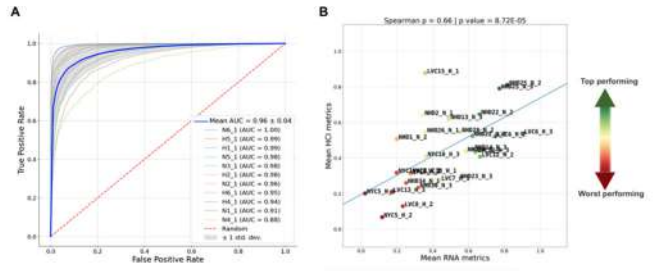

Figure 1 | ML model accurately predicted TGF-beta treatment of HSCs. (A) The ML-learned phenotype was evaluated in an out-of-line setup by reporting area under the curve (AUC) plots for TGF-beta vs PBS using a logistic regression model. Thin lines represent individual pHSC lines; dotted red line indicates random prediction; thick blue line indicates mean AUC; and shaded area indicates +/- 1 standard deviation. (B) Correlation for iHSC rankings for transcriptomic-based metrics (x-axis) and image-based metrics (y-axis) are depicted. The naming scheme for lines follows the format: {line ID}_{H=control, N=NASH}_{experiment ID}.

Conclusion: We developed a state-of-the-art approach for the characterization of HSC morphological and transcriptional phenotypes. Using the developed framework, we successfully modeled TGF-beta-induced activation signatures in HSCs. These image-based phenotypic assays paired with high-performance ML models present unique opportunities for genetic and chemical screens and the discovery of novel fibrosis targets.

Biliary epithelial cell-specific RAGE controls ductular reaction-mediated fibrosis during cholestasis

Wai Ling Macrina Lam[1,2], Amruta Damle-Vartak[1], Gisela Gabernet[3], Doris Schneller[1], Tanja Poth[4], Simone Jörs[5], Melanie Sator-Schmitt[1], Aurora De Ponti[1], Lena Weiß[1], Mathias Heikenwälder[6], Nachiket Vartak[7], Jan G. Hengstler[7], Fabian Geisler[5], Sven Nahnsen[3], Peter Angel[1]. Email: m.lam@dkfz-heidelberg.de

Background and aims: Ductular reaction (DR) is the hallmark of cholestatic diseases characterized by the proliferation of bile ductules lined by biliary epithelial cells (BECs). DR is thought to serve as a reparative and regenerative mechanism in the damaged liver to compensate for the anatomical or functional loss of the biliary system. Surprisingly, it is also commonly associated with increased risk of fibrosis, cirrhosis and liver cancer. The Receptor for Advanced Glycation End Products (RAGE, encoded by *Ager*) was identified as a critical mediator of DR during chronic injury and carcinogenesis (Pusterla et al. Hepatology. 2013.). Nevertheless, whether DR is reparative or detrimental to the liver during cholestasis remains elusive. Thus, we aimed to delineate the specific function of RAGE on DR and its potential association with fibrosis in the context of cholestasis.

Method: We utilized a biliary tracing reporter murine model (*R26^{Tom}Hnf1bCreER*) and deleted *Ager* conditionally in BECs. Choline-deficient ethionine-supplemented (CDE) diet was fed to the mice for three weeks to induce cholestasis. RNA-seq of FACS-sorted primary BECs from CDE-challenged mice, immunofluorescence (IF) staining and multi-modal 3D architectural staining were employed to investigate the role of BEC-specific RAGE activity in DR and fibrosis. *In vitro* co-culture assays of BECs and hepatic stellate cells (HSCs) combined with flow cytometry and mass spectrometry analysis were utilized to delineate the newly identified RAGE-dependent paracrine crosstalk between BECs and HSCs.

Results: BEC-specific deletion of *Ager* strongly impairs ductular reaction. Remarkably, the number of stellate cell is substantially diminished concomitantly with an attenuation of bridging fibrosis. RNA-seq data revealed a RAGE-dependent mechanistic role of BECs in the modulation of cholestasis-induced fibrosis. Classical fibrotic mediators and ECM genes were differentially expressed between *Ager* wildtype and knockout BECs. Flow cytometry of direct co-culture assay demonstrated that HSCs were activated by BECs in RAGE-dependent manner. Mass spectrometry and indirect co-culture analysis, combined with immunohistochemistry analyses of livers from CDE-treated mice showed that BEC-derived secretory JAG protein activates Notch signalling in HSC in *trans*.

Conclusion: This present study provides a novel insight into the adverse consequence of DR in cholestasis-associated fibrosis. Although hypothesized to provide a regenerative mechanism during cholestasis, it is evident that BEC-specific RAGE activity enhances DR- associated fibrosis via a trans-regulatory mechanism in the current CDE diet model. We demonstrate that Notch signaling in HSCs is activated by BEC in RAGE-dependent manner via paracrine JAG protein, thereby turning HSCs into a myofibroblastic phenotype to establish a profibrotic milieu.

Young-onset diabetes mellitus increases the risk of liver-related events in patients with non-alcoholic fatty liver disease

Xinrong Zhang[1], Grace Lai-Hung Wong[1], Terry Cheuk-Fung Yip[1], Yee-Kit Tse[1], Vicki Wing-Ki Hui[1], Huapeng Lin[1], Che To Lai[1], Henry LY Chan[1], Alice Pik-Shan Kong[1], Vincent Wai-Sun Wong[1]. [1]*The Chinese University of Hong Kong*
Email: wongv@cuhk.edu.hk

Background and aims: The prevalence of type 2 diabetes (T2D) in young people is increasing, but little is known regarding the association between age of onset of T2D and risk of liver-related events. This study aimed to determine the incidence of liver-related events of patients of different ages of onset of T2D.

Method: We conducted a retrospective territory-wide cohort study of adult patients with non-alcoholic fatty liver disease (NAFLD) diagnosed between January 1, 2000 and June 30, 2021. T2D was defined by exposure to any antidiabetic agents, haemoglobin A_{1c} ≥6.5%, fasting plasma glucose ≥7.0 mmol/L in two measurements at least one month apart, and/or ICD-9-CM diagnosis codes. The primary end point was liver-related events, defined as a composite end point of HCC and cirrhotic complications. Fine-Gray model was used to adjust for competing risk of death.

Results: We analysed data from 30, 360 NAFLD patients (mean age, 56.4 ± 13.4 years; 46.0% men); a total of 15, 430 cases of T2D and 456 cases of liver-related events were recorded over a follow-up of 151, 051 person-years. Starting the follow-up at age 60 years, liver-related event rates per 1, 000 person-years were 1.05 in patients without T2D at age 60 years, 2.90 for patients with T2D onset ≤5 years earlier, 2.77 for 6 to 10 years earlier, and 4.26 for >10 years earlier. In multivariable analysis adjusting for gender, hypertension, dyslipidaemia, cirrhosis, use of metformin, insulin and aspirin, compared with patients without T2D at age 60, the adjusted hazard ratio of liver-related events was 2.58 (95% confidence interval [CI], 1.49–4.45; $p < 0.001$) in patients with T2D onset ≤5 years earlier, 2.70 (95% CI, 1.45–5.03; $p = 0.002$) for T2D 6 to 10 years earlier, and 5.00 (95% CI, 2.35–10.60; $p < 0.001$) for diabetes onset >10 years earlier (Figure). Linear trend test ($p < 0.001$) indicated a graded association between age of onset of T2D and risk of liver-related events.

Conclusion: Younger-onset T2D increases the risk of liver-related events. Further studies should determine the role of fibrosis assessment and more aggressive treatment of steatohepatitis in this high-risk group.

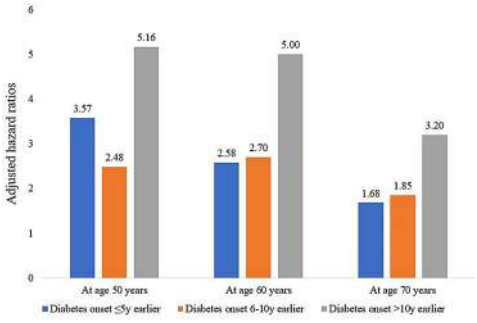

Figure: Association between age of onset of T2D and risk of liver-related events (reference group was patients who did not have T2D at the corresponding ages).

OS044

Non-alcoholic fatty liver disease patients have worse health-related quality of life compared to the general population irrespective of their fibrosis stage: results from a prospective multicenter UK study

Margarita Papatheodoridi[1], Giada Pallini[1], Guruprasad Aithal[2], Hong Kai Lim[3], Jeremy Cobbold[4], Maria Corina Plaz Torres[1], Marta Guerrero Misas[1], John Ryan[1], Jeremy Tomlinson[4], Michael Allison[3], Louise Longworth[5], Emmanuel Tsochatzis[1]. [1]*University College of London, Royal Free Hospital, Institute for Liver and Digestive Health, United Kingdom;* [2]*Nottingham University, Digestive Diseases Centre, United Kingdom;* [3]*Cambridge University Hospital NHS Foundation Trust, Liver Unit, Department of Medicine, NIHR Cambridge Biomedical Research Centre, Cambridge, United Kingdom;* [4]*Oxford University Hospitals NHS Foundation Trust, Oxford Liver Unit, Department of Gastroenterology and Hepatology, Oxford, United Kingdom;* [5]*PHMR Limited, United Kingdom*
Email: margarita.gpap@gmail.com

Background and aims: Health-related quality of life (HRQL) is impaired in patients with chronic liver disease, including those with non-alcoholic fatty liver disease (NAFLD). The primary aim of the study was to assess the HRQL of patients with NAFLD and compare this to the general population. Secondary aims were to examine the associations of fibrosis severity and metabolic comorbidities with impairments in HRQL.

Method: We included 561 consecutive patients with NAFLD prospectively evaluated in 4 UK secondary care centres between 2016 and 2019. Patients completed two HRQL questionnaires: the EQ-5D-5L and the Chronic Liver Disease Questionnaire (CLDQ). Demographic and clinical information, liver stiffness by transient elastography and/or liver biopsy results and history of cirrhosis were recorded. A general population sub-cohort of the Health Survey of England 2018 without alcohol misuse who had completed the EQ-5D-5L was used as a comparator. For the comparison of HRQL in NAFLD patients and the general population, propensity-score (PS) matching was performed, according to age, sex and body mass index (BMI).

Results: The EQ-5D-5L index was significantly lower in 514 NAFLD patients compared to the 514 PS-matched healthy controls (0.762 ± 0.276 vs 0.844 ± 0.200, $p < 0.001$). The difference was also significant in a subgroup of NAFLD patients without advanced fibrosis (F < 3 or LS <8 kPa) compared to the general population (0.781 ± 0.276 vs 0.845 ± 0.200, $p < 0.001$). Among NAFLD patients, the EQ-5D-5L index, EQ-visual analogue scale (VAS) and CLDQ scores were significantly lower in patients with cirrhosis compared to patients without cirrhosis ($p = 0.021$, $p = 0.011$ and $p = 0.001$ respectively). However, in patients with NASH, there was no difference between patients with and without advanced fibrosis on any of the HRQL measures.

Liver stiffness was the only factor significantly associated with lower scores in all HRQL measures, both in the whole patient population and in non-cirrhotic patients.

In multivariate analysis, the EQ-5D-5L index was negatively associated with type II diabetes, depression and osteoarthritis both in the whole patient population and in patients without cirrhosis. EQ-VAS was associated with age, sex, BMI, depression and osteoarthritis in all patients and non-cirrhotic patients.

Lower CLDQ scores were associated with lower age, male sex, presence of type II diabetes, ischemic heart disease, depression and osteoarthritis in all patients; in the sub-group of non-cirrhotic patients, lower CLDQ was associated with male sex, type II diabetes and depression.

Conclusion: HRQL is similar for NASH patients with or without advanced fibrosis. However, even those without advanced fibrosis (LS <8 kPa or F < 3) have worse HRQL compared to the general population, implying that a multi-disciplinary management is required for NAFLD patients, irrespectively of their disease severity.

OS045

Genetics of liver fat and volume associate with altered metabolism and whole body magnetic resonance imaging

Shafqat Ahmad[1], Germán Carrasquilla[2], Taro Langner[3], Uwe Menzel[3], Filip Malmberg[3], Ulf Hammar[3], Jenny C. Censin[4], Sergi Sayols[3], Diem Nguyen[3], Andrés Martínez Mora[3], Jan W. Eriksson[3], Robin Strand[3], Joel Kullberg[3], Håkan Ahlström[3], Tove Fall[3]. Email: shafqat.ahmad@medsci.uu.se

Background and aims: An improved understanding of the underlying biological mechanisms of genetic variation linked to liver fat and volume is pivotal for translational and prevention efforts to tackle liver disease. Here we aim to gain biological insight of liver fat and volume loci using a novel image analysis approach allowing whole-body voxel-wise associations to tissue volume and fat content as well as a large set of other phenotypes.

Method: Liver volume was measured from neck-to-knee water-fat MRI images collected in UK Biobank cohort using a deep learning-based segmentation approach. Liver proton density fat fraction (PDFF) were readily available for 4, 613 subjects. Using deep regression on the above mentioned neck-to-knee MRI images, liver PDFF was inferred for remaining subjects. We conducted a genome-wide association analysis (GWAS) of liver fat (n = 27, 243) and liver volume (n = 24, 752) on non-related European participants of the UK Biobank cohort. We further investigated the associated genetic loci in association with whole body composition in high-resolution anatomical correlation voxel-based maps ("Imiomics"). We also analyzed these loci with various biomarkers and liver disease using independent UK Biobank participants (n = 310, 239).

Results: We confirmed four previously identified liver fat variants *TM6SF2* rs8107974, *TM6SF2* rs188247550, *APOE* rs429358 and *PNPLA3* rs738408. A positive and highly specific relationship was observed between liver fat-associated variants and fat fraction in liver area (*PNPLA3* rs738408 Figure 1). The liver fat-increasing allele of all four genetic variants were positively associated with alanine aminotransferase, conjugated bilirubin while negatively associated with total cholesterol, triglycerides and low-density lipoprotein cholesterol biomarkers. For liver volume, we identified two novel independent variants *CENPW* rs1490384, *ADH4* rs6858148 and confirm eight previously identified variants *SFN* rs75460349, *GCKR* rs1260326, *TNFSF10* rs79287178, *PPP1R3B* rs4240624, *REEP3* rs7896518, *TNKS2* rs10881959, and *PDIA3* rs139974673. We observed a heterogeneous pattern for association with body composition and biomarkers, as for *CENPW* rs1490384, with strong positive association with muscle tissue volume in neck, abdomen, thigh and hip as well as heart and liver volume among both males and females (Figure 1). Two liver fat and three liver volume-associated genetic variants were positively associated with non-alcoholic fatty liver disease and chronic liver disease.

Conclusion: We report two novel liver volume loci and provide specific association with voxel-based maps body composition architecture while confirming previously reported liver fat and volume genetic variants. Liver fat-associated variants were positively associated with liver injury markers and negatively associated with dyslipidemia biomarkers.

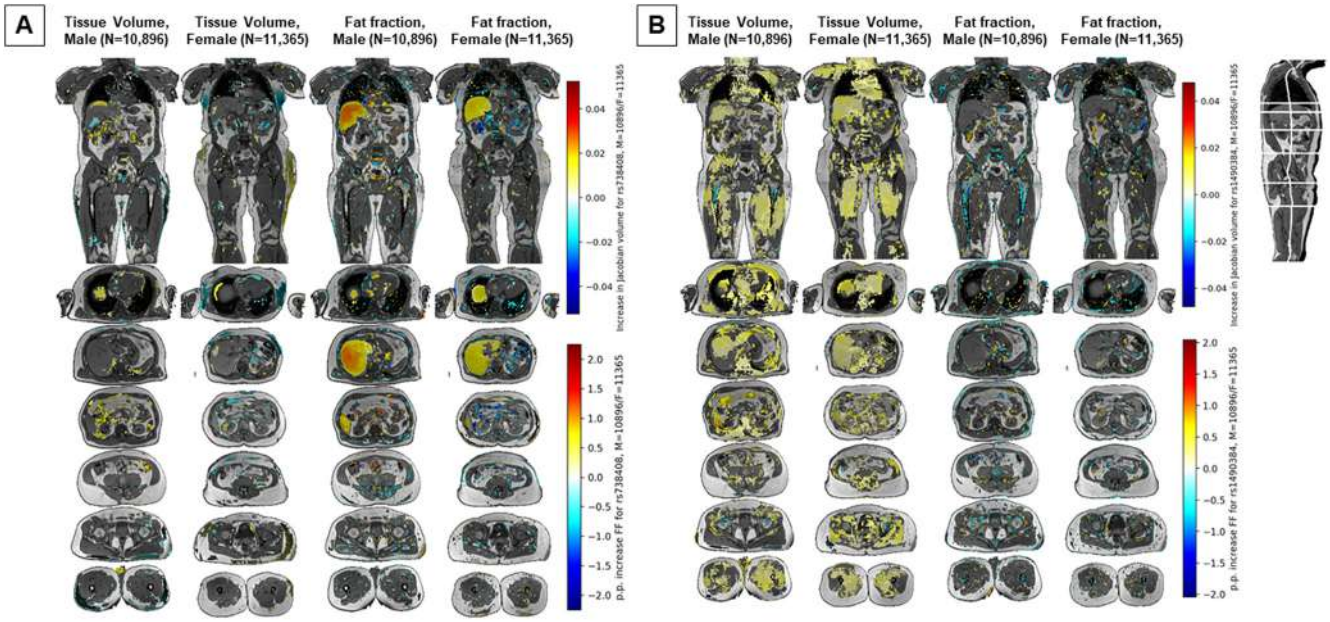

Figure 1. Liver tissue volume and Liver fat associated with PNPLA3 rs738408 (panel A) and CENPW rs1490384 (panel B) variants illustrated with Imiomics maps. Within each panel the top images represent concatenated images from all males or all females in the study from left to right, the volume maps for males, the volume maps for females, the fat fraction maps for males, and the fat fraction maps for females. The colors displayed in the colormaps in the center of the collage, using a common color scale for male and female volume maps (upper color scale), and a common scale for male and female fat fraction maps (lower color scale). Volume map units are relative volume differences (Jacobian determinant of deformation field) per SNP unit, while fat fraction units are p.p. units per SNP unit. Only body regions where the regression computations between voxel data and SNP data are significant ($p < 0.05$) are colored. Non-significant regions are ignored, not colored, and show the water and fat MR images for the chosen male and template subjects. The first row of images represent coronal views of the maps, while the remaining rows represent axial views of those maps in organs of interest (heart, liver, kidneys, abdomen, hip, and thighs). The mid-sagittal slices on the right-hand side of the plots only represent the mixed water and fat images of the male and female templates, with cuts in white color that represent the coronal and axial slices on the left-hand sides of the collage.

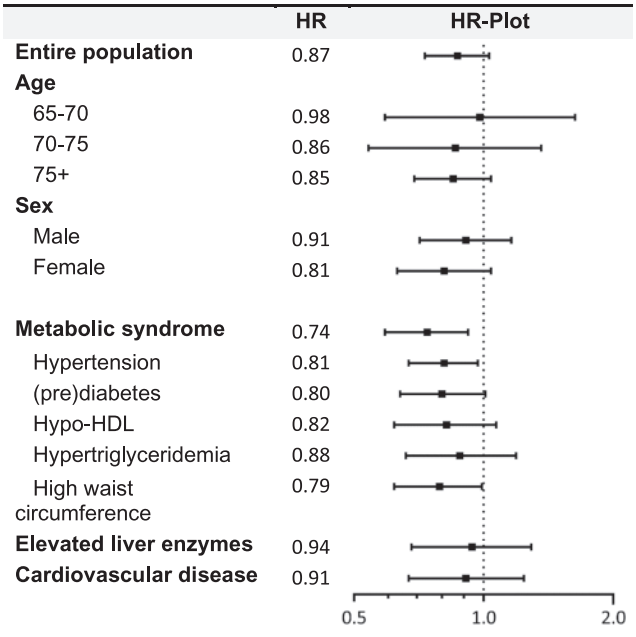
OS046

Hepatic steatosis is not associated with increased mortality in the elderly-time for a paradigm shift?

Laurens van Kleef[1], Milan Sonneveld[1], Maryam Kavousi[2], Arfan Ikram[3], Robert De Man[1], Robert De Knegt[1]. *[1]Erasmus MC, University Medical Center, Gastroenterology and Hepatology, Rotterdam, Netherlands; [2]Erasmus MC, University Medical Center, Cardiology, Rotterdam, Netherlands; [3]Erasmus MC, University Medical Center, Epidemiology, Rotterdam, Netherlands*
Email: l.vankleef@erasmusmc.nl

Background and aims: Fatty liver disease has been associated with excess mortality. Screening for hepatic steatosis in patients with metabolic dysfunction is therefore widely advocated. However, the association between hepatic steatosis and mortality amongst community-dwelling elderly individuals is unclear.
Method: We studied participants of an ongoing prospective cohort: the Rotterdam Study. Individuals aged ≥65 years were enrolled from 2009 to 2014 and were followed through 2018. Steatosis was assessed by ultrasound, and liver stiffness by transient elastography. Subsequently, NAFLD was defined as steatosis in the absence of excessive alcohol consumption, viral hepatitis, or steatogenic drug use; and MAFLD was defined as steatosis with either overweight, diabetes, or at least two minor metabolic dysfunction criteria. The association between steatosis and liver stiffness with mortality risk was assessed using Cox regression analysis adjusted for age, sex, education, smoking, the individual components of the metabolic syndrome, heart failure, coronary heart disease, and stroke.

Figure 1: Mortality risk among the elderly with steatosis



Results were obtained with Cox regression analysis. The fully adjusted model was adjusted for age, sex, education, smoking, alcohol, the individual components of the metabolic syndrome (hypertension, (pre)diabetes, hypo-HDL, hypertriglyceridemia, and high waist circumference), heart failure, coronary heart disease and stroke. Abbreviations: CI, confidence interval; HDL, high-density lipoprotein; HR, hazard rate.

Results: We included 4.093 elderly participants (aged 74.4 ± 6.6; 42.7% male, BMI 27.6 ± 4.2 kg/m^2, 44.9% metabolic syndrome), 36.8% had ultrasound-based steatosis and 7.1% had liver stiffness ≥8.0 kPa. During the median follow-up of 6.9 years, 793 participants died, resulting in a mortality rate of 29.6 per 1.000 person-years. Among the elderly, steatosis was not associated with impaired survival in multivariable analysis (aHR:0.87, 95%CI:0.73–1.03), similar results were obtained for MAFLD and NAFLD. Furthermore, findings were consistent across a range of clinically relevant subgroups, including age categories, sex, and in participants with metabolic syndrome, elevated liver enzymes, or cardiac disease, as shown in Figure 1. Sensitivity analyses showed similar results for mortality beyond five years of follow-up and for both cancer-related and cerebro-cardiovascular mortality. Furthermore, among participants with steatosis, higher liver stiffness (aHR:1.02 per kPa, 95%CI:0.93–1.12) was not associated with mortality.
Conclusion: The presence of fatty liver disease was not associated with increased mortality risk in this cohort of community-dwelling elderly subjects. Findings were consistent across a range of clinically relevant subgroups. This indicates that screening for fatty liver disease is unlikely to improve outcomes in the elderly.

OS047

Burden of hepatocellular cancer in patients with type-2 diabetes mellitus: a 2011–2020, french, longitudinal, retrospective, national, cohort study

Lucia Parlati[1], Samir Bouam[2], Michael Schwarzinger[3], Emmanuel Tsochatzis[4], Philippe Sogni[5], Stanislas Pol[5], Vincent Mallet[2,5]. *[1]Institut Cochin, Paris, France; [2]Assistance Publique Hôpitaux de Paris, Paris, France; [3]Inserm UMR 1219, Bordeaux, France; [4]UCL Institute for Liver and Digestive Health, Royal Free Hospital and UCL, London, United Kingdom; [5]Université de Paris, France, France*
Email: vincent.mallet@aphp.fr

Background and aims: There are uncertainties on the burden of hepatocellular cancer (HCC) in patients with type-2 diabetes (T2D) in France. We therefore measured national incidences and risks of in-hospital HCC.
Method: The data source was the 2011–2020 National Hospital Discharge database. We selected all T2D patients. HCC and competing death incidences were measured overall and without well-identified risk factors of liver disease progression, including alcoholic liver disease. Risks were computed with multinomial logistic regression models.
Results: The sample comprised 2, 883, 684 adults. Mean (IQR) age was 67 (58, 77) years and 54% were men. HCC incidence (95% CI) was 1.19 (1.17–1.21) per 1000 person-years at risk, totaling 26, 136 (0.9%) cases over 12, 504, 690 patient-years. A history of alcohol use disorders and non-metabolic liver-related risk factors were recorded among 55% and 21% of incident cases, respectively. In patients without well-identified risk factors of liver disease progression, HCC incidence was 0.57 (0.55–0.58) per 1000 person-years at risk. Male sex, age in the 40–70 years category, alcohol use disorders [aOR 20.8 (20.0–21.5)], and obesity [aOR 1.24 (1.2–1.28)] were independently associated with a higher risk of HCC than of competing mortality.
Conclusion: A history of alcohol use disorders was the main driver of liver disease progression to HCC in French patients with T2D. Obesity increased the risk of HCC by ~25%. Patients with T2D should be advised to abstain from alcohol.

Table: Multivariate risks for HCC and competing mortality in 2011–2020 French residents[1] with T2D

Predictors	Hepatocellular carcinoma		Competing mortality	
Age categories at cohort inception[3]	aOR[2]	P Value	aOR[2]	P Value
(30, 40]	2.34 (1.25–4.38)	0.008	1.29 (1.17–1.43)	<0.001
(40, 50]	6.29 (3.49–11.37)	<0.001	2.12 (1.94–2.32)	<0.001
(50, 60]	12.69 (7.06–22.83)	<0.001	4.33 (3.97–4.72)	<0.001
(60, 70]	20.02 (11.14–36.00)	<0.001	7.98 (7.33–8.70)	<0.001
(70, 80]	23.47 (13.05–42.20)	<0.001	18.14 (16.65–19.77)	<0.001
(80, Inf]	17.41 (9.66–31.39)	<0.001	37.66 (34.55–41.04)	<0.001
Male sex	3.22 (3.07–3.37)	<0.001	1.38 (1.37–1.39)	<0.001
Alcohol use disorders	20.76 (20.02–21.54)	<0.001	1.72 (1.69–1.74)	<0.001
Obesity	1.24 (1.20–1.28)	<0.001	0.86 (0.86–0.87)	<0.001
Non-liver-related risk factors[4]	1.05 (1.01–1.10)	0.014	1.79 (1.78–1.80)	<0.001
Smoking	0.71 (0.68–0.74)	<0.001	1.48 (1.46–1.49)	<0.001

[1]T2D patients with alcoholic liver disease or non-metabolic liver-related risk factors were excluded from the analysis. HCC cases were recorded after a 2011–2013 (3-year) washout period to reduce the risk of non-incident cases.
[2]Risks were computed with multinomial logistic regression models.
[3]Reference was the [18, 30] age category.
[4]Non-liver risk factors were extrahepatic cancer; AIDS; connective tissue disorders; ischemic heart disease; and stage 3–5 chronic kidney disease.

OS048

The impact of non-alcoholic fatty liver disease and liver fibrosis on adverse clinical outcomes and mortality in patients with chronic kidney disease: a prospective study using UK Biobank data

Theresa Hydes[1], Oliver Kennedy[2], Ryan Buchanan[2], Daniel Cuthbertson[1], Julie Parkes[2], Simon Fraser[2], Paul Roderick[2].
[1]University of Liverpool, Department of Cardiovascular and Metabolic Medicine, Liverpool, United Kingdom; [2]University of Southampton, School of Primary Care, Population Sciences and Medical Education, Southampton, United Kingdom
Email: therasa@doctors.org.uk

Background and aims: Chronic kidney disease (CKD) is a well-known extra-hepatic manifestation of non-alcoholic fatty liver disease (NAFLD), independent of common cardio-metabolic risk factors, and the two diseases frequently co-exist. Systematic review data has shown that there is minimal and conflicting data regarding the clinical implications of living concomitantly with these two conditions. We aimed to assess the impact of having of NAFLD and NAFLD fibrosis on adverse clinical outcomes and all-cause mortality for people with CKD.
Method: Data from 26, 074 individuals from the UK Biobank identified to have CKD (eGFR <60 ml/min/1.73 m^2 or albuminuria >3 mg/mmol) was analysed. Participants completed questionnaires relating to medical history, demographics and lifestyle factors and were prospectively followed-up by electronic linkage to hospital and death records. Cox-regression was used to estimate the hazard ratios (HR) associated with having NAFLD (hepatic steatosis index >36, or ICD-code) and advanced liver fibrosis (elevated fibrosis-4 (FIB-4) score, or NAFLD fibrosis score (NFS) or AST to platelet ratio index (APRI)) on cardiovascular events (CVE), progression to end-stage renal disease (ESRD) and all-cause mortality (ACM).
Results: Overall 54.5% of individuals with CKD had NAFLD at baseline, and 7.0% (NFS ≥0.676), 3.2% (FIB-4 >2.67) and 1.1% (APRI ≥1.0) had evidence of advanced fibrosis. Median follow-up was 10 years. In univariate analysis NAFLD was significantly associated with an increased risk of CVE (HR 1.39 [1.29–1.51], p < 0.0001) and ACM (HR 1.10 [1.01–1.19]), but not ESRD (HR 1.22 [0.95–1.56], p > 0.05). Following multivariate adjustment for demographics, metabolic factors and baseline renal function, NAFLD was no longer associated with increased risk of any primary outcomes. In univariate analysis, advanced liver fibrosis identified via all scores was associated with increased ACM (HR 2.34–2.90). NFS and FIB-4 were associated with elevated risk of CVE (HR 2.49 [2.11–2.93], p < 0.0001 and 1.94 [1.53–2.45], p < 0.0001) and ESRD (HR 6.85 [4.29–10.94], p < 0.0001 and 2.35 [1.19–4.67], p < 0.05). Following full adjustment FIB-4 was associated with increased incidence of CVE (HR 1.39 [1.06–1.82], p < 0.05), notably heart failure (HR 1.65 [1.16–2.33], p < 0.01); both FIB-4 and APRI were associated with ACM (HR 1.55 [1.21–2.00], p < 0.001 and 2.83 [1.95–4.11], p < 0.0001) and NFS ≥−1.455 was associated with progression to ESRD (HR 1.89 [1.13–3.17], p < 0.05).
Conclusion: In people with CKD and NAFLD, elevated non-invasive markers of liver fibrosis are associated with an increased risk of CVE, ESRD and worse survival.

Viral hepatitis elimination

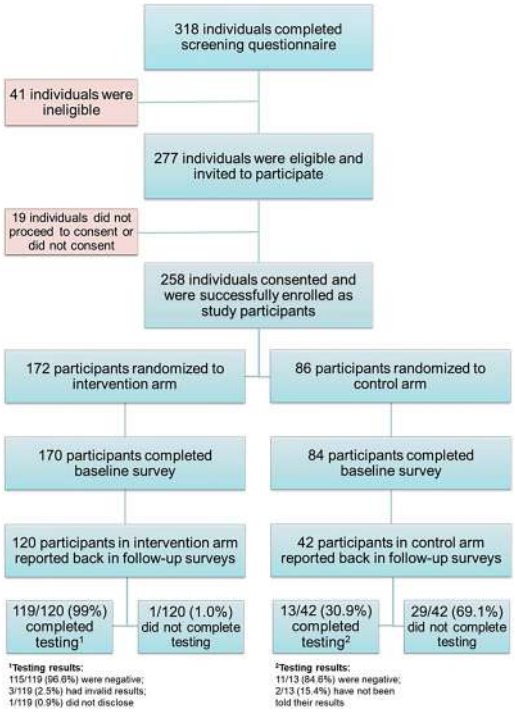
Randomized controlled trial of home-based hepatitis C self-testing for key populations in Malaysia

Xiaohui Sem[1], Sonjelle Shilton[1], Huan-Keat Chan[2], Han Yang Chung[3], Anu Karunanithy[4], Jessica Markby[1], Po-Lin Chan[5], Niklas Luhmann[6], Cheryl Johnson[6], Pamela Nabeta[1], Nazrila Hairizan Binti Nasir[7], Stefano Ongarello[1], Elena Ivanova[1], Muhammad Radzi Abu Hassan[2].
[1]FIND; [2]Clinical Research Centre, Hospital Sultanah Bahiyah; [3]Drugs for Neglected Diseases Initiative South-East Asia Regional Office; [4]Malaysian AIDS Council; [5]World Health Organization Regional Office for Western Pacific; [6]World Health Organization, Global HIV, Hepatitis and STI Programmes; [7]Ministry of Health
Email: xiaohui.sem@finddx.org

Background and aims: Malaysia is an upper middle-income country and has been expanding and decentralizing HCV care to the community. HCV self-testing (HCVST), recommended by the World Health Organization, provides an additional way to increase access and uptake of HCV testing among key populations who are disproportionately affected by HCV. We integrated HCVST with an existing online HIV self-testing platform to assess the impact of home-based HCVST on the uptake of HCV testing among key populations nationwide.
Method: This is a randomized controlled trial comparing HCVST sent via post (intervention arm, n = 500) with standard of care testing at a facility (control arm, n = 250). In the intervention arm, participants received either an oral fluid- or blood-based HCVST; in the control arm, participants were provided information about the nearest HCV testing center. All participants also received HCV information and support resources (e.g. access to a call center). We describe preliminary findings for this study reporting on the primary outcome-the uptake of HCV testing. Acceptability, feasibility and attitudes around HCV testing were also evaluated via a series of surveys.
Results: To date, 258 individuals, with a median (IQR) age of 26 (22–30.75) years, were recruited, of whom 88.8% were MSM. Most participants were male (97.6%), completed university (46.9%), and were employed (61.4%). Prior to this study, 60.6% of the participants were not tested for HCV; of these, the top reason why they did not get tested was they did not know how (57.1%). Additionally, acceptability of HCVST was high-71.7% of the participants stated that they preferred to test for HCV by themselves at home; 98.4% were willing to test themselves at home if they had a test kit and instructions on how to do it. After either receiving a HCVST or information about the nearest testing center, 99.0% (119/120) in the intervention arm and 30.9% (13/42) in the control arm reported completing HCV testing (p < 0.01) (see Figure).



Conclusion: Preliminary results show that HCVST via an online distribution model, compared with standard testing services, significantly increased the uptake of HCV testing among key populations. The outcomes of this study can further provide critical evidence about testing uptake, linkage to care, acceptability and any social harm due to HCVST. Updated data will be presented at the conference.

OS050
The disease burden of hepatitis B and hepatitis C from 2015 to 2030: the long and winding road

Devin Razavi-Shearer[1], Sarah Blach[1], Ivane Gamkrelidze[1], Chris Estes[1], Ellen Mooneyhan[1], Kathryn Razavi-Shearer[1], Homie Razavi[1]. [1]*Center for Disease Analysis Foundation, Lafayette, United States*
Email: drazavishearer@cdafound.org

Background and aims: This study aims to estimate the future disease burden of HBV and HCV at the global and continental level through 2030. 2015 was used as a baseline in line with the WHO targets to show what progress has been made to date.
Method: The results of a literature review and Delphi expert interviews were integrated into country-specific PRoGReSs and Bright Models for the HBV and HCV analyses respectively. Both are Markov models that utilize country specific inputs to estimate the natural history of the disease and future burden. Where data were unavailable, regional averages were applied to the total population of the country.
Results: 166 country level HBV and 110 HCV models were available. At the current trends, the prevalence of HBV is expected to decrease from 282 million in 2015 to 247 million in 2030, representing an 11% decrease globally with Africa's prevalence to remain relatively constant. The incidence of chronic HBV is expected to decline by 43% from 1, 459, 000 to 827, 000 new cases per year with all continents seeing a decline. Globally, the mortality of HBV is expected to increase by 39% between 2015 and 2030 from 850, 300 to 1, 109, 500 deaths annually. Similarly, the incidence of HCC is expected to increase by 34% from 682, 000 to 912, 000 cases per year. For both indicators all continents are expected to increase in this time frame. The prevalence of HCV is expected to decrease from 64 million in 2015 to 54 million in 2030, representing a 15% decrease globally. The incidence of chronic HCV is expected to decline by 7% from 1, 521, 000 to 1, 409, 000 new cases per year with Asia and North America increasing. Globally the mortality of HCV is expected to increase by 3% between 2015 and 2030 from 284, 000 to 293, 000 deaths annually. The incidence of HCC is expected to increase by 9% from 202, 000 to 220, 000 cases per year. Increases are expected in Asia, Oceania, and South America for both indicators.
Conclusion: Progress has been made particularly in regard to prevalence and incidence. However, without additional interventions almost 12 million individuals will die early from preventable deaths. Early gains made by Egypt, high income countries, and other early adopters, for HCV elimination, are offset by raising disease burden in the rest of the world. Innovative guidelines and funding mechanisms are necessary to meet countries where they are to live up to international commitments to elimination.

OS051
The HCV care cascade for children and young people in British Columbia, Canada: a large, linked administrative population-based cohort study

Email: dahn.jeong@bccdc.ca

Background and aims: In high income countries, new hepatitis C virus (HCV) infections have been occurring at the highest rate among people under 30 years of age, driven by the ongoing opioid crisis and other co-occurring socioeconomic conditions. The clinical experiences of young people living with HCV are underrepresented in research. We aimed to build the HCV care cascade for children and young people under age 30 living with HCV in British Columbia (BC), Canada.
Method: We used data from the BC Hepatitis Testers Cohort, a large population-based administrative dataset linked with data on primary care visits, hospitalizations and medication dispensations. This study includes all BC residents under age 30 who have been diagnosed with HCV by the end of 2019. The HCV care cascade was defined as: 1) HCV antibody (Ab) diagnosed 2) ribonucleic acid (RNA) tested 3) RNA positive 4) genotyped 5) initiated treatment and 6) achieved sustained virologic response (SVR). We estimated the number and proportion of people in each stage.
Results: There were 1, 350 children and young people (aged 4 to 29) diagnosed as HCV Ab positive living in BC at the end of 2019. Of these, 82.2% (1, 110/1, 350) had received an RNA test, and 60.6% (673/1, 110) were RNA positive. Among those who were RNA positive, 79.9% (538/673) had their HCV genotyped; however, only 40.3% (217/538) initiated treatment. SVR was achieved by 87.7% (121/138) of individuals for whom data on SVR assessment was available. In 2019, the proportion of HCV RNA positive persons receiving treatment varied by age group: 17.1% (6/35) in 14–19 years, 34.4% (45/131) in 20–24 years, and 34.1% (164/481) in 25–29 years. Treatment initiation increased over time, with the majority of treatments started between 2018 and 2019: 3.7% (8/217) treated between 2009–2011, 7.8% (17/217) between 2012–2014, 25.8% (56/217) between 2015–2017, and 62.7% (136/217) between 2018–2019. Many young people living with HCV were socioeconomically marginalized, had other comorbidities, particularly mood and anxiety disorders, and were accessing harm reduction services such as opioid agonist therapy.
Conclusion: By the end of 2019, more than two-thirds of people under age 30 in BC with chronic HCV remained untreated. The approval of highly effective pangenotypic direct-acting antiviral regimens provides the opportunity for early treatment for young people. Identifying and addressing the barriers that young people experience would be crucial to optimizing access to HCV care and services in this population.

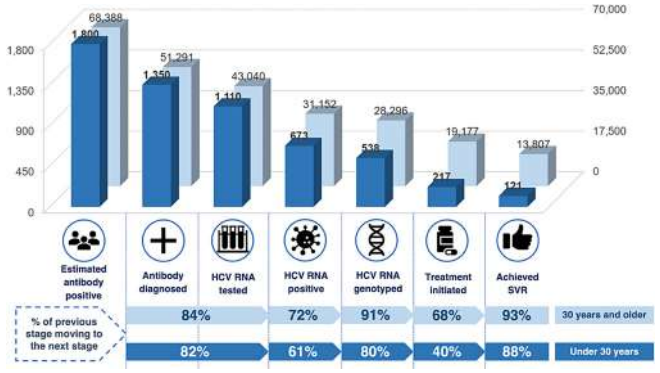

Figure 1: The HCV care cascade for people under 30 years of age and 30 years and older in 2019, British Columbia Hepatitis Testers Cohort.

OS052
Clinical impact and cost-effectiveness of hepatitis C testing in an emergency department in Barcelona, Spain

Jordi Llaneras[1], Ana Barreira[2,3], Ariadna Rando-Segura[4], Raquel Domínguez-Hernández[5], Francisco Rodríguez-Frías[3,4], Magda Campins[6], Miguel Ángel Casado[3,5], Mar Riveiro Barciela[2,3], Maria Arranz[1], Rafael Esteban[2,3], Maria Buti[2,3]. [1]*Hospital Vall Hebron, Emergency Department, Barcelona, Spain;* [2]*Hospital Vall Hebron, Liver Unit, Barcelona, Spain;* [3]*Centro de investigación biomédica en red de enfermedades hepáticas y digestivas, Madrid, Spain;* [4]*Hospital Vall Hebron, Microbiology Department, Barcelona, Spain;* [5]*Pharmacoeconomics and Outcomes Research Iberia (PORIB), Madrid, Spain;* [6]*Hospital Vall Hebron, Epidemiology Department, Barcelona, Spain*
Email: mbuti@vhebron.net

Background and aims: In primary care centers in Spain the prevalence of anti-HCV is approximately 0.8% and HCV-RNA positive 0.22%. In the emergency department (ED) of our hospital, an HCV-RNA+ screening program was initiated with linkage to antiviral treatment assessment, with the aim of increasing HCV detection and safeguarding the hospital from this infection. Results of the HCV screening strategy were analyzed and a cost-effectiveness evaluation performed.
Method: Prospective study conducted in a university hospital ED (FOCUS-A, hospital free of hepatitis C study). All individuals >16 years of age attending the ED and requiring blood extraction underwent anti-HCV screening, HCV-RNA reflex testing, and FIB-4 calculation if anti-HCV+. Individuals with detectable viral load were linked to a specialist for HCV treatment evaluation. A Markov model was developed to analyze the cost-effectiveness of opt-out HCV testing using the data obtained and a National Health Care System perspective. Lifetime liver-related mortality, hepatic complications, and associated costs were assessed.
Results: In total, 13, 479 individuals screened (February/20–September/21): 49% male, mean age 70 years. Anti-HCV detected in 553 (4%) cases and HCV-RNA in 100 (0.7%). Risk factors associated with anti-HCV: 58 (10%) HIV co-infection, 98 (18%) injecting drug users, 128 (23%) abusive alcohol consumption, and 205 (37%) diagnosed with a psychiatric disorder. Among viremic patients, 34% (n = 34) were unaware of HCV infection and 48% had an FIB-4 score suggestive of cirrhosis (FIB-4 >3.25). Among HCV-RNA+ cases, 53 (53%) were selected for treatment. Reasons for non-selection were short life expectancy or cognitive impairment (40 cases), and loss to follow-up due to serious social problems (7 cases). Of the 53 candidates linked to a specialist, 27 have received treatment and the 14 who completed treatment have achieved a sustained virological response. This strategy reduced liver-related mortality by 56% and avoided 50%-67% of liver complications with a related cost saving of €247, 942.
Conclusion: The prevalence of chronic HCV among in adults in the ED is almost four times higher than in primary care. Almost half the viremic individuals had advanced fibrosis. Screening in the ED is a cost-effective intervention. These findings are of value for informing testing guidelines.

OS053
High Intensity Test and Treat (HITT): an overview of the initiative as part of the hepatitis C elimination programme in England

Beatrice Emmanouil[1], Sean Cox[2], Rachel Halford[2], Georgia Threadgold[1], Mark Gillyon-Powell[1], Graham Foster[1]. [1]*NHS England and NHS Improvement;* [2]*Hepatitis C Trust, United Kingdom*
Email: b.emmanouil@nhs.net

Background and aims: NHS is committed to eliminating viral Hepatitis C (HCV) by 2025. To achieve this, a collaboration with the patient led charity, The Hepatitis C Trust, has been formed to support people considering treatment. To eliminate HCV in people in prison (at high risk of HCV infection) we introduced a 'High Intensity Test

and Treat program' (HITT) to assess and treat all people in a prison. We aim to provide an overview of this initiative and it's preliminary results.
Method: A team comprising of NHS staff, nurses and peers with lived experience of HCV and incarceration were sent into a prison and offered HCV testing to the whole prison population using prison-wing-based testing with point of care antibody tests, followed-up by using either blood draws or dried blood spot testing for confirmation of viraemia in antibody positive people. All infected people were offered therapy with Direct Acting Antivirals within 2 weeks, and often on the same day using point of care HCV RNA testing and pan-genotypic medication.
Results: Between June 2019 and September 2021, 34 HITT initiatives were successfully completed across England: 7 in Female prisons and 27 in Male prisons. The programme was destabilised during the COVID-19 pandemic and for around 6–9 months we were unable to access the prisons to deliver the project. Of the 23, 388 prison population, 19, 049 inmates agreed to be tested. Of those we found 1, 234 people who tested positive for presence of HCV antibodies of whom 175 tested positive for presence of HCV RNA. All 175 prisoners found to have a current infection commenced treatment. There was great variation between establishments, with remand prisons having significantly higher prevalence than re-settlement prisons. Prevalence was also higher in women's prisons compared to men's prisons.
Conclusion: The HITT Hepatitis C elimination initiative has proven invaluable in testing and treating of people in custody, where there might be increased prevalence of viral Hepatitis C, and in aiding prisons achieve micro-elimination. It has also generated useful data about the prevalence of Hep C in prisons and how it varies between establishments.

OS054
Hepatitis C elimination in diabetic population from a shared care cascade cohort- under Changhua-Integrated Program to Stop hepatitis C infection (CHIPS-C)

Email: dr.hu@msa.hinet.net

Background and aims: Several clinical studies have suggested an association between chronic HCV infection and diabetes mellitus (DM). HCV micro-elimination approach, which focuses treatment on DM population was rarely reported. We aim to conduct HCV elimination for population with diabetes mellitus in a county of Taiwan via 27 local health centers under Changhua-Integrated Program to Stop Hepatitis C Infection (CHIPS-C).
Method: Changhua County, has 26 townships and a total of 1, 289, 000 residents. In addition to hospitals and local clinics in the county, there are 27 local health centers handled by the Changhua County Public Health Bureau of government. Taking the diabetic cases in the clinics of various township health centers from 2018 to 2020 as the tracking generation, combined with the Changhua County Diabetes Common Care Network since 1996, HCV screening and treatment were implemented and evaluated. The achievement rate of HCV care chain-related indicators, and the difference in HCV positive rate and treatment rate under different influencing factors were analysed.
Results: By excluding those who were unable to enter the program such as deaths, aging, and mobility, the screening targets total 10, 684 people. The HCV antibody screening rate reached 93.4% (9, 978 people), with HCV antibody positive rate of 6.1% (608 people), HCV RNA referral rate of 93.4% (568 people), HCV RNA virus checking rate of 92.1% (523 people), detectable HCV RNA rate of 69.6% (364 people), eligible treatment rate was 97.5% (355 people), and final treatment rate was 92.1% (327 people). When compared with the situation before intervention of program, the screening rate and treatment rate have been significantly improved which achieve the goal of HCV elimination. The risk of HCV infection is 1.27 (95%CI: 0.793–2.035), 1.64 (95%CI: 1.057–2.536), 1.90 (95%CI: 1.232–2.937), for patients of 50–59 years, 60–69 years, and over 70 years respectively when compared with patients less than 50 years. Furthermore, the risk of HCV infection is 0.43 (95%CI: 0.253–0.712, p = 0.0012) in patients of senior high school; and 0.26 (95%CI: 0.108–0.624, p = 0.0026) in patients of university when compared with patients of illiterate. HCV risk is not associated with other factors such as gender, the duration of diabetes, cigarette smoking, presence of chronic kidney, retinopathy, and foot disease at all. We further evaluated the heterogeneity among townships by using the random effect model, and found that the antibody positive rate was significantly different among townships, but not different on the RNA positive rate and treatment rate.
Conclusion: A novel model was successfully implemented for HCV elimination on diabetic population in the community of Changhua county in Taiwan, by using a series of indicators for caring cascade. This population-based service was provided to the 26 townships with a homogenous quality.

Primary Liver Cancer: Experimental and pathophysiology

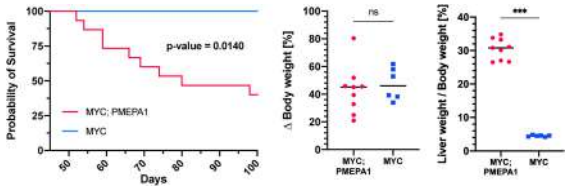
PMEPA1: an oncogene in hepatocellular carcinoma linked to TGF-beta signaling
Carmen Andreu-Oller[1,2], Marta Piqué-Gili[2], Marina Barcena-Varela[1], Roser Pinyol[2], Roger Esteban-Fabró[1,2], Judit Peix[2], Katherine E. Lindblad[1], Miguel Torres-Martín[2], Daniela Sia[1], Amaia Lujambio[1], Josep M. Llovet[1,2,3,4].
[1]Icahn School of Medicine at Mount Sinai, Division of Liver Diseases, New York, United States; [2]Institut d'Investigacions Biomèdiques August Pi i Sunyer (IDIBAPS), Translational Research in Hepatic Oncology, Liver Unit, Barcelona, Spain; [3]Universitat de Barcelona, Barcelona, Spain; [4]Institució Catalana de Recerca i Estudis Avançats (ICREA), Barcelona, Spain
Email: carmenandreuoller@gmail.com

Background and aims: Transforming growth factor beta (TGF-beta) has a dual role in cancer, including hepatocellular carcinoma (HCC). It acts as a tumor suppressor in early stages of hepatocarcinogenesis, but promotes epithelial-to-mesenchymal transition, angiogenesis and immunosuppression in advanced stages. *PMEPA1* (prostate transmembrane protein androgen induced 1), a direct target gene of the TGF-beta pathway that negatively regulates TGF-beta signaling by interacting with SMAD proteins, has been shown to promote TGF-beta oncogenic effects in other cancers. Here, we explored its role in HCC pathogenesis.
Method: We analyzed transcriptomic, genomic, epigenomic and clinicopathological data of a discovery cohort of 228 HCCs and a validation cohort of 361 HCCs. *PMEPA1* levels were quantified by qPCR and IHC in the discovery cohort. *PMEPA1* overexpression was validated in 6 independent cohorts (n = 916) using microarray and RNAseq data. We evaluated *PMEPA1* expression at the single-cell level using a publicly available scRNAseq dataset from 25 HCCs. Genetically engineered mouse models were generated through hydrodynamic

tail-vein injection. Equal amounts of plasmids overexpressing *PMEPA1*, *TGFB1* and *MYC* were injected in mice to evaluate survival. Molecular and histopathological analyses of the murine tumors are currently ongoing.

Results: *PMEPA1* was overexpressed in 18% of human HCCs [FC >2; n = 203/1144], a feature associated with TGF-beta signaling ($p < 0.001$). *PMEPA1* was expressed by both malignant and tumor microenvironment (TME) cells including endothelial cells, cancer associated fibroblasts, T cells and B cells. Overexpression of *PMEPA1* was associated with gene body hypermethylation ($p < 0.0001$). HCCs displaying both TGF-beta signaling and high *PMEPA1* levels (11% of cases) were significantly enriched in signatures of immune exhaustion, late TGF-beta activation, TME response to TGF-beta and active stroma ($p < 0.05$), compared to HCCs with TGF-beta signaling alone (8% of cases) or *PMEPA1* high levels alone (11% of cases). *In vivo*, overexpression of *MYC+PMEPA1* led to HCC development in 9/16 mice and showed a lower survival when compared to the control arm, overexpression of *MYC* alone, ($p = 0.014$) (Figure). On the contrary, only 1/12 mice in the *MYC+PMEPA1+TGFB1* condition developed HCC and none of the *MYC+TGFB1* mice.



Conclusion: *PMEPA1* upregulation is linked to TGF-beta activation and an aggressive phenotype in human HCC. Overexpression of *PMEPA1* in combination with *MYC in vivo* led to HCC development, showing for the first time the oncogenic role of *PMEPA1* in this cancer.

Background and aims: Cholangiocarcinoma (CCA) comprises a heterogeneous group of malignant tumors with dismal prognosis. Alterations in post-translational modifications (PTMs), including NEDDylation, result in abnormal protein dynamics, cell disturbances and disease. Here, we investigate the role of NEDDylation in CCA development and progression.

Method: Levels and function of NEDDylation, together with response to Pevonedistat (NEDDylation inhibitor) or CRISPR/Cas9 against *NAE1* were evaluated *in vitro*, *in vivo* and/or in patients with CCA. Development of preneoplastic lesions in *Nae1*$^{\pm}$ mice was investigated using an oncogene-driven CCA model. The impact of NEDDylation in CCA cells on tumor-stroma crosstalk was assessed using CCA-derived cancer-associated fibroblasts (CAFs). Proteomic analyses were carried out by mass spectrometry.

Results: NEDDylation machinery was found overexpressed and overactivated in human CCA cells and tumors, correlating with poor prognosis. Most NEDDylated proteins found upregulated in CCA cells, after NEDD8-immunoprecipitation and further proteomics, participate in cell cycle, proliferation or survival. Genetic (CRISPR/Cas9-*NAE1*) and pharmacological (pevonedistat) inhibition of NEDDylation reduced CCA cell proliferation and impeded colony formation *in vitro*. NEDDylation depletion (pevonedistat or *Nae1*$^{\pm}$ mice) halted tumorigenesis in subcutaneous, orthotopic, and oncogene-driven models of CCA *in vivo*. Moreover, pevonedistat potentiated chemotherapy-induced cell death in CCA cells *in vitro*. Mechanistically, impaired NEDDylation triggered the accumulation of cullin RING ligase or NEDD8 substrates, inducing DNA damage and cell cycle arrest. Furthermore, NEDDylation impairment in CCA cells reduced the secretion of proteins involved in fibroblast activation, angiogenesis, and oncogenic pathways, ultimately hampering CAF proliferation and migration.

Conclusion: aberrant protein NEDDylation contributes to cholangiocarcinogenesis by promoting cell survival and proliferation. Moreover, NEDDylation impacts the CCA-stroma crosstalk. Inhibition of NEDDylation with pevonedistat may represent a potential therapeutic strategy for patients with CCA.

Induction of branching morphogenesis in cholangiocarcinoma organoids in vitro improves similarity with the original tumour

Gilles van Tienderen[1], Kathryn Monfils[1], Floris Roos[1], Luc J.W. van der Laan[1], Monique M.A. Verstegen[1]. *[1]ErasmusMC Transplant Institute, Department of Surgery, Rotterdam, Netherlands*
Email: g.vantienderen@erasmusmc.nl

Background and aims: Cholangiocarcinoma (CCA) is an aggressive, heterogeneous cancer with low survival rates. Patient-derived cholangiocarcinoma organoids (CCAOs) hold potential for understanding disease progression and developing novel treatment options, based on their ability to mimic the original tumor. Currently, most organoid expansion protocols focus on stimulation of the canonical WNT/β-catenin pathway, however there is growing evidence showing that non-canonical WNT pathways also play a crucial role in cancer progression. This project aims to establish a novel in vitro model for CCA, better recapitulating the in vivo tumor, by stimulating both canonical and non-canonical WNT pathways.

Method: Branching cholangiocarcinoma organoids (BRCCAOs) (n = 3 patients) were established with a two-step protocol. First, CCAOs were initiated and cultured under standard conditions in canonical

WNT stimulating expansion medium. Next, expansion medium was replaced by medium that stimulates canonical WNT-signaling (through R-spondin) and non-canonical WNT-signaling (with Dickkopf-related protein 1) simultaneously, after which a branching-like morphology could be observed. Tumor cell behavior in BRCCAOs and CCAOs was assessed and compared through immunohistochemical stainings, bulk RNA-sequencing, and drug response studies.
Results: BRCCAOs presented a distinct branching morphology, displaying a morphological architecture similar to in vivo tumors, while maintaining tumorigenic potential and expression of cytokeratin-7, with an accompanying lack of defined cellular polarity. Bulk RNA-sequencing of BRCCAOs showed significant upregulation of cancer-associated molecular pathways, including hypoxia, compared to CCAOs and a close correlation (coefficient 0.80 ± 0.05) to the transcriptome of the original tumor tissue. BRCCAOs also exhibited a strong resistant phenotype to a large panel of 166 anti-cancer drugs, including multiple drugs that have previously failed in clinical trials for CCA patients (e.g. docetaxel, palbociclib, and irinotecan). Specifically, compared to CCAOs, BRCCAOs showed an approximately 10.000-fold ($p < 0.0001$) increase in chemo resistance against gemcitabine and cisplatin, first-line chemotherapy drugs for CCA, independent of patient variance.
Conclusion: These results demonstrate that BRCCAOs better resemble in vivo CCA tumor tissue compared to conventional CCAOs, particularly with regards to morphology, transcriptome, and drug responses. Gemcitabine and cisplatin combinational therapy only provides CCA patients with a modest benefit in overall survival, and BRCCAOs appear to mimic this response more closely, thus providing possibilities for personalized medicine applications.

Cross-talk between MerTK-expressing stromal cells and cholangiocarcinoma

Mirella Pastore[1], Öykü Gönül Geyik[1,2], Jesper Andersen[3], Monika Lewinska[3], Ana Lleo[4], Paolo Kunderfranco[4], Chiara Raggi[1], Fabio Marra[1]. *[1]University of Florence, Firenze, Italy; [2]Istinye University, Turkey; [3]Copenhagen University, København, Denmark; [4]Humanitas University, Italy*
Email: fabio.marra@unifi.it

Background and aims: A typical feature of cholangiocarcinoma (CCA) is a dense stromal reaction populated by fibrogenic myofibroblasts and immune cells, creating a complex tumor microenvironment where malignant cells survive and proliferate. Cancer stem cells (CSCs) have been proposed as a driving force of tumor initiation, dissemination and drug-resistance in many solid tumors, including cholangiocarcinoma (CCA). Increasing evidence indicates that myeloid-epithelial-reproductive tyrosine kinase (MerTK) is highly expressed by a macrophage subset defined as M2c. The present study aims to investigate whether signals generated by MerTK-expressing macrophages modulate the biology of CCA.
Method: 3D-tumor sphere cultures enriched in CSC were generated from intrahepatic CCA cell lines (HuCCT-1 and CCLP-1). Circulating monocytes were differentiated into M2c macrophages in vitro. Recombinant Gas-6, a MerTK ligand, was used to activate this receptor. MERTK mRNA expression in human CCA tissues was also analyzed.
Results: In CCA cell lines cultured with conditioned medium from Gas-6-stimulated M2c macrophages, cell survival, invasion, sphere-forming efficiency and drug resistance were significantly increased. These effects were reduced following macrophage pre-treatment with the MerTK inhibitor, UNC2025. Analysis of the transcriptome of laser-captured, micro-dissected epithelium and stroma from 23 CCA patients showed that MerTK mRNA expression is significantly higher in intratumoral stroma. Single-cell RNA sequencing of CD45+ sorted cells from paired non-tumoral and tumoral specimens from iCCA patients ($n = 6$) defined eleven clusters characterized by their gene expression profiles. A further reclustering of myeloid cells showed MerTK expression in Kupffer cells, lipid macrophages, TREM2+ macrophages, and non-classical monocytes.
Conclusion: These data suggest a cross-talk between MerTK-expressing cells in the stroma and CCA cells, to induce increased malignant features.

OS059

Mixed HCC-CCA originates from hepatic progenitor cells, is dependent on IL6 singling and is ablated by senolytic agents

Nofar Rosenberg[1], Matthias Van Haele[2], Maria Garcia Beccaria[3], Mirian Fernández-Vaquero[3], Danijela Heide[3], Neta Barashi[1], Amnon Peled[1], Yuval Nevo[4], Shrona Elgavish[4], Dirk Schmist-Arras[5], Hanan Edler[1], Alina Simerzin[1], Michal Shoshkes-Carmel[6], Klaus Kaestner[6], Hilla Giladi[1], Stefan Rose-John[5], Tania Roskams[2], Mathias Heikenwälder[3], Eithan Galun[1]. *[1]The Goldyne Savad Institute of Gene and Cell Therapy, Hadassah Hebrew University, Jerusalem, Israel; [2]University of Leuven, Department of Translational Cell and Tissue Research, Leuven, Belgium; [3]DKFZ, Department of Traslational Cell and Tissue Research, Germany; [4]Hebrew University of Jerusalem, Hadassah Medical School, Bioinformatics Unit, Israel; [5]Christian-Albrechts-Universität zu Kiel, Institut für Biochemie, kiel, Germany; [6]University of Pennsylvania Perelman School of Medicine, Penn Center for Molecular Studies in Digestive and Liver Diseases, Philadelphia, United States*
Email: nofar.ros@gmail.com

Background and aims: Primary liver cancer is the 3rd leading cause of cancer-related death worldwide. Primary liver cancers include: Hepatocellular carcinoma (HCC), intrahepatic cholangiocarcinoma (CCA) and Mixed HCC-CCA tumors. Chronic liver inflammation, which develops to cirrhosis, is a risk for the development of primary liver cancer. It has been suggested that hepatic progenitor cells (HPCs) could contribute to hepatocarcinogenesis. However, this has not yet been proven. HPCs proliferate in response to injury and chronic inflammation. In this study, we aimed to determine whether HPCs contribute to HCC, Mixed HCC-CCA or both types of tumors, in the MDR2 KO mouse model of inflammation-induced cancer.
Method: In order to enable tracing of progenitor cells, we generated a transgenic mouse based on the MDR2 KO that harbours a YFP reporter gene driven by the Foxl1 promoter. Foxl1 is expressed specifically in adult HPCs. These mice (MDR2 $KO^{Foxl1CRE;\ RosaYFP}$) develop chronic inflammation by the age of 1 month and develop HCCs by the age of 14–16 months, followed by mixed HCC-CCA tumors at the age of 18 months, as we have first observed, suggesting that the aged mice are a suitable model for mixed HCC-CCA tumors.
Results: In this model, we show that liver progenitor cells are the source of mixed HCC-CCA tumors, but they are not the source of HCC in the chronically inflamed liver. By generating mice with a Diphtheria toxin (DT) receptor in HPCs and administering DT, we ablated the progenitors, and we observed a significant reduction in the development of mixed HCC-CCA tumors but no change in HCCs. RNA-seq analysis revealed enrichment of the IL6 signaling pathway in mixed HCC-CCA tumors in comparison to HCC tumors. A single cell RNA-seq analysis revealed that in the liver, IL6 is expressed from both, immune cells and parenchymal cells which are in senescence, and that IL6 is part of the senescence-associated secretory phenotype (SASP). Upon administration of anti-IL6 antibodies to the MDR2 $KO^{Foxl1CRE;\ RosaYFP}$ mice, we inhibited the development of the mixed HCC-CCA tumors. Furthermore, by blocking IL6 transsignaling with sgp130, we also decreased mixed HCC-CCA tumors, indicating that mixed HCC-CCA tumors are dependent on IL6 transsignaling. The administration of a senolytic agent to these mice, also inhibited the development of mixed HCC-CCA tumors.
Conclusion: Our results suggest that mixed HCC-CCA but not HCC tumors, originate from HPCs in the inflammation induced liver cancer model, and that the driver of this process involves the IL6 signalling pathway that at least in part, derives from SASP of cells in senescence. These findings could enhance the development of new therapeutic approaches for mixed HCC-CCA liver cancer.

Email: mlmartinez@cicbiogune.es

Background and aims: Epithelial-mesenchymal transition (EMT), a key process during embryonic development, promotes cell migration and resistance to apoptosis during tumour invasion and metastasis. In hepatocellular carcinoma (HCC) an amoeboid behaviour tends to increase the aggressiveness and metastatic capacity of epithelial tumours.

MAP17 is a 17 kDa membrane protein expressed during embryogenesis, absent in most adult organs. The presence of MAP17 correlates with an inflammatory environment, hypoxia and increased reactive oxygen species (ROS). MAP17 has been identified in several types of cancer, including HCC. Modulation of EMT and amoeboid behaviour via MAP17 offers an attractive approach to prevent metastasis.

Method: Two separated HCC patient cohorts were used to characterise MAP17 levels. *In vitro*, expression of MAP17 was measured in mesenchymal and epithelial hepatoma cells, and its levels were modulated to study its implication in cell proliferation, drug resistance, mitochondrial dynamics, metabolic rewiring, and proteome homeostasis. *In vivo*, the role of MAP17 in the metastatic capacity was evaluated using orthotopic HCC mice models.

Results: A positive correlation of MAP17 and mesenchymal markers was established in 751 HCC patients *in silico* study and by mRNA expression in 246 HCC patients. Additionally, MAP17 appeared statistically associated with RAC/RHO family genes, markers of amoeboid movement, in the same patient cohort. MAP17 overexpression in 3D epithelial cell experiments let to the formation of rosette invadopodia, proinvasive structures with high metastatic capacity.

MAP17 overexpression *in vitro* produced a reprogramming of energy metabolism in hepatoma cells with epithelial phenotype, increasing mitochondrial dynamics and Warburg effect-mediated lactic acidosis, which support a tumour microenvironment conducive to cancer cell proliferation. ROS generation was increased as a protective mechanism to avoid apoptotic and senescence processes. Rewiring in the one-carbon metabolic pathway was also identified, proving an accelerated metabolism of the cell. Accordingly, overexpression of MAP17 in PLC/PRF/5 cells in the orthotopic model led to the formation of multiple tumour foci in the liver.

MAP17 silencing in hepatoma mesenchymal cells provided the opposite results, regressing the tumour phenotype and slowing down the cell metabolism and proliferation.

Conclusion: Modulation of MAP17 in epithelial and mesenchymal cells leads to the reprogramming of the transitional genes that define each phenotype. Our findings have identified the metastatic potential of MAP17 in liver cancer, as it triggers the mesenchymal phenotype and amoeboid behaviour in HCC.

Cirrhosis and its complications: ACLF and Critical illness

OS061

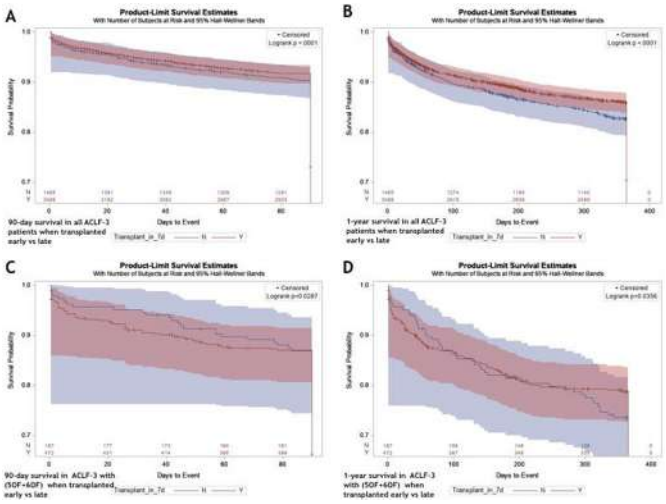
Liver transplantation within 7-days of listing improves survival in ACLF-3

Joseph Alukal[1], Feng Li[1], Paul J. Thuluvath[1]. *[1]Institute of Digestive Health and Liver Disease, Gastroenterology, Baltimore, United States*
Email: jjalukal@gmail.com

Background and aims: ACLF-3 is associated with a very high short-term mortality without liver transplantation (LT). The timing of LT, therefore, may be critical for optimal outcomes. The objective of our study was to determine if early LT (<7 days from listing), stratified by the number of organ failures (OF), had an impact on 90-day and 1-year survival in ACLF-3 patients.

Method: United network for organ sharing (UNOS) database was queried to identify adults (>18 years) with ACLF-3 who underwent LT between 2005–2021. We excluded those listed with status 1, 1A, or 1B, multi-organ transplant, living donor transplant and HCC. ACLF patients were identified using EASL-CLIF criteria. Unadjusted Kaplan-Meier (KM) survival curves were used to evaluate patient survival. The Cox proportional hazards (CPH) regression model was used to evaluate the risk factors for survival

Results: We identified 3, 498 patients with ACLF-3 who underwent early LT while 1, 485 had transplant >7 days from listing. 90-day and 1-year survival in ACLF-3 patients who underwent early LT were 92% and 87% respectively. KM survival analysis showed that those who were transplanted early (≤7 days) had significantly better 90-day and 1-year survival than who underwent late LT (>7 days) (Figure A and Figure B). This survival benefit was seen across all sub-groups of ACLF-3 including those with 5 and 6 OF (Figure C and Figure D). On multivariable analysis, age (Hazard Ratio [HR]1.02), body mass index (HR 1.01), donor risk index >1.7 (HR 1.3), respiratory failure (HR1.9), and etiology of cirrhosis were independent predictors of higher 90-day post-transplant mortality. Similarly, age (HR1.01), donor risk index >1.7 (HR1.3), diabetes (HR1.3), respiratory failure (HR 1.7) and etiology of cirrhosis were independent predictors of higher 1-year mortality while higher albumin (HR 0.87) was associated with a reduced mortality.



Conclusion: Early LT (≤7 days from listing) in ACLF-3 after listing is associated with a better 90-day and 1-year survival than those who were transplanted late (>7 days). This survival benefit was seen even in those with 5 and 6 OF.

OS062

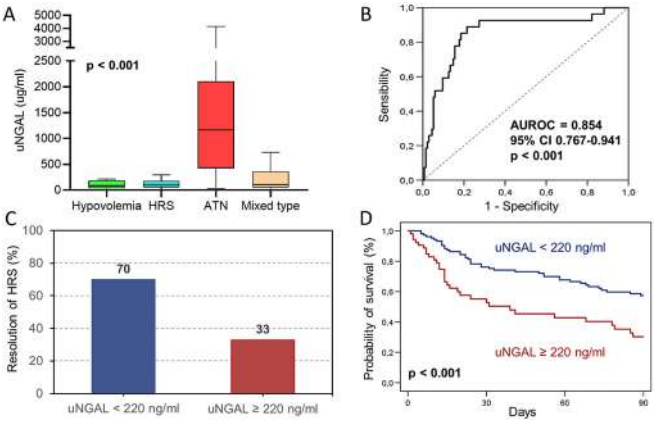
Neutrophil gelatinase-associated lipocalin predicts response to terlipressin and albumin in patients with hepatorenal syndrome

Carmine Gabriele Gambino[1], Matteo Stenico[1], Marta Tonon[1], Alessandra Brocca[1], Valeria Calvino[1], Simone Incicco[1], Chiara Cosma[2], Martina Zaninotto[2], Patrizia Burra[3], Umberto Cillo[4], Mario Plebani[2], Paolo Angeli[1], Salvatore Piano[1]. *[1]Unit of Internal Medicine and Hepatology, Department of Medicine, University of Padova, Padova, Italy, Padova, Italy; [2]Laboratory Medicine Unit, Department of Medicine, University of Padova, Padova, Italy; [3]Multivisceral Transplant Unit, Department of Surgery, Oncology and Gastroenterology, University of Padova, Padova, Italy; [4]Hepatobiliary Surgery and Liver Transplantation, Department of Surgery, Oncology and Gastroenterology, University of Padova, Padova, Italy*
Email: salvatorepiano@gmail.com

Background and aims: Acute Kidney Injury (AKI) commonly occurs in patients with decompensated cirrhosis. Neutrophil Gelatinase-associated Lipocalin (NGAL) is a novel urinary biomarker that could help in discriminating between different etiologies of AKI. The aim of this study was to investigate the ability of urinary NGAL (uNGAL) in: (1) the differential diagnosis of AKI, (2) predicting the response to treatment with terlipressin and albumin in patients with Hepatorenal Syndrome (HRS)-AKI and (3) predicting in-hospital and 90-day mortality.

Method: We included cirrhotic patients with AKI not solved within 48 hours, who were consecutively admitted from 2015 to 2020 at the University Hospital of Padova. uNGAL and standard urinary biomarkers were measured. Data on the type of AKI, AKI treatment, resolution of AKI were collected during the hospitalization and patients were followed up until transplant, death or 90 days.

Results: We enrolled 162 patients (mean age: 62 ± 10 years, male: 77%; alcoholic etiology: 48%; mean MELD: 25 ± 8). Thirty-five patients (22%) had hypovolemic AKI, 64 (39%) HRS-AKI, 27 (17%) acute tubular necrosis (ATN)-AKI and 36 (22%) a mixed form. uNGAL values were significantly higher in patients with ATN-AKI than in patients with other types of AKI (1162 [423–2105] vs 109 [52–192] ng/ml; p < 0.001; Fig. A). uNGAL showed a high discrimination ability in predicting ATN-AKI (AUROC = 0.854; [95% CI = 0.767–0.941]; p < 0.001; Fig. B) and the best threshold was 220 ng/ml (sensitivity 89%; specificity 78%).



Sixty-two patients with HRS-AKI were treated with terlipressin and albumin. Among them, patients with uNGAL ≥220 ng/ml had a significantly lower rate of response to terlipressin and albumin (33 vs 70%; p = 0.015; Fig. C). After adjusting for serum creatinine, uNGAL ≥220 ng/ml was independently associated with a higher risk of non-response (aOR = 4.55, 95% CI = 1.28–16.67; p = 0.02).

In multivariable analysis (adjusted for age, MELD, ACLF, leukocytes and type of AKI) uNGAL was an independent predictor of in-hospital mortality (aOR = 1.74 [95% CI = 1.26–2.38]; p = 0.001) and 90-day mortality (aHR = 1.32 [95% CI = 1.13–1.55]; p = 0.001). Probability of survival was significantly lower in patients with uNGAL ≥220 ng/ml (57% vs 30%; p < 0.001; Fig. D).

Conclusion: uNGAL is an excellent biomarker for the differential diagnosis of AKI in cirrhosis, it predicts response to treatment with terlipressin and albumin in patients with HRS-AKI and is an independent predictor of mortality.

OS063

CLEARED Global consortium results highlight regional variation and need for equity in inpatient outcomes in hospitalized patients with Chronic Liver Disease

Background and aims: A global study with equitable participation for cirrhosis and chronic liver disease (CLD) outcomes is needed. We initiated the Chronic Liver disease Evolution And Registry for Events and Decompensation (CLEARED) study to provide this global perspective. Aim to evaluate determinants of inpatient mortality and organ dysfunction in a multi-center worldwide study.

Method: We prospectively enrolled pts with CLD/Cirrhosis >18 years without organ transplant or COVID-19 who were admitted non-electively. To maintain equity in outcome analysis, a maximum of 50 pts/site were allowed. Data for admission variables, hospital course, and inpatient outcomes (ICU, death, organ dysfunction [ODF]) were recorded. This was analyzed for death and ODs using significant variables on admission and including World Bank classification of low/middle-income countries (LMIC). A model for in-hospital mortality for all variables during the hospital course, including ODs) was analyzed.

Results: 1383 pts (55 ± 13 yrs, 64% men, 39% White, 30% Asian, 10% Hispanic, 9% Black, 12% other) were enrolled from 49 centers (Fig A). 39% were from high-income while the rest were from LMICs. Admission MELDNa 23 (6–40) with history in past 6 months of hospitalizations 51%, infections 25%, HE 32%, AKI 23%, prior LVP 15%, hydrothorax 8% and HCC 4%. Leading etiologies were Alcohol 46% then NASH 23%, HCV 11% and HBV 13%. Most were on lactulose 52%, diuretics 53%, PPI 49% and statins 11%, SBP prophylaxis 16%, beta-blockers 35% and rifaximin 31%. 90% were admitted for liver-related reasons; GI bleed 30%, HE 34%, AKI 33%, electrolyte issues 30%, anasarca 24% and 25% admission infections. In-hospital course: Median LOS was 7 (1–140) days with 25% needing ICU. 15% died in hospital, 3% were transplanted, 46% developed AKI, 15% grade 3–4 HE, 14% shock, 13% nosocomial infections and 13% needed ventilation. Logistic Regression: Fig B shows that liver-related/unrelated factors on admission which predicted in-hospital mortality and development of organ dysfunction with MELDNa and Infections being common among all models. Nosocomial infections and organ dysfunctions predicted mortality when all variables were considered. High-income countries had better mortality outcomes likely due to transplant and ICU availability. AUCs were >0.75.

Fig B	AUC(95% CI)	Variables linked with higher risk of Outcome			Variables linked with lower risk of Outcome		
		Variable	OR (95% CI)	P value	Variable	OR (95% CI)	P value
Inpatient mortality admission variables	0.81 (0.77-0.84)	Age	1.02 (1.0-1.03)	0.013	Transplant listing	0.46 (0.26-0.84)	0.01

		Infection in 6 mths	1.55 (1.04-2.33)	0.03			
		Statin use	2.04 (1.14-3.67)	0.01			
		MELD-Na	1.07 (1.04-1.09)	<0.0001			
		Adm Infection	1.64 (1.13-2.39)	0.001			
Shock admission variables	0.78 (0.75-0.82)	Others vs Asian	1.80 (1.19-2.71)	<0.0001	Prior hydrothorax	0.38 (0.17-0.87)	0.05
		MELD-Na	1.08 (1.05-1.10)	<0.0001	Hospitalized prior 6 mths	0.65 (0.43-0.99)	0.04
		Adm Infection	2.40 (1.67-3.47)	<0.0001			
AKI admission variables	0.85 (0.83-0.88)	Age	1.03 (1.02-1.05)	<0.0001	Hospitalized prior 6 mths	0.73 (0.53-0.99)	0.05
		Others vs Asian	1.67 (1.13-2.49)	0.004			
		MELD-Na	1.15 (1.12-1.17)	<0.0001			
		Adm Infection	2.45 (1.80-3.33)	<0.0001			
		Prior AKI	6.78 (4.48-10.25)	<0.0001			
		Prior HE	1.46 (1.06-2.02)	0.02			

Conclusion: In this worldwide equitable experience, admission cirrhosis severity and infections are associated with inpatient outcomes, which are greater in low-income settings. Liver-related and unrelated factors and regional variations are important in defining critical care goals and outcome models in inpatients with cirrhosis.

OS064

Maladaptive tubular repair is a harbinger of chronic kidney disease development in critically-ill cirrhosis patients admitted to intensive care unit-a prospective cohort study

Rakhi Maiwall[1], Sama Siva Rao Pasulapeti[2], Archana Rastogi[3], Ashini Hidam[4], Guresh Kumar[5], Sherin Thomas[3], Anupam Kumar[4], Shiv Kumar Sarin[1]. [1]*ILBS, Hepatology, India;* [2]*Pachhunga University College, Statistics, Aizawl, India;* [3]*ILBS, Pathology, New Delhi, India;* [4]*ILBS, Clinical and Molecular Medicine, New Delhi, India;* [5]*ILBS, Statistics, New Delhi, India*
Email: shivsarin@gmail.com

Background and aims: Critically ill cirrhosis (CIC) patients with acute kidney injury (AKI), are predisposed to increased CKD risk. Renal tubular epithelial cells (RTECs) initiate repair mechanisms following tubular injury and failure of repair causes renal fibrosis. We evaluated serum Cystatin C (CysC), urinary neutrophil gelatinase-associated lipocalin (u-NGAL) and RTECs as risk factors of progressive AKI (AKI-Pro) and CKD in CIC.
Method: At enrolment we performed CysC, u-NGAL and urine microscopy (repeated at day 7) in all included patients. In a subset of patients (n = 30, 15-AKI-Prog and 15-AKI resolution), a panel of 17 renal biomarkers (in urine), endothelial injury and repair markers and monocyte-chemoattractant-protein-1 (MCP-1) (in plasma), mitochondrial biogenesis markers by QRT-PCR in RTECs was performed. Immunohistochemistry (IHC) for alpha-smooth muscle actin (α-SMA) and collagen (col) 1 and 3 was performed on post-mortem renal biopsies.
Results: Altogether, 369 CIC patients, aged 47.9 ± 11.4 years, 87% males, 84% with AKI at enrolment, sepsis-related AKI in 47%, hepatorenal syndrome in 42%, acute tubular necrosis in 27% were enrolled from august 2016 to September 2020. Of these, 24.9% patients had coarse granular casts, 34.4% had RTECs and 5.7% had albuminuria (>300 mg) at enrolment. At day seven, 58% had AKI-Prog. On median follow-up of 204 days [range 43–365]; 46% developed CKD and 30% died or underwent liver transplant. uNGAL and CysC correlated significantly with AKI cause, severity, presence of sepsis and progression at day 7 ($p < 0.001$). Presence and persistence of granular casts and RTECs, u-NGAL, serum CysC, SOFA scores and AKI-Prog at day seven were independent predictors CKD development in different multivariate competing risk models. Patients with AKI-Prog showed higher MCP-1, increase in renal endothelial injury and markers of fibrosis, a decrease in repair markers of tubular injury [significantly lower osteopontin, calbindin and epidermal growth factor] and failure of mitochondrial biogenesis [figure]. Post-mortem renal biopsies showed a predominance of chronic inflammatory infiltrate comprising of monocyte-macrophages and tubulointerstitial fibrosis, which correlated with uNGAL, CysC, AKI duration and IHC staining for α-SMA, col-1 and 3 [$p < 0.05$].
Conclusion: Almost two-thirds of CICs have AKI, which is often progressive, and associated with sepsis. NGAL and CysC can accurately predict AKI progression and CKD development. Persistence of RTECs in urinalysis at day-7 correlates with AKI progression and CKD development. The RTECs of patients with progressive AKI show loss of renal repair markers and failure of mitochondrial biogenesis. Infiltration with monocyte-macrophages plays a dominant role in renal fibrogenesis in CICs.

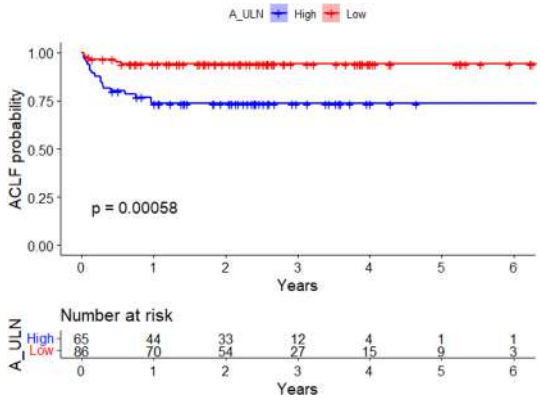
Email: t.tranah@nhs.net

Background and aims: Ammonia level correlates with the severity of hepatic encephalopathy and organ failure and is an independent predictor of mortality in patients with acute decompensation or acute-on-chronic liver failure (ACLF). However, its utility as a prognostic biomarker in patients with cirrhosis remains unclear. We hypothesized that hyperammonaemia predisposes to ACLF in outpatients with cirrhosis. We aimed to determine (i) whether hyperammonaemia is an independent risk factor for ACLF in clinically stable outpatients with cirrhosis, (ii) a threshold value of ammonia that defines this risk of ACLF, and (iii) its association with mortality.
Method: A prospective observational study of clinically stable cirrhotic outpatients followed-up in two tertiary hospitals was performed. Main outcomes were development of ACLF and mortality. Ammonia levels were normalized according to the upper limit of normality (A_ULN). Multivariable frailty competing risk modelling was performed with ACLF as event of interest and liver transplantation as a competing risk. Cut-off for A_ULN was calculated using maximally selected rank statistics and Kaplan-Meier curves with log-rank test were used to compare ACLF in the high and low risk groups and ACLF as risk factor for mortality.
Results: 603 patients were included (69% males; mean 56 years) with median follow-up of 215 days (range: 2–2453). A total of 68 (11%) patients developed ACLF. A_ULN was an independent predictor of ACLF (HR = 2.62; 95CI = 2.34–3-51; $p < 0.001$). Other risk factors were diabetes (HR = 2.6; 95CI = 1.57–4.37; $p < 0.001$), MELD score (HR = 1.1; 95CI = 1.03–1.10; $p < 0.001$) and albumin (HR = 0.5; 95CI = 0.30–0.85; $p = 0.001$). Using 1.48 as cut-off from the training set, statistically differences were found between high and low levels of A_ULN for ACLF ($p < 0.001$) in the test set (Figure 1). Overall survival was significantly lower in patients with ACLF (log-rank = 162; $p < 0.001$) and in patients with A_ULN >1.48 (log-rank = 19; $p < 0.001$).



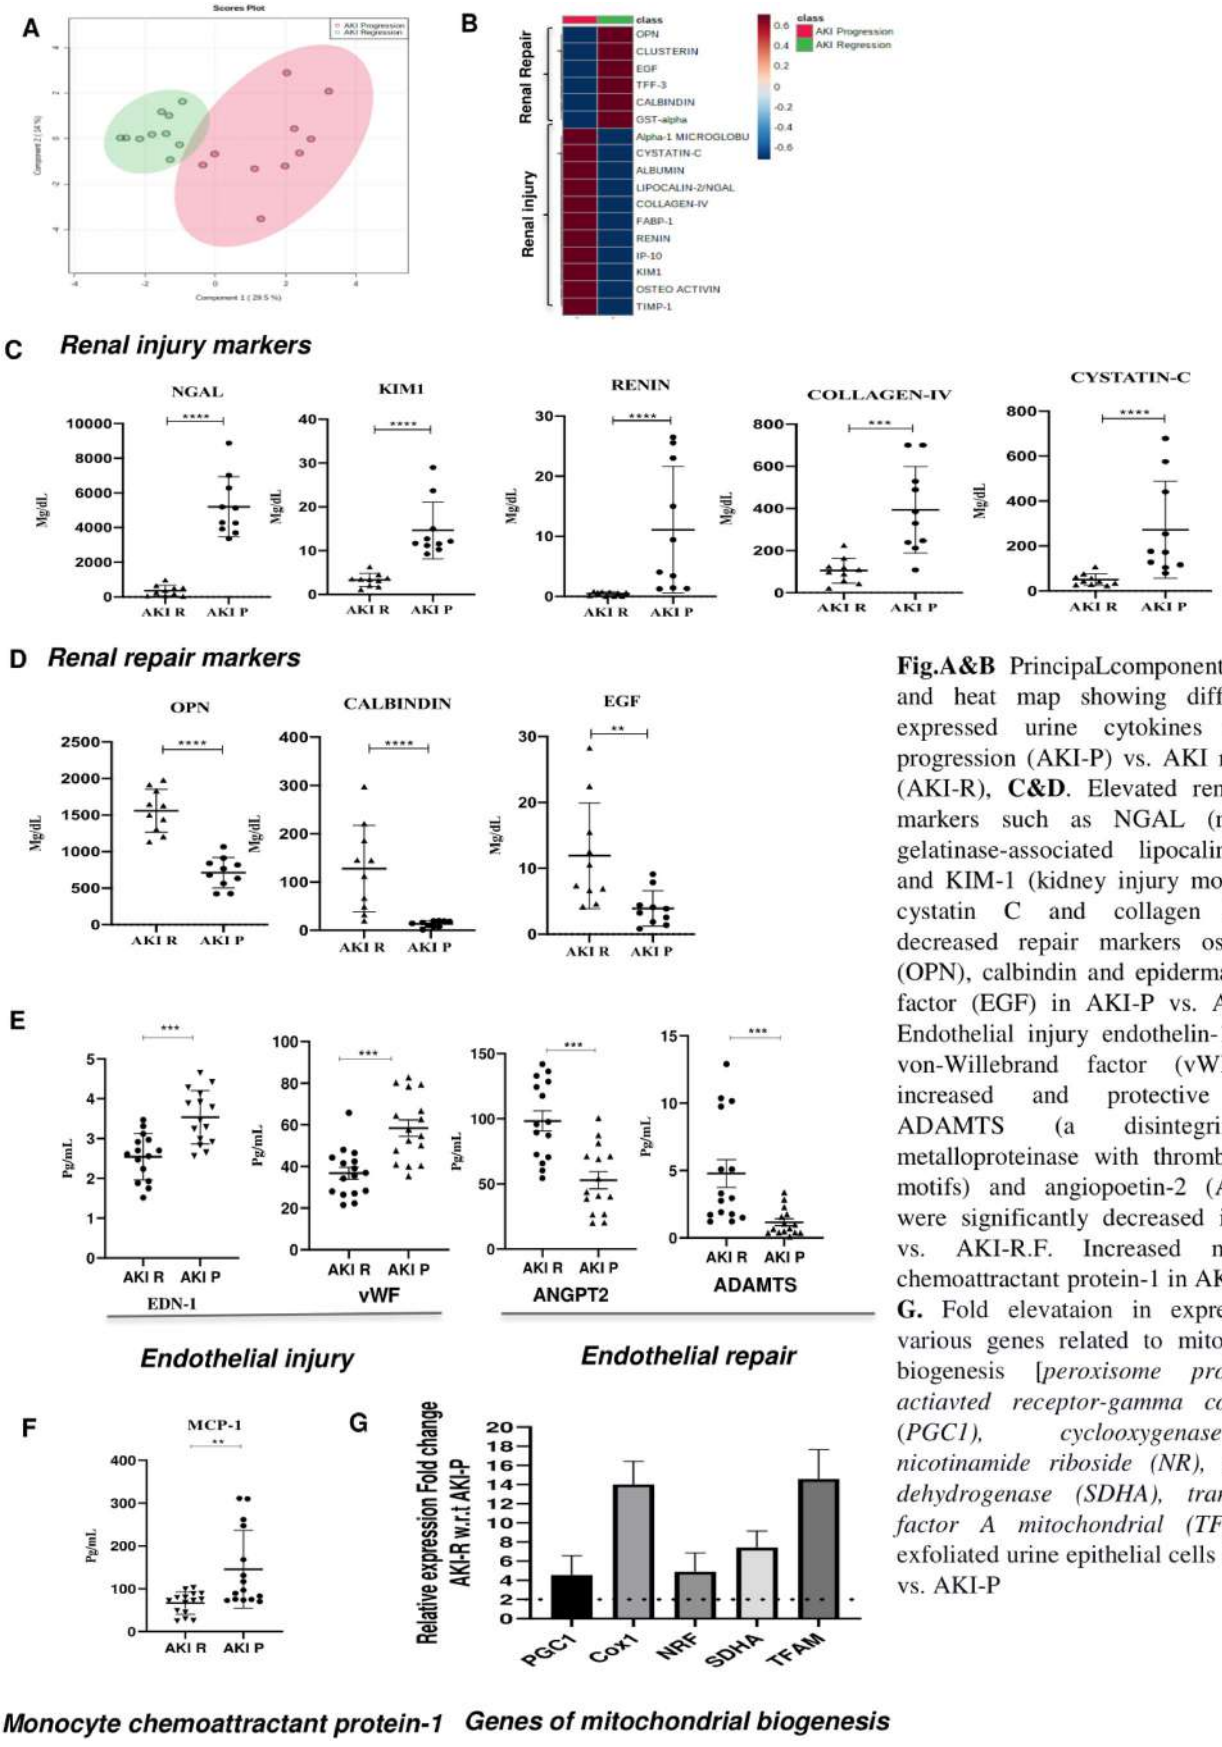


Fig.A&B PrincipaLcomponent analysis and heat map showing differentially expressed urine cytokines in AKI progression (AKI-P) vs. AKI resolution (AKI-R), **C&D**. Elevated renal injury markers such as NGAL (neutrophil gelatinase-associated lipocalin), renin and KIM-1 (kidney injury molecule-1), cystatin C and collagen IV and decreased repair markers osteopontin (OPN), calbindin and epidermal growth factor (EGF) in AKI-P vs. AKI-R **E.** Endothelial injury endothelin-1 (EDN), von-Willebrand factor (vWF) were increased and protective marker ADAMTS (a disintegrin and metalloproteinase with thrombospondin motifs) and angiopoetin-2 (ANGPT2) were significantly decreased in AKI-P vs. AKI-R.F. Increased monocyte-chemoattractant protein-1 in AKI-P

G. Fold elevataion in expression of various genes related to mitochondrial biogenesis [*peroxisome proliferator-actiavted receptor-gamma coactivator (PGC1), cyclooxygenase-1(Cox1), nicotinamide riboside (NR), succinate dehydrogenase (SDHA), transcription factor A mitochondrial (TFAM)*] in exfoliated urine epithelial cells in AKI-R vs. AKI-P

Figure: (abstract: OS064)

Conclusion: Ammonia is an independent predictor of ACLF and its associated mortality in clinically stable outpatients with cirrhosis. An ammonia level over 1.48 times the ULN defines the high-risk group for ACLF.

OS066

Predicting prognosis in large cohort of decompensated cirrhosis of liver (DCLD)- a machine learning (ML) approach

Ashok Choudhury[1], Vinod Arora[1], Kajali Mishra[2], Harshvardhan Tevethia[1], Vishal Kaushik[1], Babita Prasad[1], Manoj Kumar[1], Shiv Kumar Sarin[1]. *[1]Institute of Liver and Biliary Sciences, New Delhi, India; [2]Henry Ford Hospital, Detroit, United States*
Email: doctor.ashokchoudhury@gmail.com

Background and aims: Onset of decompensation in cirrhosis is associated with poor outcome. The current clinico-biochemical tools have limited accuracy in predicting outcomes reliably. Identifying the predictors with precision model on the big data using artificial intelligence may improve predictability. We aimed to develop a machine learning (ML) based prognostic model for predicting 90 day survival in patients of cirrhosis presenting with decompensation.
Method: We analysed electronic medical records retrospectively of hospitalised cirrhosis patients at the ILBS, with a complete 90-day follow-up. Clinical data, laboratory parameters and organ involvement were serially noted. AI-modelling was done after appropriate mining, feature engineering, splitted randomly into train and test-sets (20:80). The class imbalance problem was handled by random over-sampling technique, to make balanced 50:50 ratios. After 10-fold cross validation, 3 repetitions and grid search for optimal hyper parameters, the XGB-CV model was chosen. AUC was the primary selection criteria and confusion matrix was used to compare AUCs between AI-models and existing indices; CTP and MELD-score.
Results: Total of 6326 patients [mean age 48.2 ± 11.5 years, 84% male, Mean CTP 10.4 ± 2.2 and MELD Na-30.4 ± 11.9, alcohol 49.4%] were included. Ninety day mortality was 29.2%. Acute insult was identified in 80% cases; of which extra-hepatic 49%, hepatic 46% and unknown 5% cases respectively. The XGB-CV model had the best accuracy for prediction of 90 days event in the train set 0.90 (0.90–0.93), validation set 0.80 (0.79–0.81) and for overall dataset 0.80 (0.79–0.81). The AUC of the XGB-CV model was better than CTP and MELD Na-score by 16% and 15% respectively. The prediction model considered 43 variables; 18 of which predicted the outcome, and 10 maximum contributors are shown in concordance classifier. The most contributors to poor outcome included, index presentation as HE, diagnosis of AD/ACLF/ESLD, PT-INR, serum creatinine, total bilirubin, acute insult etiology, prior decompensation, acute hepatic or extrahepatic insult, leukocyte count and present duration of illness. In the Decision Tree Model, the presence of HE, PT-INR and syndromic diagnosis of AD or ACLF/ESLD was able to stratify the patients into low (22%), intermediate (23–46%) and high risk (>75%) of mortality at 90 days.
Conclusion: The AI based current model developed using a large data base of CLD patients presenting with decompensation immensely adds to the current indices of liver disease severity and can stratify patients at admission. Simple ML algorithms using HE and INR besides syndromic presentation, could help treatment decisions and prognostication.

OS067

Differential changes in global and antigen-specific B cell frequencies and function associate with the outcome of HBV nucleos (t)ide analog treatment withdrawal

Sabela Lens[1,2], Alice Burton[1], Jessica Davies[1], Mireia García-López[2], Anna Jeffery-Smith[1], Nikolai Novikov[3], Simon Fletcher[3], Sofía Pérez-del-Pulgar[4], Xavier Forns[2], Mala Maini[1]. *[1]University College of London, Division of Infection and Immunity, United Kingdom; [2]Hospital Clinic, Liver Unit, Barcelona, Spain; [3]Gilead Sciences, United States; [4]Liver Unit, Hospital Clínic, University of Barcelona, IDIBAPS, CIBERehd, Barcelona, Spain*
Email: slens@clinic.cat

Background and aims: Despite HBsAg loss and the development of anti-HBs being the hallmark of natural resolution of HBV or achievement of 'functional cure', humoral immunity has not yet been examined in the setting of nucleos (t)ide analog (NA) discontinuation. We analysed HBcAg and HBsAg-specific frequencies and functional potential longitudinally in HBeAg-negative chronic Hepatitis B (CHB) patients stopping NA therapy to assess whether HBsAg loss ± off-treatment viral control associated with a recovery of the defective B cell response characteristic of CHB.
Method: Twenty-one HBeAg- CHB patients with complete viral suppression (>3 years) and without cirrhosis were studied prospectively. 16-colour flow cytometry was used to quantitate and phenotype circulating HBsAg- and HBcAg-specific B cells (dual fluorochrome-labelled antigen baits), global B cells, plasmablasts and Tfh at baseline, 12 and 48 weeks after stopping NA (W12 and W48). Cultured ELISPOTs were used to longitudinally evaluate antibody-secreting cells against HBsAg and HBcAg.
Results: After a median follow-up of 34 months (IQR 26–37), 16 (76%) patients remained off-therapy, with 5 (24% of the total cohort) losing HBsAg, whilst 5 (24%) required NA reintroduction. Frequencies of HBsAg and HBcAg-specific B cells were comparable between groups at baseline and did not correlate with levels of qHBsAg or HBcrAg respectively, but did show differential temporal dynamics according to clinical outcome. HBcAg-specific B cells increased at W12 in all groups in association with viral rebound, but decreased to baseline values by W48 only among those achieving HBsAg loss or being re-treated. By contrast, patients remaining off-therapy had a significant increase in HBsAg-specific B cells by W48 compared to re-treated patients. Compared to patients remaining HBsAg+ after NA discontinuation, B cells in patients with HBsAg loss were enriched for the

activated memory phenotype and had a marked expansion of plasmablasts by W48. In parallel, ELISPOT data showed an increase in SFU against HBsAg in the 3 patients with HBsAg loss and anti-HBs+ by W48, confirming the recovery of antibody-producing functionality.
Conclusion: Functional cure (HBsAg loss) and viral control following NA withdrawal associate with recovery of the low frequencies and poor functionality of HBV-specific B cells in CHB. These findings support larger studies to explore the use of B cells as biomarkers of clinical outcome and as targets for further immunotherapeutic boosting.

Enforced cytotoxic signature of HBV pol455-specific CD8+ T cells in chronic HBV infection

Kathrin Heim[1,2], Sagar Sagar[1], Maike Hofmann[1], Robert Thimme[1].
[1]*University Hospital Freiburg, Freiburg im Breisgau, Germany;*
[2]*University of Freiburg Faculty of Biology, Freiburg im Breisgau, Germany*
Email: robert.thimme@uniklinik-freiburg.de

Background and aims: T-cell exhaustion represents a distinct T-cell differentiation program associated with chronic viral infections. Several studies have shown that exhausted CD8+ T cells are heterogeneous. In chronic HBV infection, we and others observed major differences in the phenotype and function as well as in the degree of dysfunction of HBV-specific CD8+ T cells targeting different antigens. The aim of this study was to investigate the molecular heterogeneity of HBV-specific CD8+ T cells targeting different antigens.
Method: To determine the subset diversification of HBV-specific CD8 + T cells targeting different antigens, we performed high-throughput single-cell RNA sequencing using CEL-Seq2 technology. We obtained $HBVcore_{18}$- and $HBVpol_{455}$-specific CD8+ T cells from HBeAg negative chronically HBV-infected patients who endogenously control the viral infection as well as under NUC treatment. Phenotypic and functional analyses were performed after pMHCI tetramer-based enrichment and peptide-specific expansion.
Results: Cluster analysis of single-cell transcriptomes revealed a different subset diversification of $HBVcore_{18}$- versus $HBVpol_{455}$-specific CD8+ T cells. In particular, $HBVcore_{18}$-specific CD8+ T cells were mostly comprised of precursor/memory-like exhausted T-cell subsets. Within $HBVpol_{455}$-specific CD8+ T cells, we could identify a cluster of cells that highly expressed cytotoxic genes including *GNLY, GZMB* and *PRF1*. Moreover, the cytotoxic regulator *NKG7* was also elevated in this subset. Interestingly, we further observed that the cytotoxic subset is restricted to $HBVpol_{455}$-specific CD8+ T cells obtained from patients who endogenously control the viral infection indicating that the enforced cytotoxic signature may be linked to virological HBV control in these patients. The differential transcriptional profile of $HBVpol_{455}$-specific CD8+ T cells was further confirmed *ex vivo* after pMHCI tetramer-based enrichment. Indeed, at the protein level, we detected a terminal effector differentiation and higher cytotoxic effector capacity of $HBVpol_{455}$-specific CD8 T cells obtained from treatment-naïve patients in comparison to patients requiring antiviral therapy.
Conclusion: In sum, our data highlight an enforced cytotoxic signature in $HBVpol_{455}$-specific CD8+ T cells of treatment-naïve patients which may be related to virological control in these patients. This observation might have potential implications for the design of immunotherapeutic approaches in HBV cure.

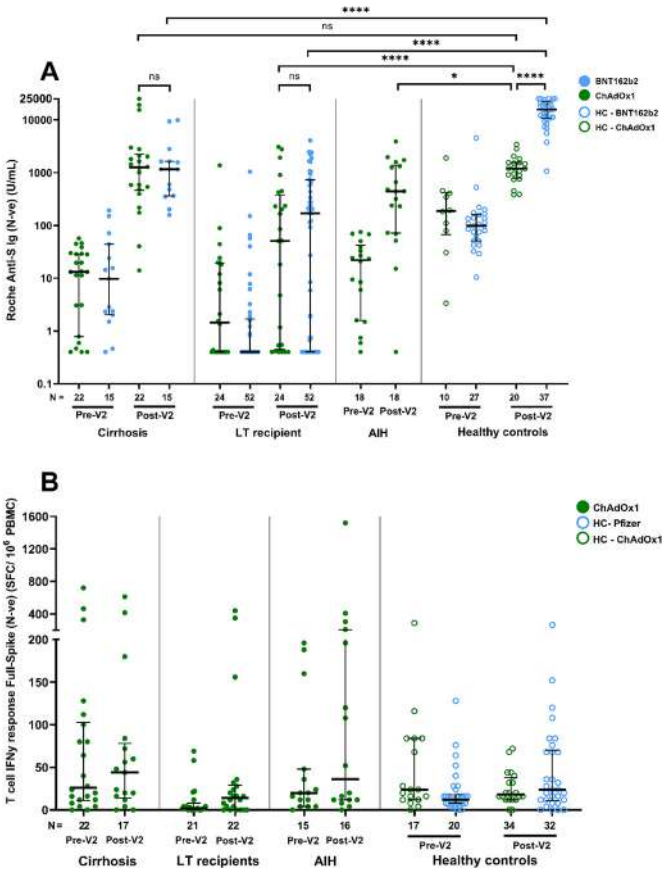
Background and aims: Emerging data have demonstrated suboptimal immune responses to SARS-CoV-2 vaccination in immunosuppressed cohorts. However, unified assessments comparing multiple vaccine platforms across the spectrum of liver disease are lacking. We aimed to investigate humoral and cellular immune responses in patients across Europe with cirrhosis, autoimmune hepatitis (AIH), liver transplantation (LT), and vascular liver disorders using coordinated sampling timepoints and laboratory assays.

Method: Serum and peripheral blood mononuclear cells were collected for 792 and 283 patients respectively by the EASL COVID-Hep network and UK OCTAVE study across 4 European countries. Data for 93 healthy controls (HC) were derived from the UK PITCH consortium. Samples were taken <1-week before second vaccination (V2), 28-days post V2, and at baseline where possible. As of 28/11/2021, anti-Spike (S) and nucleocapsid (N) Ig titres (Roche) and Spike specific T-cell responses (IFN-γ ELISpot) were available in 151 and 75 patients respectively, and all controls. Ongoing analysis using proliferation, intracellular cytokine stimulation, tetramer, and AIM assays will define cellular function.



Results: In HC, two doses of BNT162b2 induced a 10-fold increase in median anti-S Ig titre compared to two doses of ChAdOx1 (15634 vs 1198 U/ml; p < 0.0001) (Fig 1A). LT recipients had diminished median anti-S Ig titres compared to HC after two vaccine doses of either BNT162b2 (169 vs 15634 U/ml; p < 0.0001) or ChAdOx1 (51 vs 1198 U/ml; p < 0.0001). Compared to HC, patients with cirrhosis had reduced anti-S Ig titres when vaccinated with BNT162b2 (1155 vs 15634 U/ml; p < 0.0001) but comparable titres when vaccinated with ChAdOx1 (1259 vs 1198 U/ml; p = 0.97). There was no difference in response to ChAdOx1 according to Child-Pugh class. Data was available for AIH patients vaccinated with ChAdOx1 who had lower anti-S Ig titres compared to HC (443 vs 1198 U/ml; p = 0.0241). There were suboptimal antibody responses to a single vaccine dose across all disease groups relative to HC (Fig 1A). Seroconversion (anti-S Ig >0.8 U/ml) occurred in 100% of cirrhosis patients, 99.5% of AIH, but only 70% of LT recipients versus 100% of HC (p < 0.0001). Four LT recipients receiving BNT162b2 were positive for N-protein antibodies and had elevated anti-S Ig compared to those negative for N-protein antibodies (25 000 vs 170 U/ml; p < 0.0001). T-cell responses were heterogeneous across all cohorts (Fig 1B) however a higher proportion of LT recipients failed to generate an IFN-γ response after V2 compared to HC (32% vs 10%; p = 0.0369).

Conclusion: LT recipients had markedly reduced antibody and T-cell responses to SARS-CoV-2 vaccination. Responses to BNT162b2 were significantly reduced in patients with cirrhosis compared to healthy controls. Ongoing analysis across the rest of the cohort will define SARS-CoV-2 specific T- and B-cell function.

Background and aims: Despite being bathed in bacterial products, the liver maintains a state of tolerance, exploited by HBV and tumours. The cellular basis mediating immune tolerance, yet allowing a rapid switch to immunity, needs to be better defined to deliver successful immunotherapy for the treatment of chronic HBV infection.

Method: We analysed the phenotype and function of CD14-expressing CD8 T cells directly *ex vivo* from resected/explanted human liver and explored their derivation, functionality, expansion and LPS-responsiveness in multiple *in vitro* and *in vivo* models.

Results: CD8 T cells expressing CD14 (and other LPS receptor components) were found to be compartmentalised in human liver and to preferentially accumulate amongst donor lymphocytes surviving in liver allografts, within HCC-infiltrating lymphocytes, and in cirrhotic ascites. Moreover, HBV-specific CD8 T cells were significantly enriched for the expression of CD14 compared to the residual, global CD8 T cell pool. $CD14^{+}$CD8 T cells were highly activated and proliferative, with constitutive immunomodulatory features at rest (IL-10, IL-2 production) compared to CD14-CD8 T cells. They selectively expressed receptors (CXCR4/CD49a/CD49b) supporting retention with the stromal cell network to acquire CD14 from neighbouring macrophages. Human CD8 T cells acquire CD14, TLR4 and MD-2 from mononuclear phagocytes by actin cytoskeleton-dependent trogocytosis, promoted by E.coli, stromal cells and CXCL12. CD14 acquisition conferred the capacity to bind LPS and respond with a unique functional profile of chemotactic cytokines. Instead, upon TCR engagement, *ex vivo* and *in vitro*-derived $CD14^{+}$CD8 T cells were poised to mount rapid, potent anti-viral effector function (IFNg/TNF/MIPI1b). Importantly, CD14 acquisition by HBV-redirected CD8 T cells (HLA-A0201/HBs183-91) could be exploited to induce superior immunotherapeutic efficacy, with enhanced lysis of hepatoma cells expressing HBsAg (HepG2-PreS1-GFP).

Conclusion: A proportion of CD8 T cells compartmentalised in the liver express CD14/TLR4/MD2, recapitulated *in vitro* by trogocytosis from mononuclear phagocytes. CD14+CD8 T cells have enhanced TCR-directed effector function and can be induced to target HBV infection. Thus bacterial products in the gut-liver axis can therefore

fine tune organ-specific immunity by shaping stromal-interacting CD8 T cells with unique functionality.

OS071

A novel immunophenotyping of hepatocellular carcinoma based on amplified and mutated neoantigens for mRNA vaccine development

He Jing[1], Boqiang Liu[1], Liang Shi[1], Xiujun Cai[1]. [1]*Zhejiang University, China*
Email: srrsh_cxj@zju.edu.cn

Background and aims: Hepatocellular carcinoma (HCC) is the most common malignancy with poor prognosis. Genetic and phenotypic heterogeneity is a hallmark of HCC and also poses a daunting challenge for treatment. Recently, accumulating evidence suggests that immunotyping can indicate the comprehensive immune microenvironment, which is closely associated with therapeutic response and vaccination potential. In this study, we try to identify potent neoantigens in HCC for tumor immunotherapy, and further distinguish immune subtypes of HCC to construct an immune landscape for predicting the prognosis.
Method: Gene expression profiles, clinical information and simple nucleotide variation data of 328 HCC samples were obtained from TCGA. GEPIA was used to calculate differential expression levels, prognostic indices, and compare genetic alterations. TIMER was used to explore correlation between genes and immune infiltrating cells. Consensus cluster was used for consistency matrix construction and data clustering.
Results: Nineteen novel tumor neoantigens associated with poor prognosis and infiltration of antigen presenting cells were identified in HCC, including CDK1, CCNB1, CDC25C, PTTG1, CHEK1, KPNA2, MKI67, KIF2C, MCM3, EZH2, CDT1, PES1, PRC1, PPM1G, NEK2, TRIP13, TUBG1, AURKA, G6PD (Fig. A–C). Based on these neoantigens, we construct six immune subtypes (IS1-IS6, Fig. D). The immune subtypes showed distinct molecular, cellular and clinical characteristics. Patients with IS1 and IS3 tumors had a superior survival than those with the other subtypes (Fig. E). IS4 and IS6 tumors had immunosuppressive phenotype, and were also associated with higher tumor mutation burden and tumor stage (Fig. F–H). Furthermore, distinct expression of immune checkpoints and immunogenic cell death modulators was observed between different immune subtype tumors (Fig. I).
Conclusion: This study constructed a novel immunophenotyping of HCC for predicting the prognosis of patients. Meanwhile, CDK1, CCNB1, CDC25C, PTTG1, CHEK1, KPNA2, MKI67, KIF2C, MCM3, EZH2, CDT1, PES1, PRC1, PPM1G, NEK2, TRIP13, TUBG1, AURKA, G6PD are potent neoantigens for HCC-mRNA vaccine development, specifically for patients with IS4 and IS6 type.

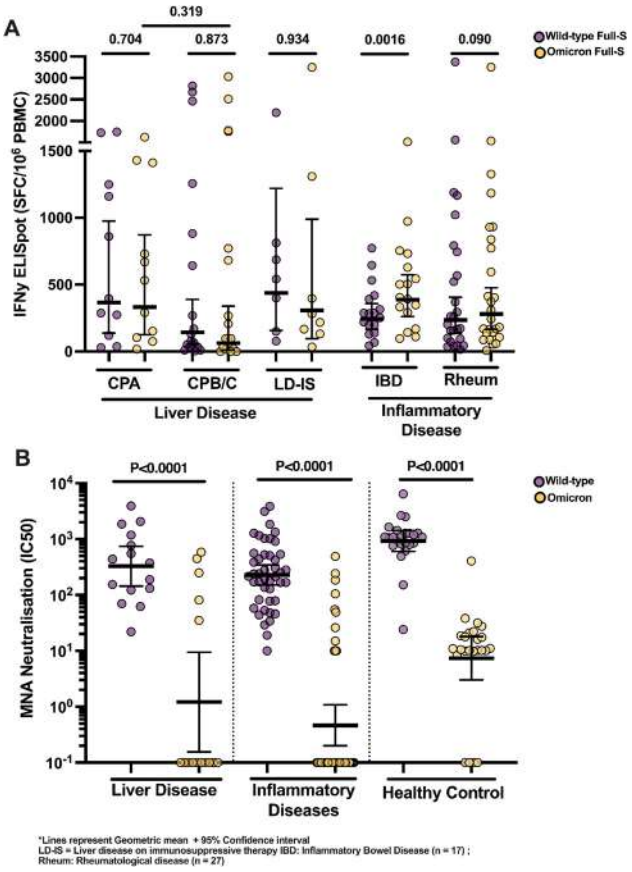
Email: ellie.barnes@ndm.ox.ac.uk

Background and aims: Whilst immunocompromised patients, including those with liver diseases, have diminished COVID-19 vaccination responses to the wild-type (WT/Victoria) SARS-CoV-2 strain, immunogenicity to the dominant omicron variant (B1.1.529, BA.1) remains unknown. We present combined data from the EASL COVID-Hep 2.0 registry, UK OCTAVE, OCTAVE DUO and PITCH studies reporting on T cell and serological responses to a range of SARS-CoV-2 variants, 28-days after either two-doses (V2) of ChAdOx1 nCoV-19 or mRNA (mRNA-1273/BNT162b2) vaccination.

Method: WT and omicron full-Spike (S) specific T cell responses were assessed by IFNγ ELISpot assay in 52 patients with liver disease including 16 on immunosuppressive therapy (2 liver transplant recipient and 14 autoimmune hepatitis), 18 Child-Pugh (CP) A cirrhosis, and 18 CP-B/C cirrhosis. For comparison, 44 immunosuppressed patients with other inflammatory conditions were also included. Paired serological assessments were performed in 59 patients and in samples taken 7-days post V2 in 25 healthy controls (PITCH Consortium, [HC]), representing an optimal serological response. Assessments included S antibody (Ab) binding and ACE2-RBD blockade assay to WT and 5 prominent SARS-CoV-2 variants (alpha, beta, gamma, delta, omicron), and live microneutralisation assay for WT and omicron variants.

Results: Full S T cell responses to omicron were well conserved compared to WT with no decrease in the magnitude of responses between omicron and WT in any disease group (Fig. 1A). Overall, there was marked heterogeneity in the magnitude of T cell responses to both WT and omicron (Fig. 1A). Most patients across the entire cohort had high-magnitude T cell responses to both WT and omicron, except patients with CP-B/C cirrhosis, who had the lowest geometric mean responses to both variants (Fig. 1A). In contrast to antigen-specific T cells, there were substantial differences in serological responses to WT compared to omicron variants. Neutralising Ab (nAb) titres to omicron were significantly reduced compared to WT in the combined liver disease, inflammatory disease cohorts and HC (Fig. 1B). Ab binding to S and percentage inhibition of RBD-binding to the ACE2 receptor was significantly decreased across all variants compared to WT in all disease groups and HC.



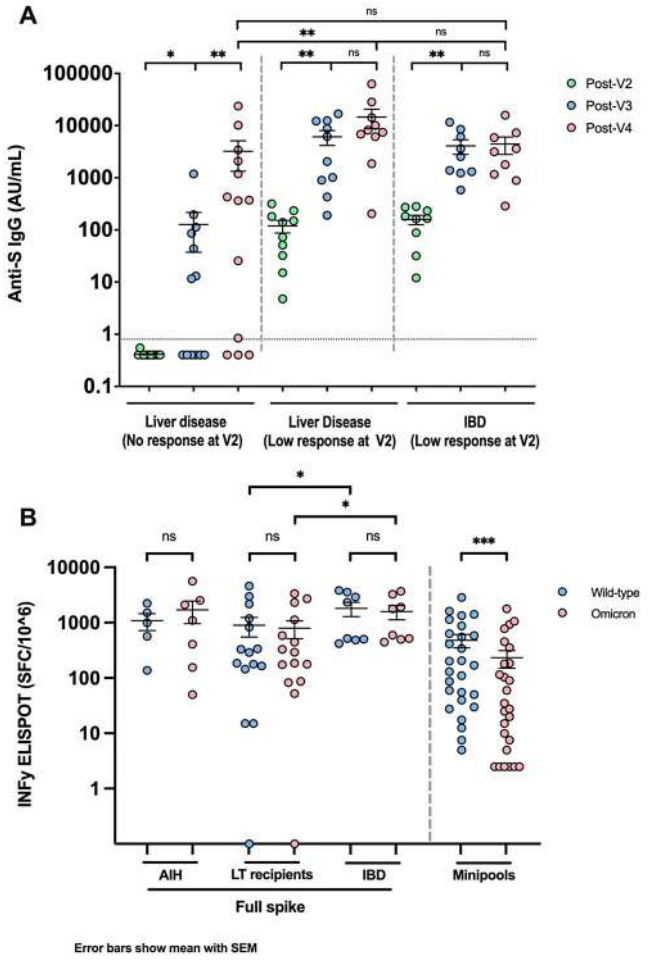
Conclusion: Omicron specific nAb IC50 after COVID-19 vaccination is significantly reduced compared to WT in patients with liver disease, inflammatory disease and in HC. This contrasts with antigen-specific T cell responses which were equivalent for omicron compared to WT. Detailed serological profiling suggests that Ab response to spike proteins of multiple prominent SARS-CoV-2 variants were severely impaired compared to WT. Ongoing analysis will decipher whether differences in vaccine-induced humoral and cellular responses to omicron persist after three doses of COVID-19 vaccination.

OS072B

Humoral and cellular immune responses to wild-type and omicron (B.1.1.529) SARS-CoV-2 variants following a fourth COVID-19 vaccination in liver transplant recipients and patients with autoimmune hepatitis

Stavros Dimitriadis[1], Georgina Meacham[1], Sophie Irwin[1], Victoria Walker[1], Sam Murray[2], Zixiang Lim[3], Thomas Marjot[1,4], Jack Satsangi[5], Eleanor Barnes[2]. *[1]University of Oxford, Nuffield Department of Medicine, United Kingdom; [2]Peter Medawar Building for Pathogen Research, Nuffield Department of Clinical Medicine, United Kingdom; [3]Oxford University Hospitals NHS Foundation Trust, Department of Gastroenterology, United Kingdom; [4]Oxford University Hospitals NHS Foundation Trust, Oxford Liver Unit, Oxford, United Kingdom; [5]University of Oxford, Translational Gastroenterology Unit, United Kingdom*
Email: ellie.barnes@ndm.ox.ac.uk

Background and aims: Waning SARS-CoV-2 specific antibody (Ab) responses and high infection rates has led to the widespread use of 3rd/4th vaccine doses (V3/V4) in vulnerable patients. However, the immune response to V4 in patients with suboptimal prior vaccine responses is unexplored. We recruited liver transplant recipients (LT) and autoimmune hepatitis patients (AIH) to assess the immune responses to V4, including to SARS-CoV-2 omicron (B.1.1.529) variant.
Method: Anti-spike (S) and anti-nucleocapsid (N) IgG titres were assessed (Roche assay) after V4 (24 Pfizer BNT162b2, 8 Moderna mRNA-1273) in 32 immunosuppressed patients, including 23 with liver disease (15 LT, 8 AIH) and 9 inflammatory bowel disease (IBD) patients. All patients had absent (13/32 (41%); 11 LT, 2 AIH) or low Ab responses (19/32 (59%); 4 LT, 6 AIH, 9 IBD) after 2 vaccines (V2) defined as anti-S IgG level <400 AU/ml. Anti-S and anti-N IgG titres performed after V2/V3. WT and omicron specific T cell responses were assessed by IFN-γ ELISpot assay in 30/32 patients using peptide pools covering whole-S and minipools of S-specific mutated peptides.
Results: There were significant increases in anti-S IgG titres following V3 in all groups, stratified by those with absent and low anti-S Abs post V2 (Fig. 1A). All patients with a low post V2 response had a significant increase in anti-S Ab responses after V3 that was sustained (but not further enhanced) after V4. In liver patients with no anti-S Ab responses after V2, 7/13 (54%) developed anti-S Abs after V3 (0.41 AU/ml vs. 126.72 AU/ml; p = 0.016), and importantly these responses were further significantly enhanced following V4 (126.72 AU/ml vs. 3212.90 AU/ml; p = 0.002). However, 3/13 (23%) with absent anti-S Abs after V2 remained nonresponsive after V3 and V4. T cell responses to full-S WT and omicron peptides were heterogenous, but generally of high magnitude and detectable in 29/30 patients (Fig. 1B). There was a loss against Omicron (51.8%) when T cell responses were assessed using the variant mini pools (Fig. 1B). LT had significantly reduced response compared to IBD against omicron (mean 796.3 SFC/10^6 vs. 1589 SFC/10^6; p = 0.0294) and WT (mean 897.6 SFC/10^6 vs. 1817 SFC/10^6; p = 0.0274) (Fig. 1B). Importantly, the 3 seronegative patients after V4, mounted a robust T cell response to WT (mean 882.5 SFC/10^6) and omicron (mean 2280 SFC/10^6). There was no correlation between humoral and cellular responses (R^2 = 0.01).
Conclusion: In liver and IBD patients, low anti-S Ab responses after 2 COVID19 vaccines may be enhanced by V3 and sustained by V4. Patients with absent anti-S Ab responses after 2 doses may have a significant increase in anti-S Ab titres after both V3 and V4. However, a small subset remain non-responsive and should be prioritised for prophylactic strategies. Importantly, immunosuppressed liver patients develop robust T cell responses to WT and omicron independent of anti-S Ab titres.



Rare liver diseases (including paediatric and genetic)

OS073

In vivo CRISPR/Cas9 editing of the TTR gene with NTLA-2001 in patients with transthyretin amyloidosis- dose selection considerations

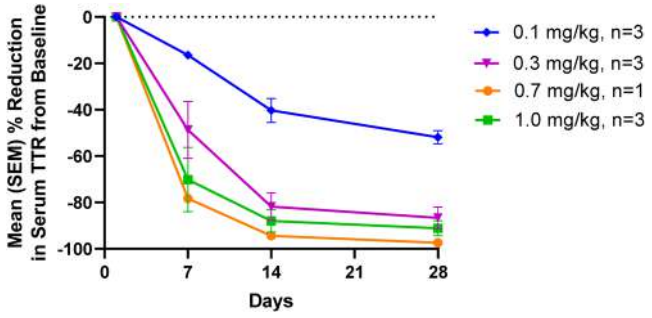
Edward J. Gane[1], Jörg Täubel[2], Björn Pilebro[3], Marianna Fontana[4], Justin Kao[5], Michael Maitland[6], Mark Stroh[6], Jessica Seitzer[6], Jonathan Phillips[6], Kristy Wood[6], Yuanxin Xu[6], Carri Boiselle[6], Adam Amaral[6], Adam Boyd[6], Jeffrey Cehelsky[6], David Gustein[7], Odelya Pagovich[7], Laura Sepp-Lorenzino[6], Liron Walsh[6], David Lebwohl[6], Gillmore Julian[8]. *[1]The University of Auckland, New Zealand Liver Transplant Unit, Auckland, New Zealand; [2]Richmond Pharmacology Limited, London, United Kingdom; [3]Umeå University, Department of Public Health and Clinical Medicine, Sweden; [4]University College London, National Amyloidosis Centre, Division of Medicine, United Kingdom; [5]Auckland City Hospital, Department of Neurology, New Zealand; [6]Intellia Therapeutics, Inc., Cambridge, United States; [7]Regeneron Pharmaceuticals, Inc., Tarrytown, United States; [8]University College London, United Kingdom*
Email: edgane@adhb.govt.nz

Background and aims: The liver produces the toxic precursor protein transthyretin (TTR) in ATTR amyloidosis, a fatal disease of misfolded protein accumulation. Until recently, the only therapeutic

intervention for variant ATTR amyloidosis (ATTRv) was liver transplantation. Gene-silencing agents targeting TTR mRNA prevent disease progression but require lifelong administration. In contrast, gene editing is designed as a single-dose treatment. NTLA-2001 comprises a lipid nanoparticle (LNP) encapsulating mRNA for SpCas9 protein and single guide RNA targeting the transthyretin (*TTR*) gene. After infusion, LNP uptake into hepatocytes results in precise *TTR* knockout regardless of disease-causing mutation. This is the first report of the dose, exposure and pharmacodynamic (PD) response relationship in humans for systemically administered liver-directed gene-editing therapy.

Method: The first-in-human phase 1 trial (NCT04601051) enrolls adults with confirmed ATTRv amyloidosis and peripheral neuropathy. Safety, pharmacokinetics (PK), and PD of NTLA-2001 are assessed in 3 + 3 dose escalation, with a subsequent expansion cohort. Circulating serum TTR was measured in samples collected at baseline, Days 7, 14, and 28, and every 2 months thereafter. Dose selection for the expansion cohort is based on review of safety, PK and PD in the escalation phase.

Results: As of this submission, 14 subjects received NTLA-2001 as single-ascending doses [3 subjects each at 0.1, 0.3, and 0.7 mg/kg, and 5 subjects at 1 mg/kg]. Mild and transient infusion reactions were the most common adverse event with NTLA-2001. Interim pharmacokinetic data suggest that following intravenous (IV) infusion NTLA-2001 ionizable lipid exhibited a rapid decline from peak levels followed by a secondary peak and then a log-linear phase. Serum TTR levels were significantly reduced from baseline in a dose-dependent manner; patients receiving 0.3 mg/kg achieved durable reductions with mean Day 28 TTR reduction of 87% (n = 3) and greater reductions at higher doses (Figure 1, interim data to Day 28 from 10 subjects as of September 13, 2021). Additional data will be available for presentation.



Conclusion: A single IV infusion of the gene editing therapeutic NTLA-2001 resulted in dose-dependent reductions in serum TTR protein with predominately mild adverse events reported. NTLA-2001 represents a potential paradigm shift in the treatment of ATTR amyloidosis.

Email: martaalonsop@gmail.com

Background and aims: A variant (p.Arg225Trp) in peroxisomal acyl-CoA oxidase 2 (ACOX2), involved in bile acid (BA) side-chain shortening, has recently been associated with persistent unexplained hypertransaminasemia and accumulation of C27-BAs, mainly trihydroxycholestanoic acid (THCA). Our aim was to investigate the prevalence of ACOX2 deficiency-induced liver fragility (ADILF) among patients with hypertransaminasemia of unknown origin and their response to ursodeoxycholic acid (UDCA), to identify other inborn errors that could cause this alteration and to elucidate its pathophysiological mechanisms.

Method: Serum BA profile was determined by HPLC-MS/MS. Genetic analysis of ACOX2 was performed by exon sequencing. In HuH-7 cells exposed to THCA, viability was determined by MTT, reactive oxygen species (ROS) production by flow cytometry and endoplasmic reticulum (ER) stress by analyzing GRP78 and CHOP levels (RT-qPCR and Western Blot), and XBP1-S/XBP1-U ratio (RT-qPCR). The 1000-Genomes database and SIFT and Polyphen scores were used to select ACOX2 variants that were expressed in HuH-7 cells to determine by HPLC-MS/MS its ability to metabolize THCA.

Results: Among 33 patients with suspected ADILF from 11 hospitals and 13 relatives, 7 individuals with abnormally high C27-BA levels (>50% of total BAs) were identified. The p.Arg225Trp variant was found in homozygosity in 2 patients and 3 relatives. Moreover, other 2 non-related patients were heterozygous carriers of different alleles, for c.673C>T (p.Arg225Trp) and c.456_459del (p.Thr154fs). Impaired expression of ACOX2, but not ACOX3 in the liver of these patients was found (immunohistochemistry). Treatment with UDCA normalized

transaminases levels. Culture of HuH-7 liver cells with THCA increased ROS production and the ER stress biomarkers GRP78, CHOP and XBP1-S/XBP1-U ratio, whereas decreased cell viability. THCA-induced toxicity was higher than that of major BAs. Among 14 in silico selected genetic variants, in vitro functional tests identified 6 ACOX2 variants as a potential cause of ADILF.
Conclusion: Dysfunctional ACOX2 is found in a substantial proportion of patients with unexplained hypertransaminasemia, suggesting that this disorder of BA metabolism causes enhanced liver fragility, which can be attenuated by UDCA treatment.

OS075

Efficacy and safety of givosiran in patients with acute hepatic porphyria: 36-month results of the phase 3 ENVISION randomised clinical trial

Manish Thapar[1], Herbert L. Bonkovsky[2], Susana Monroy[3], Gayle Ross[4], Encarna Guillén-Navarro[5,6], Maria Domenica Cappellini[7], Anna-Elisabeth Minder[8], Shangbin Liu[9], Marianne T. Sweetser[9], David Kuter[10]. [1]*Thomas Jefferson University, Philadelphia, United States;* [2]*Wake Forest University/North Carolina Baptist Medical Center, Winston-Salem, United States;* [3]*Instituto Nacional de Pediatría, Mexico City, Mexico;* [4]*Royal Melbourne Hospital, Melbourne, Victoria, Australia;* [5]*Medical Genetics Section, Virgen de la Arrixaca University Hospital, IMIB-Arrixaca, Universidad de Murcia, Murcia, Spain;* [6]*CIBERER-ISCIII, Madrid, Spain;* [7]*University of Milan, Milan, Italy;* [8]*Division of Endocrinology, Diabetes and Porphyria, Stadtspital Zürich, Zürich, Switzerland;* [9]*Alnylam Pharmaceuticals, Cambridge, United States;* [10]*Massachusetts General Hospital, Boston, United States*
Email: manish.thapar@jefferson.edu

Background and aims: Acute hepatic porphyrias (AHPs) are caused by defects in hepatic heme biosynthesis leading to accumulation of neurotoxic heme intermediates 5-aminolevulinic acid (ALA) and porphobilinogen (PBG). AHP is characterized by acute disabling and sometimes life-threatening neurovisceral attacks that can become recurrent in some patients. Givosiran treatment in the open-label extension (OLE) period of the ENVISION study (NCT03338816) led to sustained clinical benefit, with >75% of patients attack-free at 21–24 months (M). Data from the 36M analysis are reported here.

Figure. Urinary ALA and PBG Levels

A, Median ALA levels over time. B, Median PBG levels over time. OLE data for 1.25 mg/kg and 2.5 mg/kg are pooled. Reference ranges: ALA (ULN, 1.47 mmol/mol Cr), PBG (ULN, 0.14 mmol/mol Cr).
ALA, delta-aminolevulinic acid; Cr, creatinine; DB, double-blind; OLE, open-label extension; PBG, porphobilinogen; ULN, upper limit of normal.

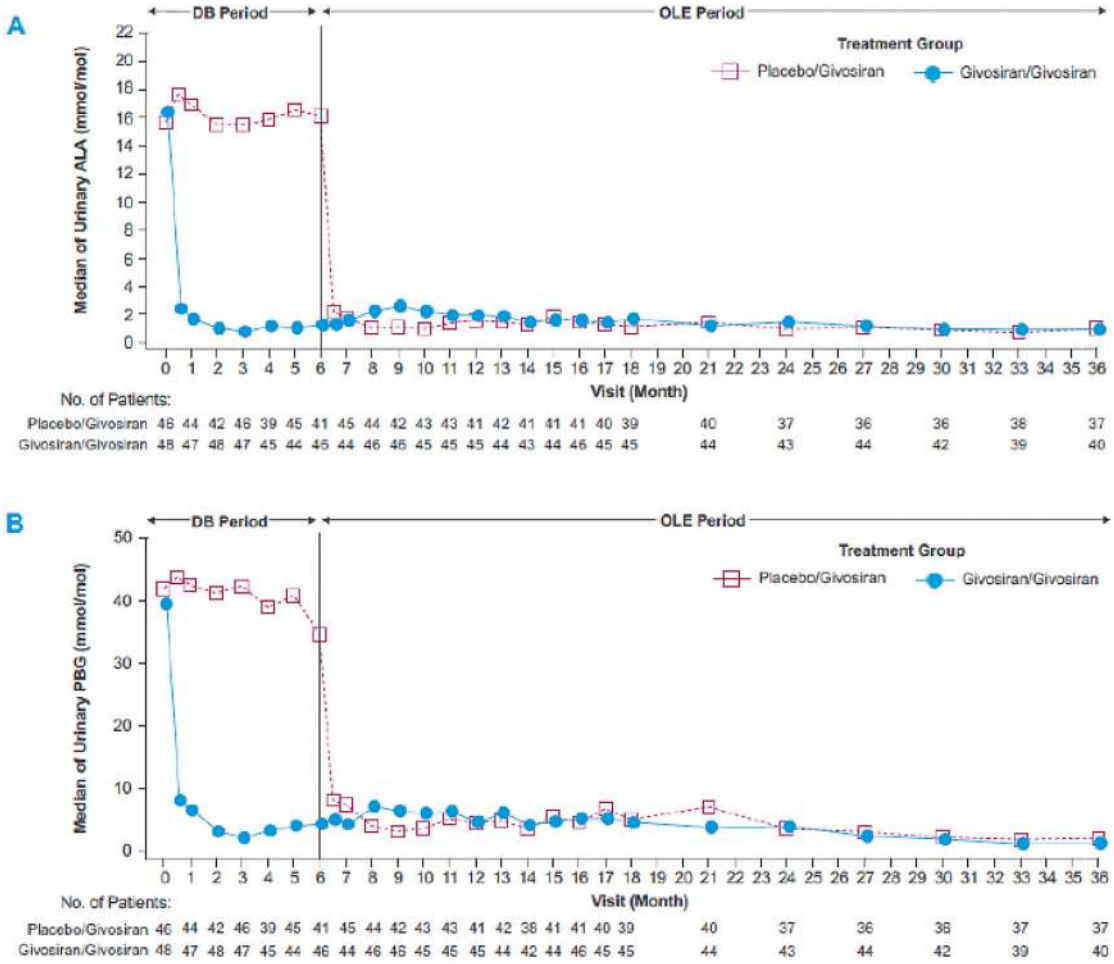

Figure: (abstract: OS075)

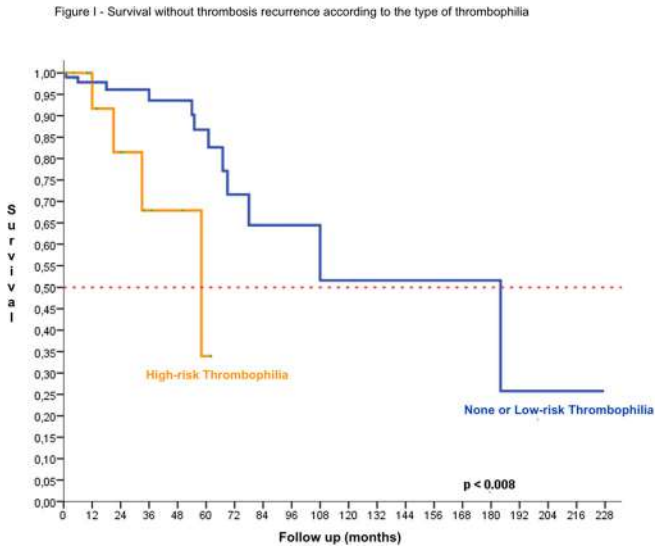
Method: ENVISION is a phase 3, randomised, placebo-controlled trial in patients ≥12 years old with AHP who had experienced ≥2 attacks requiring hospitalization, urgent care, or intravenous hemin at home in the past 6M, with a 6M double-blind (DB) period followed by a 30M OLE period.
Results: Of 94 patients enrolled, 93 patients entered the OLE period. Givosiran treatment led to sustained lowering of median urinary ALA to near-normal levels and to lowering of PBG levels by >90% in the continuous givosiran and placebo crossover groups at 36M. Continued givosiran treatment also led to a sustained reduction in attacks and hemin use in both groups. The proportion of patients with 0 attacks per 3 M interval improved over the OLE period, with 86% of patients in the continuous givosiran group and 92% of patients in the placebo crossover group attack-free at 33–36 M. Similarly, the proportion of patients with 0 days of hemin use improved over the OLE period, with no days of hemin use in 88% of patients in the continuous givosiran group and 90% of patients in the placebo crossover group at 33–36 M. Exploratory measures showed further improvements in quality of life and activities of daily living during the OLE versus the DB period (Short Form 12-Item Health Survey, EuroQol visual analogue scale, and Porphyria Patient Experience Questionnaire). Most common treatment-related adverse events (AEs) (>10%) were injection-site reactions (ISRs), nausea, and fatigue. Six patients discontinued study drug due to AEs; 4 of these patients discontinued due to treatment-related AEs.
Conclusion: Long-term givosiran treatment provides sustained benefit to patients with AHP, maintaining reduced frequency of attacks and hemin use and further improving physical functioning and quality of life. Most common treatment-related AEs were ISRs, nausea, and fatigue.

OS076

High-risk Thrombophilia predict early thrombosis recurrence in acute non-cirrhotic portal vein thrombosis related to local factors: LOCAPORT

Louise Lebedel[1], Aurélie Plessier[2], Odile Goria[3], Christophe Bureau[4], Alexandra Heurgue-Berlot[5], Pierre-Emmanuel Rautou[2], Audrey Payance[2], Kamal Zekrini[2], Thi Thu Nga Nguyen[1], Thong Dao[1], Rémi Morello[1], Isabelle Ollivier-Hourmand[1]. *[1]University of Caen Normandie Hospital Center, Caen, France; [2]Beaujon Hospital, Clichy, France; [3]Hospital Center University De Rouen, Rouen, France; [4]Hospital Center University De Toulouse, Toulouse, France; [5]CHU Reims, Department of Hepato-Gastroenterology, Reims, France*
Email: louise.lebedel@gmail.com

Background and aims: A local factor is identified in 21% of acute non-cirrhotic portal vein thrombosis (PVT). We aim to determine the risk of thrombosis recurrence in this situation, and risk factors associated with recurrence.
Method: This is a retrospective multicenter study from the French Vascular Liver Diseases cohort between 1992 and 2021. We included acute non-cirrhotic portal vein thrombosis (right or left branch or portal vein extending or not to mesenteric and splenic veins), with at least one local factor (infectious, inflammatory, traumatic, surgical or neoplasic) identified, either concomitantly or in the last 3 months. We screened for prothrombotic factors such as 1st degree unprovoked personal or family history of deep vein thrombosis, High-risk Thrombophilia (myeloproliferative neoplasm, homozygous or composite heterozygous mutation of factor V Leiden and G20210 prothrombin gene, antiphospholipid syndrome, familial antithrombin deficiency), Low-risk Thrombophilia (heterozygous factor V Leiden or prothrombin gene G20210 mutation, hyperhomocysteinemia, protein C or S deficiency, homozygous MTHFR mutation), ongoing oestroprogestative or pregnancy up to 6 weeks post-partum, paroxysmal nocturnal haemoglobinuria and Behçet's disease.



Results: A thrombophilia was identified in 34/118 (29%) patients, of which 18/118 (15%) were a High-risk Thrombophilia. Thrombosis recurrence incidence rate was 2.94, 95CI = [0.00–6.22] per 100 patient-years (PY) at one year and 4.75, 95CI = [2.46–7.04] per 100 PY after a median follow-up of 19.5 months. The prevalence of thrombophilia did not differ significantly between groups with or without thrombosis recurrence (p = 0.775). However, presence of at least a High-risk Thrombophilia was significantly associated with thrombosis recurrence (RR = 4.2, 95CI = [1.18–14.91], p = 0.026) (Figure 1). Absence of portal recanalisation was significantly associated with thrombosis recurrence as compared to partial recanalisation (66.7% vs 32.4%, p = 0.019). Anticoagulation duration did not appear to be significantly associated with the risk of thrombosis recurrence. However, 91/115 (79%) received long-term anticoagulation (>6 months) while short-term anticoagulation (≤6 months) was administered in 24/115 (21%) patients. Thrombosis incidence rate was 5.48, 95CI = [0.00–11.50] per 100 PY in short term anticoagulation group as compared to 4.83, 95CI = [2.16–7.50] per 100 PY in long term anticoagulation group (p = 0.47).
Conclusion: In acute non-cirrhotic PVT secondary to local factors, a High-risk Thrombophilia is frequently identified, and increase the risk of thrombosis recurrence. The high number of patients treated by long term anticoagulation in our cohort, does not allow us to draw any conclusion about the potential protective role of anticoagulant.

OS077

Clinical utility of non-ceruloplasmin copper determined by copper speciation for monitoring Wilson disease therapy: comparative data analysis with 24-hour urinary copper excretion from the CHELATE trial

Michael Schilsky[1], Aurelia Poujois[2], Massimo Giovanni Zuin[3], Peter Ott[4], Karl Heinz Weiss[5], David Cassiman[6], Aftab Ala[7], Anna Czlonkowska[8], Nicolas Dubois[9], Naseem Amin[10], C. Omar Kamlin[11]. *[1]Yale University, Departments of Medicine and Surgery, Divisions of Digestive Diseases and Transplant and Immunology, Conneticut, United States; [2]Fondation Hopital Rothschild, Paris, France; [3]University of Milan, Milan, Italy; [4]Aarhus University Hospital, Denmark; [5]Salem Medical Center, Heidelberg, Germany; [6]University of Leuven, Belgium; [7]Kings College University Hospital, Institute of Liver Studies, London, United Kingdom; [8]Institute of Psychiatry and Neurology, Warsaw, Poland; [9]International Drug Development Institute (IDDI), Belgium; [10]Orphalan SA France, Paris, France; [11]Orphalan SA France, France*
Email: omarkamlin@doctors.org.uk

Background and aims: Monitoring efficacy of therapy in Wilson disease (WD) is challenging; 24-hour urinary copper excretion (24 hr

UCE) is cumbersome, and results show large intra-subject variability. A new non-ceruloplasmin copper assay using liquid chromatography and ICP mass spectroscopy (NCC-Sp) was developed for the CHELATE Trial [trientine tetrahydrochloride (TETA4) vs. d-Penicillamine (DPA)]. We aim to describe the intra-patient variability and compare the clinical utility of UCE and NCC-Sp in monitoring WD therapy.

Method: A multicentre, open label, non-inferiority randomised controlled trial was conducted in which 53 stable adult WD subjects were randomly allocated after a 12-week baseline observation period to either DPA or TETA4 for 24 w with a primary end point (NCC-Sp). An independent adjudication committee blinded to site and treatment allocation assessed clinical stability at randomisation and end of study. Paired samples for NCC-Sp and 24 hr UCE were compared pre- and 24w post-randomisation. Validation studies for NCC-Sp included 50 healthy adults, identifying a range (2.5% to 97.5%) of 40–150 mcg/L. This was used as reference target range for the study population and compared to UCE (recommended therapeutic range of 200–500 mcg/24 hr). Intra-patient (SD) variability was computed for NCC-Sp and UCE measurements during baseline and post-randomisation periods.

Results: The independent adjudication committee unanimously assessed all subjects as clinically stable at randomisation and study end point. NCC-Sp was in the reference range at randomization versus study end in 86% vs. 84% of subjects respectively, while UCE was in the recommended therapeutic range in only 41% vs. 37% respectively (Table). Agreement when both NCC-Sp and UCE were in range at randomization/study end was 17/49 (35%) and 17/51 (33%) respectively. Mean (SD) NCC-Sp and UCE intra-patient variability during baseline (all receiving DPA) was 15.5 (7.8) mcg/L and 196 (125) mcg/24hr respectively. Mean (SD) NCC-Sp intra-patient variability for DPA and TETA4 post randomisation was 17.9 (11.6) and 14.9 (12.1) mcg/L respectively ($p < 0.0001$). Mean (SD) UCE intra-patient variability for DPA and TETA4 post randomisation was 148.9 (127) and 107 (101) mcg/24 hr respectively ($p = 0.74$).

Conclusion: UCE is a test with significant intra-patient variability for WD patients on chelation therapy with either DPA or TETA4. That NCC-Sp had less intra-patient variability than UCE suggests NCC-Sp is a more reliable biomarker for monitoring chelation therapy in WD.

Table: Comparative analysis of "in range" data for NCC-Sp and UCE at randomization and study end point.

	At Randomisation			Primary End point (wk 24 post randomisation)		
	UCE in range**	UCE not in range**	Total	UCE in range**	UCE not in range**	Total
NCC-Sp in range	17	25	42	17	26	43
NCC-Sp not in range	3	4	7	2	6	8

*range for NCC-Sp = 40–150 mcg/L; **range for UCE = 200–500 mcg/24 hr.

OS078

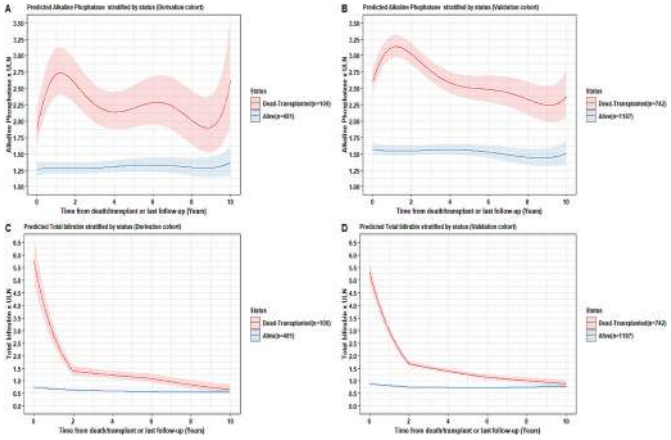
North American evaluation of 2519 patients with primary sclerosing cholangitis: longitudinal patterns of disease activity identify and validate stable and progressive phenotypes

Marwa Ismail[1], John Eaton[2], Aliya Gulamhusein[1], Morven Cunningham[3], Christina Plagiannakos[3], Bettina Hansen[1], Gideon Hirschfield[1]. [1]*Institute of Health Policy Management and Evaluation, Health Services Research, Toronto, Canada;* [2]*Mayo Clinic, Rochester, United States;* [3]*UHN, Toronto Centre for Liver Disease, Toronto, Canada*
Email: marwa.ismail@uhn.ca

Background and aims: Markers of outcome in patients with primary sclerosing cholangitis fluctuate, reducing utility at single time points. Longitudinal assessment offers an opportunity to improve surrogate marker utility.

Method: Using retrospectively collected data on 2519 North American patients diagnosed as per AASLD criteria with PSC, a derivation (Toronto: Jan. 2000 to Dec. 2020) and validation cohort (Mayo: Apr. 1978 to Dec. 2017) were evaluated to define progressive and stable disease states (PDS/SDS). Progressive disease was defined as death or transplant. Linear mixed-effects regression with random intercept and random slope was used to study biochemical and transient elastography (fibroscan) trajectories longitudinally over time. Piecewise linear splines and polynomial terms were employed. Time was calculated backwards from death, transplant, or last follow-up (time zero).

Results: Across combined cohorts median follow-up (IQR) was 8.3 (3.6–15) yrs, 63% were male, and mean age at diagnosis 39.5 (SD:16.1) yrs. 88.3% had large duct disease and 78% had IBD at last follow-up. Throughout the 10 yrs prior to death or transplant, patients with PDS in the derivation cohort had estimated ALP means ranging from 1.87–2.64 the upper limit of normal (ULN) with major fluctuations ($p < 0.01$); patients with SDS had lower and stable ALP courses (ALP 1.27–1.37 × ULN). A similar pattern existed for the validation cohort, where patients with progressive disease had ALP 2.25–3.12 × ULN, while patients with stable disease had ALP around 1.44–1.57 × ULN ($p < 0.0001$). The derivation cohort experienced bilirubin (TB) elevation 6 yrs before experiencing death or transplant; similarly for the validation cohort bilirubin elevation was 8 yrs before event. Patients with SDS maintained normal bilirubin values. Both cohorts experienced increases in the 2 yrs prior to death or transplant to reach an estimated mean TB of ~5 × ULN ($p < 0.0001$). ALB and PLT estimated means were lower for patients with progressive disease than those with stable disease in both cohorts; estimated AST and ALT means were notably higher for patients with PDS vs those with SDS (derivation cohort: AST: 1.64–3.34 × ULN vs 1.21–1.28 × ULN; ALT: 2–2.83 × ULN vs 1.56–1.7 × ULN; validation cohort AST: 1.66–2.88 × ULN vs 1.09–1.32 × ULN; ALT 1.65–2.06 × ULN vs 1.15–1.56 × ULN) in both derivation and validation cohorts. In the Toronto derivation cohort patients with PDS had progressively increasing estimated transient elastography measurements from 10.8–31.3 kPa between yr 6 and time of death or transplant. Patients with SDS had transient elastography measurements over 6 yrs of study ranging from 7.7–9 kPa.



Conclusion: We evaluate progressive and stable disease phenotypes in >2500 PSC patients. A stable disease course was validated for patients with sustained ALp <1.5 × ULN, as well as those with longitudinal transient elastography values <10 kPa.

Nurses and AHP

OS079

Nurse-led inpatient fibrosis assessment for patients with suspected alcohol related liver disease and previous poor engagement with services

Rebecca Fennell[1], Dianne Backhouse[1], George Abouda[1], Lynsey Corless[1]. [1]*Hull University Teaching Hospitals NHS Trust, Kingston upon Hull, United Kingdom*
Email: lynsey.corless@nhs.net

Background and aims: Identification and staging of fibrosis is a critical part of assessment for people with alcohol related liver disease. For those presenting acutely in hospital, staging tests are frequently deferred until out-patient review. However, engagement with elective services is often poor in those with ongoing alcohol use, leaving investigation incomplete and the need for hepatology follow-up uncertain. To mitigate this, we instituted an in-patient fibrosis assessment service within our Alcohol Care Team (ACT) and evaluated the results.

Method: From February 2020-October 2021, we sought out acutely admitted patients who had been identified as drinking excessively (more than the United Kingdom guidance of 14 units/week) and who had previously not engaged with the ACT for staging of suspected liver disease. All patients were staged by Fibroscan (Echosens). Enhanced Liver Fibrosis (ELF) test was additionally performed when it became available at our facility. Implementation of the pilot was delayed and disrupted due to the impact of Covid-19 on service delivery, with most patients identified from March 2021 onwards.

Results: 70 patients were identified-45 (64%) male, 25 (36%) female, with median age 53 years (range 25–80 yr). Fibroscan results ranged from 3.4 kPa–75 kPa. 40 (57%) were normal (<7.0 kPa), 13 (19%) F1–F3 (7.1 kPa–18.5 kPa) and 17 (24%) F4 (>18.5 kPa). ELF was performed in 32 (46%) patients; 19 (59%) showed severe fibrosis (score 9.8–14.3) and 13 (41%) moderate fibrosis (score 7.9–9.6). ELF and Fibroscan were well matched for identification of cirrhosis, with cirrhotic range Fibroscan results only found in those with severe fibrosis on ELF, suggesting either test could be used to rule out cirrhosis in this group. Following Fibroscan assessment, annual ACT follow-up was arranged for all patients in F1–F3 range, and the 25 patients with a normal Fibroscan who continued to drink excessively. Patients with any results in the cirrhotic range were referred to hepatology for ongoing management.

Conclusion: By performing fibrosis assessment during an inpatient stay, we were able to exclude significant liver disease in many people we had previously been unable to stage, providing important information to the patient and avoiding unnecessary hepatology follow-up. Provision of in-patient non-invasive fibrosis assessment may therefore be a valuable addition to hospital ACT services for capturing patients who poorly engage.

OS080

Natural history of hepatic steatosis associated to metabolic syndrome. Longitudinal study with 5 years of follow-up.

Marta Cervera[1,2,3,4], Marta Carol[1,2,3,4], Ana Belén Rubio[1,2,3], Martina Perez[1,2,3,4], Carlota Riba[1,2,3], Rosario Hernández[5], Ann Ma[1,2,3], Emma Avitabile[1,2,3], Anna Soria[1,2,3], Octavi Bassegoda[1,2,3], Sara Martinez[1,2,3], Jordi Gratacós-Gines[1,2,3], Adria Juanola[1,2,3], Laura Napoleone[1,2,3], Elisa Pose[1,2,3], Isabel Graupera[1,2,3], Pere Ginès[1,2,3], Núria Fabrellas[1,2,3,4]. [1]*Hospital Clinic de Barcelona, Liver Unit, Barcelona, Spain;* [2]*Institut d'Investigacions Biomèdiques August Pi i Sunyer (IDIBAPS) CIF: G59319681, Barcelona, Spain;* [3]*Centro de Investigación Biomédica en Red de Enfermedades Hepáticas y Digestivas (CIBEReHD), Madrid, Spain;* [4]*University of Barcelona, School of Medicine and Health Sciences, Barcelona, Spain;* [5]*Institut Catalá de la Salut (ICS), Centre d'Assistència Primària La Marina, Barcelona, Spain*
Email: mcerverac@clinic.cat

Background and aims: Non-alcoholic fatty liver disease (NAFLD) has a wide range of clinical severity from fatty liver to cirrhosis. Most cases of fatty liver are diagnosed in the community setting. There is lack of information on the evolution of fatty liver in subjects diagnosed in primary care. The objective of this study was to perform a longitudinal analysis of hepatic steatosis, as estimated by controlled attenuation parameter (CAP), in a cohort of patients with fatty liver associated with metabolic syndrome.

Method: Patients with fatty liver with moderate-to-severe steatosis (CAP >280 dB/m) without significant fibrosis (liver stiffness measurement-LSM-<8 kPa) previously included in a population-based cohort randomly selected from primary care (Plos One 2018 PMD 30226889) were again assessed after a median of 5 years of follow-up. Demographic, clinical, and laboratory data, as well as CAP and LSM were assessed at two time points, baseline and 5 years later. Nurse education and counseling about NAFLD was provided at time of first assessment. Improvement of hepatic steatosis was defined as decrease in CAp >10% compared to baseline. Remaining cases were considered as persistent or worsening (CAP increase of >10%).

Results: Seventy-one patients were included (60 ± 11 years; 49% female; BMI 29.9 ± 4.8; 22.5% with diabetes). Baseline CAP and LSM values were 315 ± 32 dB/m and 4.9 ± 1.4 kPa. Twenty-six of the 71 (37%) patients showed improvement in hepatic steatosis (CAP 320 to 231 dB/min; $p < 0.001$). In 15 of these patients CAP decreased to <240 dB/m, the threshold generally used to define presence of liver fat. Improvement of steatosis was associated with significant decrease in ALT and GGT levels. The remaining 45 patients, showed persistent or worsening of hepatic steatosis (32 and 13 patients, respectively). LSM increased >8 kPa in 3 patients from the latter group (8.1, 11.6 and 12.2) and none from the former. Patients with improvement of hepatic steatosis had significantly lower BMI and ALT at baseline compared to values in patients with persistent/worsening of hepatic steatosis.

Conclusion: In this population-based cohort of patients with fatty liver from primary care, a significant proportion of subjects (37%) show mobilization of liver fat during a 5-yr follow-up period with no intervention other than nurse education and counseling. The remaining two thirds of subjects show persistence/worsening of hepatic steatosis. Reduction of liver fat is associated with improvement in ALT and GGT levels.

OS081

The effort for HCV elimination- dedicated nurse based protocol, single center experience

Assaf Issachar[1,2], Evelin Oxtrud[1], Yael Harif[1], Orly Sneh Arbib[1,2], Amir Shlomai[1,2], Ran Tur-Kaspa[1,2], Marius Brown[1,2], Michal Cohen-Naftaly[1,2]. [1]*Rabin Medical Center, Beilinson Hospital, Liver Institute, Petah Tikva, Israel;* [2]*Tel Aviv University, Sakler Medical School, Tel Aviv, Israel*
Email: assafissa@gmail.com

Background and aims: As part of the global effort for elimination of HCV, Israel, as other countries, adopted a simplified guidelines for HCV treatment.
Our center is a referral center for liver diseases, since the introduction of the first generation of DAA (INF based protocols) we adopted a protocol based on open access for HCV patient, dedicated nurse that communicate with the patients and primary physician before and during treatment, same day fibroscan test for every patient followed by physician recommendation for HCV treatment. Following very good SVR results after this treatment (higher from SVR reported in literature), we implement the dedicated nurse protocol for the INF free protocols.
The aim of our study is to present the result of our experience.
Method: Using our prospective collected database of HCV patients who was treated with DAA in our center, we analyzed SVR rate and some of the patients were asked to complete a questionnaire about the added value of nurse intervention.
Results: During 2011–2013 we treated 105 patients with first generation Peginterferon based DAA with SVR rate of 81%. In the end of 2014, we started to treat with INF free DAA regimens DAA. 831 patients were treated with SVR rate of 98.9%. 33 of the patients were organ transplant patient. 426 patients were diagnosed to have F3–4 fibrosis based on their fibroscan results and these patients continue surveillance post SVR. 74 patients completed the questionnaire about the value of the dedicated nurse intervention. All patients were satisfied with the professionalism of the team. 85% of the patients felt that the explanation provided by the nurse during the appointment contributed to their understanding of their medical situation and the importance of the treatment.
Conclusion: SVR rate of DAA based HCV treatment in our center is very high. The patients pointed the added value of nurse explanations, instruction and follow-up for better understanding of the disease and the importance of treatment and follow-up. Intervention by dedicated nurses improves the communication and compliance.

OS082

Advanced liver disease: master's students' perception. An exercise of introspection

Eva Roman[1,2], Montserrat Guillaumet[1], German Soriano[2], Maria Poca[2], Edilmar Alvarado-Tapias[2], Àngels Escorsell[2]. [1]*School of Nursing. Universitat Autònoma de Barcelona, Spain;* [2]*CIBERehd. Instituto de Salud Carlos III., Madrid*
Email: eroman@santpau.cat

Background and aims: Advanced liver disease (ALD) produces physical and mental changes that drastically affect the lived experience of people who suffer from it, affects self-image and self-perception, social and affective relationships, activities and the idea of the future. Empathy allows us to understand each other's experiences, concerns, and perspectives, as well as communicate this understanding (Moser, *Intensive Crit Care Nurs* 2003). To analyze the understanding of the losses and changes experienced by persons with ALD, their experience and transformation, through the narrative based on an exercise of introspection centred on reflection by resident physicians studying a master on digestive diseases.
Method: 3rd year resident doctors of the gastroenterology speciality, students of the master's degree of the Catalan Society of Gastroenterology during the 2019–2020 academic year. Students had to do an introspection exercise and tell in the first person how they would feel if they were diagnosed with liver cirrhosis: what would change in their life and what would not? Family role, work and social life, economic situation, leisure activities, priorities, future perspective, image (physical and sexual appearance). The writings were analyzed following a semantic interpretive approach (van Manem 1977), and compared with the literature on patients' point of view and perception.
Results: Thirty-three stories were collected of which 30 were written in the first person. Four emerging issues were identified: family, friends and social circles, work situation and self-esteem. The expressed emotions showed higher coincidence with those previously described by patients with ALD. The most recurrent unit of meaning was: "*Being diagnosed with cirrhosis would mean a radical change in my life*"
Conclusion: The narrative is a useful pedagogical tool in training and provides elements of learning to understand responses to complex situations. In the narratives, issues and emotions coincided with those described by patients with ALD were identified. Observing and analyzing oneself by interpreting the cognitive and emotional processes generated by a disease allows one to identify aspects that contribute to becoming aware of the other's reality and thus fostering empathy.

OS083

Nurse-driven post-discharge intervention reduces risk of readmission and non-attendance in patients with decompensated liver cirrhosis: a randomized controlled study

Malene Barfod O'Connell[1], Lise Hobolth[1], Anne Broedsgaard Madsen[2,3], Flemming Bendtsen[1,4], Nina Kimer[1]. [1]*Copenhagen University Hospital, Amager Hvidovre, Gastro Unit, Medical Division, Hvidovre, Denmark;* [2]*Copenhagen University Hospital, Amager Hvidovre, Department of Paediatrics and Adolescent Medicine, Hvidovre, Denmark;* [3]*Aarhus University, Department of Public Health, Research Unit for Nursing and Health Care, Aarhus C, Denmark;* [4]*Copenhagen University Hospital, Amager Hvidovre, Department of Clinical Medicine, Hvidovre, Denmark*
Email: malene.barfod.oconnell@regionh.dk

Background and aims: Patients with decompensated liver cirrhosis are on average admitted 3 times per year and 20–37% of the patients are readmitted within 30 days from discharge. Repeated admissions have great personal and societal consequences and non-attendance at out-patient visits may impact clinical outcome. In this study we investigated how a post-discharge nurse-driven intervention affected readmissions and outpatient attendance for patients with decompensated liver cirrhosis
Method: This randomized controlled intervention was conducted in the Gastro Unit of a university hospital in the Capital region of Denmark. Patients admitted with decompensated liver cirrhosis were eligible for inclusion. The control group received standard post-discharge care. The intervention group participated in a nurse-driven post-discharge intervention based on concepts from Family Nursing. Before discharge the patient and family received a pamphlet with information on preventive measures. After discharge the participants received three monthly home visits by a nurse specialist in liver diseases comprising: therapeutic conversations; evidence-based information and help to initialize contact to municipal offers. After three months the patients received three monthly follow-up telephone calls, to a total of six months follow-up.
Results: Between December 2019 and October 2021, 111 participants were included. Twenty-four participants were excluded due to cancer, death before intervention or withdrawal of consent, leaving 42 participants in the intervention group and 44 participants in the control group. Fifty-three (62%) were male, mean age was 60.7 years, 81 (94%) had alcohol related cirrhosis, and 43 was classified as Child-Pugh C (Child score ≥10), without significant difference between the two groups. Nineteen (45%) participants in the intervention group were readmitted within six months compared to 27 (61%) in the

control group; (HR 0.42; 95% CI: 0.253 to 0.692; stratified log-rank p = 0.002). Therefore, the intervention was associated with a 58% reduction in the risk of readmission compared to the control group. Median time to readmission was 42 days in the intervention group as compared to 21 days in the control group (p = 0.0596). Five participants in the intervention group did not appear for a total of six outpatient visits during the follow-up period, compared to 17 participants in the control group who did not appear for 29 visits (HR 0.21; 95% CI 0.07 to 0.65; stratified log-rank p = 0.007).
Conclusion: In a randomized controlled study, a nurse-driven post-discharge intervention for patients with liver cirrhosis proved a significant reduction in readmissions and in non-attendance for out-patient visits in the intervention group. The period from discharge to first readmission was longer in the intervention group but not statistically significant from the control group.

Gut microbiota in liver disease and liver regeneration

OS084
Monoacylglycerol lipase inhibition specifically in macrophages compromises liver regeneration by inducing interferon type 1 that negatively impacts on hepatocyte proliferation

Manon Allaire[1], Rola Al-Sayegh[1], Morgane Mabire[1], Matthieu Siebert[1], Mathilde Cadoux[1], JingHong Wan[1], Maude Le Gall[1], Catherine Postic[2], Hervé Guillou[3], Pierre de la Grange[4], Sophie Lotersztajn[1], Hélène Gilgenkrantz[1]. *[1]Université de Paris, Centre de Recherche sur l'Inflammation (CRI), Paris, France; [2]Université de Paris, Institut Cochin, INSERM U1016, CNRS, Paris, France; [3]Toxalim (Research centre in Food Toxicology), INRAE, ENVT, INP-Purpan, PS, Université de Toulouse, Toulouse; [4]GenoSplice, Paris, France*
Email: allama5@hotmail.fr

Background and aims: Monoacylglycerol lipase (MAGL) is a proinflammatory enzyme that reprograms lipid metabolism by converting monoacylglycerols into free fatty acids, in particular arachidonic acid. We have previously shown that MAGL displays pro-regenerative properties in the liver by demonstrating the direct contribution of MAGL from hepatocytes and the indirect effects of MAGL from liver macrophages in this impact (Allaire et al, EASL 2021). The aim of this study is to uncover the mechanisms by which MAGL from macrophages modulates liver regeneration.
Method: Mice with genetic invalidation in myeloid cells ($MAGL^{Mye-/-}$) were submitted to a liver regeneration stimulus induced by an acute intraperitoneal injection of carbon tetrachloride (CCl_4). Gene expression profiling of liver $MAGL^{Mye-/-}$ macrophages was assessed by RNASequencing analysis. The role of identified pathways was confirmed *in vitro* in primary hepatocyte cell culture and *in vivo* by injecting neutralizing antibodies.
Results: Mice with a specific MAGL deletion in myeloid cells showed a regeneration defect compared to their wild type counterparts. *RNASeq* analysis demonstrated an induction of interferon-stimulated genes in MAGL depleted liver macrophages, suggesting that interferon type I (IFN-I) pathway plays a major role in the delayed regeneration. The induction of IFN-I was also confirmed in the liver of $MAGL^{Mye-/-}$ mice 24 h after the injury and in bone marrow derived macrophages (BMDM) exposed to the MAGL pharmacological inhibitor MJN110.. We cultured primary hepatocytes with IFN-α and/or -β and found that both reduce hepatocyte proliferation *in vitro* with a cumulative effect of IFN-α and IFN-β. The link between IFN pathway and liver regeneration defect was finally demonstrated in an *in vivo* rescue experiment since the injection of IFN type I receptor neutralizing antibodies in $MAGL^{Mye-/-}$ mice before and during the regeneration process restored hepatocyte proliferation to the level of control mice.
Conclusion: Inhibition of MAGL macrophages compromises liver regeneration by inducing IFN-I pathway that negatively impacts on hepatocyte proliferation.

OS085
Complete vascular tree reconstruction in rat decellularized liver scaffolds using differential recellularization pressures

Sandra Melitón Barbancho[1,2], Pedro Baptista[1,3,4,5], Alba Pueyo Moliner[2]. *[1]Aragón Health Research Institute (IIS Aragón), CIBA, Zaragoza, Spain; [2]University of Zaragoza, Zaragoza, Spain; [3]Centro de investigación biomédica en red, Hepatic Diseases, Madrid, Spain; [4]Universidad Carlos III de Madrid, Department of Biomedical and Aerospace Engineering, Madrid, Spain; [5]Fundación ARAID, Zaragoza, Spain*
Email: smelitonb01@gmail.com

Background and aims: There are still several challenges slowing the translation of bioengineered livers to the clinic in order to reduce the shortage of organs. One of the most important is to provide the whole organ with a robust vascular network that allows its perfusion and maintenance *in vivo*. Effective revascularization of decellularized liver scaffolds (DLS) is still elusive, so this work focused on the revascularization of DLS, presenting an effective approach for generating functional vasculature that allows us to be closer to the bioengineered liver.
Method: Whitin a bioreactor setup, endothelial cells [unlabelled for *vena cava* and labelled with GFP and tdTomato, for portal vein (PV) and hepatic artery (HA), respectively] (pUVECs), smooth muscle cells (pA-SMCs) and mesenchymal stem cells (pBM-MSCs) were injected through HA, PV, and *vena cava* using distinct seeding pressures to target the different vessel diameters. Next, maturation was enhanced by providing growth factors for vasculogenesis and angiogenesis process keeping constant mechanical-stimulation for 14 days. Microscopic analysis was performed by hematoxylin-eosin (HandE) and immunofluorescence (IF) staining's. Finally, pUVECs function was evaluated by nitric oxide (NO) and prostacyclin (PGI2) secretion and the contraction of pA-SMC after carbachol inoculation was observed.
Results: HandE analysis confirmed the lining growth of the different kind of cells inside of the decellularized vascular tree. Moreover, IF confirmed the accurate arrangement of pUVECs into vascular-like structures with pBM-MSCs/pA-SMCs arranged around them. Also, pUVEC-TdTomato and pUVECs-GFP differential seeding through HA and PV respectively showed a targeting layout. Secretion of NO and prostacyclin was confirmed upon bradykinin challenge and a pressure increase in the vascular tree was observed because of the contraction of pA-SMC after exposure to carbachol.

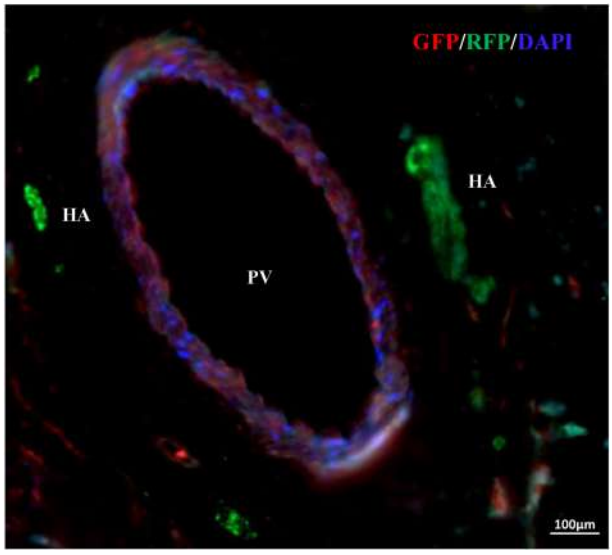


Figure: Recellularized portal vein (red) and hepatic artery (green) with pUVEC-TdTomato and pUVECs-GFP respectively in a bioreactor system after 14 days. GFP: Green fluorescent protein; RFP: Red fluorescent protein and DAPI: 4 ', 6-diamidino-2-phenylindole.

Conclusion: The generation of a complete and functional vascular tree in DLS using distinct cell types and seeding pressures in a bioreactor system with defined maturation conditions is now possible with the validation of the revascularization method here presented.

OS086

Orthotopic transplantation of the functional bioengineered liver prolonged survival in rats with total hepatectomy

Beibei Guo[1], Li Jiang[2], Jing Jiang[1], Qian Zhou[1], Jiaxian Chen[1], Jiaojiao Xin[1], Dongyan Shi[1], Keke Ren[1], Xingping Zhou[1], Genren Yang[2], Jun Li[1]. [1]*The First Affiliated Hospital, Zhejiang University School of Medicine, State Key Laboratory for Diagnosis and Treatment of Infectious Diseases, National Clinical Research Center for Infectious Diseases, Collaborative Innovation Center for Diagnosis and Treatment of Infectious Diseases, Hangzhou, China;* [2]*The First Affiliated Hospital, Zhejiang University School of Medicine, Hangzhou, China*
Email: lijun2009@zju.edu.cn

Background and aims: Functional bioengineered liver (FBL) is a promising alternative to orthotopic liver transplantation. This study aims to determine the therapeutic potency of the FBLs with whole decellularized liver scaffold (DLS) using orthotopic transplantation in rat.

Method: The FBLs were developed using the whole rat DLSs with 1.5*107 human umbilical vein endothelial cell lines (HUVECs) implanted through portal vein, 6*107 human bone marrow mesenchymal stem cells (hBMSCs) and 3*108 mouse hepatocyte cell lines implanted through bile ducts. The FBLs evaluated with endothelial barrier function, bio-synthesis and metabolism were used to orthotopically transplanted into rats for determining survival benefit.

Results: The morphological observation exhibited the well-organized vascular structure lining by HUVECs in vascularized bioengineered liver. Histological and scanning electronic microscopy analysis showed endothelial barrier function with lower leakage of blood cells of the vascularized bioengineered liver. The new developed bioengineered liver displayed that hBMSCs and hepatocytes were, well-aligned, and uniformly distributed over parenchymal space, and HUVECs formed the endothelialized microvascular structure. Significant increases of urea productions and albumin level in culture medium demonstrated that FBLs possessed ammonium translation and albumin synthesis functions. Orthotopic transplantation with FBLs rescued rats with a survival time of up to 100 min,

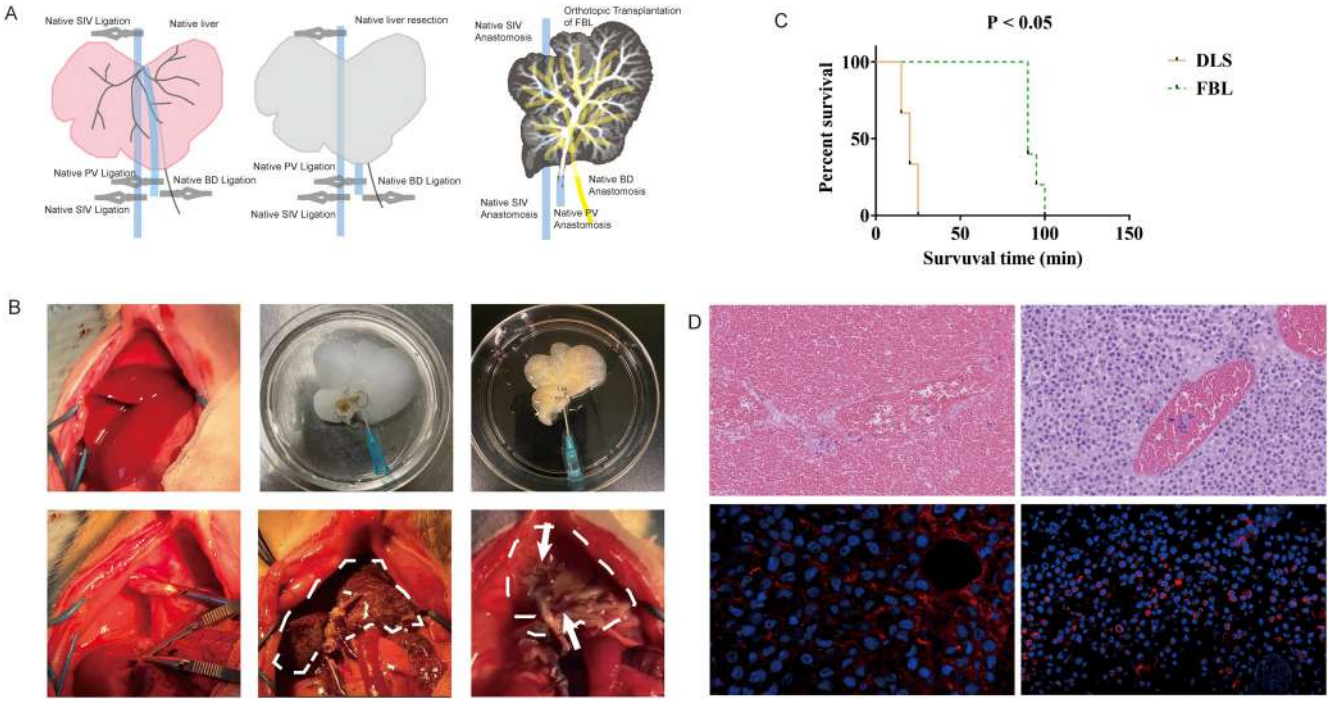

Figure: (abstract: OS086): A. Schematic diagram of orthotopic transplantation of a functional liver-like organ; B. orthotopic transplantation of decellularized liver scaffolds and functional liver-like organs; C. Survival curve after orthotopic transplantation; D. Histological identification after transplantation.

whereas all rats transplanted with DLS died within an average of 25 min. Histological staining showed that most perfused blood cells were limited into vascular lumen and the implanted cells, with positive immunofluorescence staining of CD90 and ALB, evenly distributed into the parenchymal space around vessels in the transplanted FBLs, but the transplanted DLSs became a pool entirely filled with blood cells.

Conclusion: The orthotopically transplanted FBLs effectively prolonged the survival time of rats with total hepatectomy. This study first determined the therapeutic potency of FBLs using orthotopic transplantation, which provides a promising alternative to the liver donor shortage for future clinical therapeutic applications.

OS087

Bacterial infections in cirrhosis are associated with reduction in gut microbial phage-bacterial interactions

Amirhossein Shamsaddini[1], Marcela Peña Rodríguez[2], Andrew Fagan[3], Sara McGeorge[3], Masoumeh Sikaroodi[1], Patrick Gillevet[1], Jasmohan S. Bajaj[3]. [1]*George Mason University;* [2]*Universidad de Guadalajara;* [3]*Virginia Commonwealth University*
Email: jasmohan.bajaj@vcuhealth.org

Background and aims: The impact of bacterial infections on gut microbiota in cirrhosis is unclear since disease severity and antibiotic use could affect these changes. There is increasing evidence of the role of bacteriophages in the modulation of infection risk and as potential treatment strategies. However, changes in the interaction of the virome with metagenome in infected patients with cirrhosis are unclear. Determine change in the metagenome of pts with cirrhosis with infection versus uninfected patients and interaction with virome.

Method: Patients with cirrhosis were recruited, including outpatients with/without decompensation and inpatients admitted with/without infections. All pts underwent stool collection for metagenomics for bacterial and phage species. In inpts, stool was collected before antibiotics. DESeq2, PCoA, and correlation network analyses were performed between (a) all uninfected vs. infected patients and (b) inpatients with/without infections matched 1:1 by MELD score, demographics, and medications.

Results: 231 pts with cirrhosis were recruited, of which 30 were infected (20 SBP, 10 UTI). Unmatched comparison showed that infected pts had worse cirrhosis severity. PPI use was similar (Fig A). After matching for MELD score, inpatients with infections had similar disease severity (Ascites, HE) and medication use compared to those without infections (Fig A).

Metagenomics: Unmatched analysis: Pathobionts (*Enterococcus* spp, C.difficile) were higher, while short-chain fatty acid producers (*Ruminococcus. Alistipes* spp) were lower in infected patients. CrAssphages, *Bifidobacterium,* and *Streptococcus* phages were lower in infected patients. There was also a clear separation on β diversity (PERMANOVA $p < 0.0001$) between groups on bacterial and phage species. Matched analysis: Higher pathobionts (E.faecalis, E.faecium, C.difficile) along with *Lactobacillus* spp and oral-origin taxa (Fig B) persisted even after matching. Phages corresponding to these bacteria were also higher vs. uninfected pts (Fig C). PCoA showed β-diversity changes in bacteria (Fig D) and phages (Fig E) between groups. *Correlation network:* between phages and bacteria showed a collapse between linkages in infected patients centred around

Fig A Variables	Infected (n=30)	Unmatched Uninfected (N=201)	Matched cohort Uninfected (n=30)	P-value Matched uninfected vs infected (n=30)	P-value unmatched uninfected (N=201) vs infected (n=30)
Age	56.5±11.6	58.4±13.9	59.0±13.6	0.45	0.42
Male sex	27	170	23	1.0	0.15
Diabetes	15	92	11	0.65	0.66
MELD score	18.3±8.2	11.5±4.7	17.6±7.2	0.73	**<0.0001**
PPI	17	112	17	1.0	0.92
Lactulose	20	83	22	0.15	**0.009**
Rifaximin	15	58	14	0.71	0.06
HE	22	98	23	0.14	**0.01**
Ascites	24	119	27	1.0	0.06

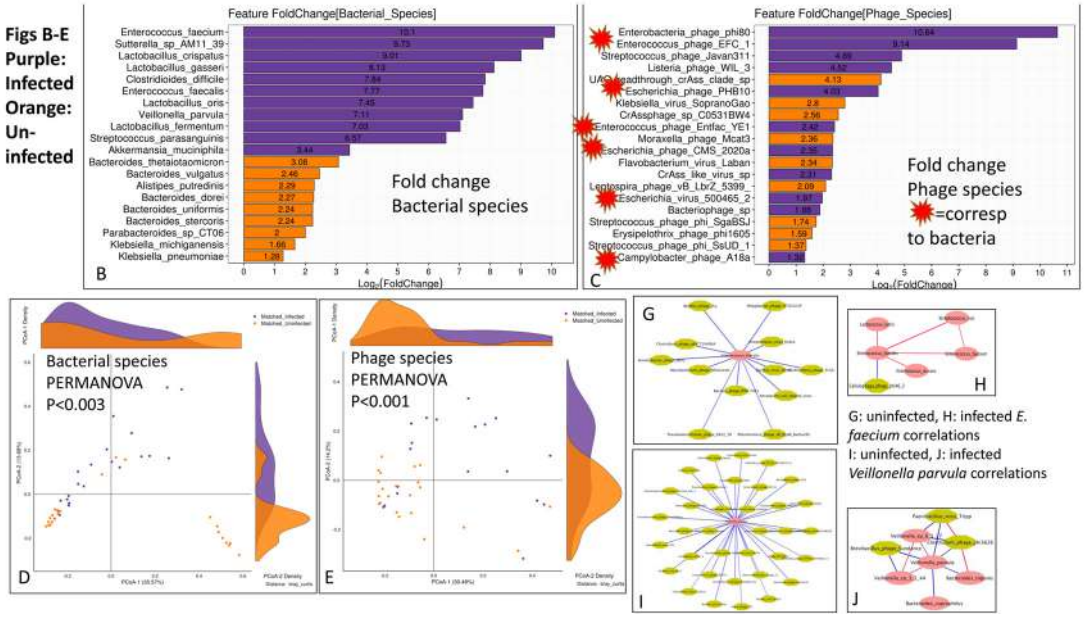

Figure: (abstract: OS087): Characteristics and comparisons between infected and uninfected patients.

Enterococcus (Fig G/H) and *Veillonella* spp (Fig I/J). Network heterogeneity was higher in infected vs matched uninfected (1.066 vs 1.027) and in unmatched cohorts (1.183 vs 1.025).
Conclusion: Collapse of phage-bacterial interactions centred around *Enterococcus,* Enterobacteriaceae spp and oral-origin taxa are linked with bacterial infections. This pattern persists even when infected pts are compared to disease severity-matched inpatients without infections before antibiotics. Phages directed against pathobionts could be targeted to prevent these infections.

OS088

Altered gut microbiome, metabolome and bile acid composition in sarcopenia in liver cirrhosis

Benard Aliwa[1,2], Nicole Feldbacher[1,3], Angela Horvath[1,3], Julia Traub[4], Tobias Madl[5], Günter Fauler[6], Vanessa Stadlbauer[1,3]. *[1]Medical University of Graz, Department of Gastroenterology and Hepatology, Graz, Austria; [2]University of Nairobi, Department of Food Science, Nutrition and Technology, Nairobi, Kenya; [3]CBmed Center of Biomarker Research in Medicine, Area Microbiome Research, Graz, Austria; [4]University Hospital Graz, Dietology Services, Graz, Austria; [5]Medical University of Graz, Gottfried Schatz Research Center for Cell Signaling, Metabolism and Aging Molecular Biology and Biochemistry, Graz, Austria; [6]Medical University of Graz, Klinisches Institut für Medizinische und Chemische Labordiagnostik (KIMCL), Graz, Austria*
Email: vanessa.stadlbauer@medunigraz.at

Background and aims: 50–70% of liver cirrhotic patients suffer from sarcopenia leading to high mortality risk. The gut microbiome can metabolize bile acids and in turn bile acids can shape the gut microbiome community structure. We aimed to study differences in gut microbiome, bile acids and metabolite composition between sarcopenia and non-sarcopenia in liver cirrhosis and control.
Method: We analyzed 16 s rDNA sequencing of fecal microbiome and measured bile acids and metabolites of cirrhotic patients with and without sarcopenia (n = 78 and n = 38, respectively) as well as control with and without sarcopenia (n = 39 and n = 20, respectively). LEfSe, ANCOM, and LASSO regression, and multivariate logistic regression were applied.
Results: We demonstrated that both in cirrhotic and control patients, sarcopenia associates with a significant reduction in bacteria capable of generating branched-chain amino acids and short-chain fatty acids and a significant increase in bacteria capable of generating secondary bile acid (Sec-BAs). *Sutterella species*, *Vellionella parvula*, *Bacteroides (B.) fragilis*, and *Blautia marseille* were associated with sarcopenia and *B. ovatus*, *Alistipes putredinis*, *Eubacterium,* and *Ruminococcaceae* were associated with non-sarcopenia. In sarcopenic cirrhotic patients, we observed significantly elevated Sec-BAs, including deoxycholic acid (DCA), glycodeoxycholic acid (GDCA), lithocholic acid (LCA), and significantly elevated deoxycholic acid to cholic acid (DCA:CA), lithocholic acid to chenodeoxycholic acid (LCA:CDCA), glycolithocholic acid to chenodeoxycholic acid (GLCA:CDCA) and reduced total ursodeoxycholic acid to total secondary bile acid (T-DCA:T-sec BAs), serum valine, and serum acetate. We further observed that genes coding for 7α-hydroxysteroid dehydrogenase enzyme (7α-HSDH) were significantly increased in sarcopenic controls compared to non-sarcopenic controls. Multivariate logistic regression showed that MAMC, BMI, serum valine, serum acetate, GLCA:CDCA, T-DCA:T-sec BAs, and *B. ovatus* were independent predictors for sarcopenia in liver cirrhosis even when corrected for severity of disease and drug use.
Conclusion: *B. ovatus*, serum valine, serum acetate and bile acid profiles are independent predictors for sarcopenia and potential biomarkers for muscle health in liver cirrhosis. Further studies are needed to assess whether increasing *B. ovatus* abundance, serum valine, serum acetate, or altering bile acid composition may affect muscle health.

OS089

In-depth shotgun metagenomic analysis of the oral and gut microbiome identifies striking overlap in microbial community structure, virulence factors and antimicrobial resistance genes based on stage and severity of cirrhosis

Sunjae Lee[1], Bethlehem Arefaine[2], Neelu Begum[1], Elizabeth Witherden[1], Marilena Stamouli[2], Azadeh Harzandi[1], Ane Zamalloa[3], Eleanor Corcoran[4], Roger Williams[2,5], Shilpa Chokshi[2,5], Gordon Proctor[1], Adil Mardinoglu[1,6], Mathias Uhlen[6], Saeed Shoaie[1,6], Vishal C. Patel[2,5,7]. *[1]Centre for Host Microbial Interactions, King's College London, London, United Kingdom; [2]The Roger Williams Institute of Hepatology, Foundation for Liver Research, London, United Kingdom; [3]Institute of Liver Studies and Transplantation, King's College Hospital NHS Foundation Trust, London, United Kingdom; [4]Department of Critical Care, King's College Hospital NHS Foundation Trust, London, United Kingdom; [5]School of Immunology and Microbial Sciences, Faculty of Life Sciences and Medicine, King's College London, London, United Kingdom; [6]SciLifeLab, KTH — Royal Institute of Technology, Sweden, Sweden; [7]Institute of Liver Studies and Transplantation, King's College Hospital, London, United Kingdom*
Email: vishal.patel@nhs.net

Background and aims: Alterations in the gut microbiome in decompensated cirrhosis (DC) and acute on chronic liver failure (ACLF) are recognised as being critical in influencing clinical outcomes (Trebicka *et al*., Nat Rev Gastro Hepatol, 2020). Knowledge of the oral microbiome is evolving and is increasingly recognised as predisposing to hepatic decompensation (Acharya *et al*., JCI Insight, 2017). Our aims were to interrogate simultaneously the gut and oral microbiome by shotgun metagenomic sequencing of faecal and saliva samples, respectively, in cirrhosis patients of varying severities, with healthy and positive disease controls.
Method: 18 healthy controls (HC), 20 stable cirrhotics (SC), 50 DC, 18 ACLF and 15 with non-liver sepsis (NLS) i.e. severe infection but without cirrhosis were prospectively recruited. DNA extractions were undertaken from saliva and faecal samples and Illumina sequenced on a NovaSeq 6000 to a minimum depth of 20 million reads. Filtered and trimmed reads were aligned to a human microbiome integrated gene catalogue. Salivatypes and enterotypes were calculated by scaling genus profile abundance and clustering by Dirichlet multinomial mixture models. Comprehensive Antimicrobial Resistance Gene (ARG) and KEGG Orthology databases were used to evaluate ARGs and functional annotations, respectively.
Results: There was a striking decrement in Shannon diversity in the DC and ACLF cohorts *vs* HC and NLS (Fig A, D). Specific saliva- and enterotypes were identified based on clustering of genera, with a greater proportion of pathobionts and simultaneous reduction in autochthonous genera detected in specific clusters as cirrhosis severity progressed (Fig B, C, E, F). The degree of overlap between oral and gut microbiome communities (independent of antimicrobials, beta-blockers and acid suppressant therapies) and functional changes specific to virulence factor over-expression were significantly higher in DC and ACLF vs SC and HCs. Substantial total numbers of ARGs (1, 218 and 672] were detected in the oral and gut microbiome samples, respectively. 575 of ARGs were common to both sites, but a greater proportion of these were harboured in the gut (>85%) compared to the oral niche (47%), with overall ARG frequency incrementing with worsening cirrhosis (Fig G–I).
Conclusion: Oral and gut microbiome profiles differ significantly according to severity of cirrhosis, with specific saliva- and enterotype clusters reflecting dominance by pathobionts and loss of commensals. The degree of microbial community overlap between the mouth and gut, virulence factor and ARG frequency all increment significantly as cirrhosis worsens. These alterations that predispose to higher infection risk, poorer response to antimicrobial therapy and triggers for hepatic decompensation now form the rationale for non-antibiotic-dependant microbiome-modulating targeted therapies.

Hepatitis B emerging therapies

OS090

Longer treatment duration of monthly VIR-2218 results in deeper and more sustained reductions in hepatitis B surface antigen in participants with chronic hepatitis B infection

Young-Suk Lim[1], Man-Fung Yuen[2], Daniel Cloutier[3], Vaidehi Thanawala[3], Ling Shen[3], Sneha V. Gupta[3], Andre Arizpe[3], Andrea Cathcart[3], Carey Hwang[3], Edward J. Gane[4]. Email: limys@amc.seoul.kr

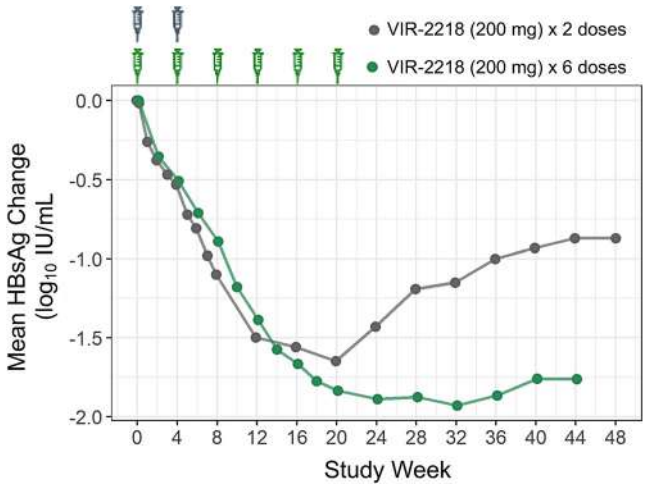
Background and aims: Chronic hepatitis B virus (HBV) infection is a substantial global health issue affecting more than 290 million people worldwide. VIR-2218 is a small interfering ribonucleic acid (siRNA) therapeutic targeting the hepatitis B virus X region of the HBV genome currently in development for the treatment of HBV infection. Here, we report preliminary data from an ongoing study evaluating the safety, tolerability, and antiviral activity of 2 dosing regimens of VIR-2218 in participants with HBV infection.

Method: This open-label phase 2 study enrolled adult, virally suppressed, hepatitis B e antigen (HBeAg)-positive or negative participants with chronic HBV infection without cirrhosis. Dosing regimens of 2 doses (n = 6) or 6 doses (n = 15) of VIR-2218 200 mg given subcutaneously every 4 weeks were evaluated. Preliminary data up to the final follow-up visits for the 2-dose (week 48) and 6-dose (week 44) regimens are presented.

Results: Five of 6 participants receiving the 2-dose regimen completed study week 48 and, to date, 7 of 15 participants receiving the 6-dose regimen have completed study week 44. All participants achieved >1-log reduction in hepatitis B surface antigen (HBsAg). The 6-dose regimen was associated with greater mean maximum HBsAg reduction (−1.96 vs −1.61 $\log_{10}$ IU/ml), and more sustained HBsAg reductions (−1.76 vs −0.87 $\log_{10}$ IU/ml at week 44) compared with the 2-dose regimen (Figure). In both cohorts, adverse events (AEs) were generally grade 1 or 2 and no AEs resulted in discontinuation of study drug. Most participants had normal alanine aminotransferase

(ALT) levels throughout the study; 2 participants in each regimen had grade 1 ALT elevations. No treatment-related serious AEs were reported.



Conclusion: These preliminary data support that a longer duration of treatment with VIR-2218 results in deeper and more sustained reductions in HBsAg. In both regimens of VIR-2218, no differences in safety or tolerability were observed.

OS091

ALT flares were linked to HBsAg reduction, seroclearance and seroconversion: interim results from a phase IIb study in chronic hepatitis B patients with 24-week treatment of subcutaneous PD-L1 Ab ASC22 (Envafolimab) plus nucleos (t)ide analogs

Guiqiang Wang[1], Yimin Cui[2], Yao Xie[3], Qianguo Mao[4], Qing Xie[5], Ye Gu[6], Xin-Yue Chen[7], Guoxin Hu[8], Yongfeng Yang[9], Jiajie Lu[10], Guizhou Zou[11], Qin Zhang[12], Lei Fu[13], Yongping Chen[14], Xiaolin Guo[15], Jinlin Hou[16], Yuemei Yan[17], Handan He[17], Jinzi Wu[17]. *[1]Peking University First Hospital, Infectious Diseases Department, Beijing, China; [2]Peking University First Hospital, Clinical Trial Center, Beijing, China; [3]Beijing Ditan Hospital Capital Medical University, Beijing, China; [4]Xiamen Hospital of Traditional Chinese Medicine, Xiamen, China; [5]Ruijin Hospital of Medical College of Shanghai Jiaotong University, Infectious Diseases Department, Shanghai, China; [6]Shenyang Sixth People's Hospital, Shenyang, China; [7]Beijing YouAn Hospital Capital Medical University, Beijing, China; [8]Peking University Shenzhen Hospital, Shenzhen, China; [9]Nanjing Second Hospital, Nanjing, China; [10]West China Hospital of Sichuan University, Chengdu, China; [11]The Second Affiliated Hospital of Anhui Medical University, Hefei, China, [12]Shanghai Tongren Hospital, 上海, China; [13]Xiangya Hospital of Central South University, Changsha, China; [14]The First Affiliated Hospital of Wenzhou Medical University, Wenzhou, China; [15]The First Hospital of Jilin University, Changchun, China; [16]Nanfang Hospital of Southern Medical University, Guangzhou, China; [17]Ascletis BioScience Co., Ltd., Hangzhou, China*
Email: john131212@sina.com

Background and aims: Blockade of PD-1/PD-L1 pathway can restore T cell functions and lead to a potential cure for chronic hepatitis B (CHB). Hepatitis flares are considered to be mainly immune-mediated and may be linked or mark transitions to HBsAg reduction, even clearance. Previous studies indicated that PegIFN treatment may result in 18–24% of patients with ALT flares since it is an immune modulators. siRNA, a direct antiviral, however, caused as low as 6% of patients with ALT flares. Here we reported characterization of ALT flares and their relationship with HBsAg reduction, seroclearance and seroconversion from the interim analysis of a Phase IIb clinical trial in CHB patients with 24-week subcutaneous PD-L1 antibody ASC22 (Envafolimab) plus Nucleos (t)ide analogs (NAs) treatment.

Method: This randomized, single-blind, multi-center Phase IIb trial enrolled a total of 149 CHB patients (negative HBeAg, HBsAg ≤10000 IU/ml and HBV DNA <20 IU/ml) in two cohorts for 24-week treatment of ASC22 (1 or 2.5 mg/kg) and 24-week follow-up (NCT04465890). The relationship between ALT flares and HBsAg reduction/loss was analyzed in patients who completed 24-week treatment of 1 mg/kg ASC22 Q2W (n = 33) or PBO Q2W (n = 11) + NAs. An ALT flare is defined as a transient elevation in serum ALT greater than 3-fold baseline level and more than 2X ULN (upper limit of normal).

Results: The baseline serum levels of HBsAg, ALT and AST were comparable between patients receiving ASC22 or PBO plus NAs. Seven patients had HBsAg reduction >0.5 $\log_{10}$ IU/ml, and were all with baseline HBsAg ≤500 IU/ml. Three patients even experienced HBsAg seroclearance (undetectable, <0.05 IU/ml). One patient with HBsAg loss had seroconversion of HBsAb 6 weeks after the last dosing of ASC22 (Figure 1A). ALT flares were observed in 5/33 (15%) patients in ASC22 group compared to none in PBO group. Among the patients with HBsAg reduction >0.5 $\log_{10}$ IU/ml or HBsAg loss, 4/7 (57%) and 2/3 (67%) experienced ALT flares, respectively (Figure 1B). No clinically meaningful changes of total or direct bilirubin were observed in patients with ALT flares. However, more immune-related AEs (irAEs) occurred in ASC22 group. Most common irAEs were Grade 1 ALT/AST elevation and rash.

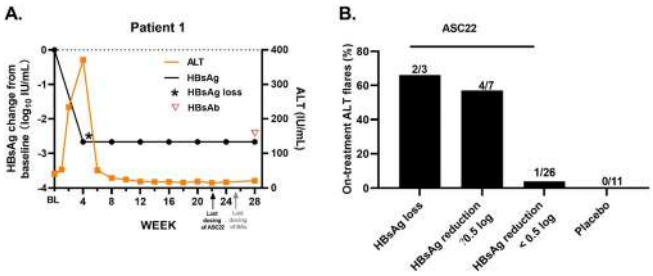


Figure 1:(A) One patient with HBsAg loss had seroconversion of HBsAb 6 weeks after last dosing of ASC22. (B) Percentage of on-treatment ALT flares among patients with different responses or treatments.

Conclusion: ALT flares occurring during ASC22 treatment were shown to be an indicator of a clinically meaningful immune response, resulting in significant HBsAg reduction and subsequent HBsAg loss/HBsAb seroconversion.

Lonafarnib combination with peginterferon Lambda diminished triphasic HDV kinetic pattrn seen under Lambda monotherapy: the LIFT HDV study

Sarah Duehren[1], Christopher Koh[2], Julian Hercun[2], Farial Rahman[2], Pallavi Surana[2], Anusha Vittal[2], Walter Lai[2], Ohad Etzion[3], Scott Cotler[1], Jeffrey Glenn[4], Harel Dahari[1], Theo Heller[2]. *[1]Program for Experimental and Theoretical Modeling, Division of Hepatology, Department of Medicine, Stritch School of Medicine, Loyola University Chicago, Maywood, United States; [2]Liver Diseases Branch, NIDDK, NIH, Bethesda, United States; [3]Soroka University Medical Center, Beer-Sheba, Israel; [4]Division of Gastroenterology and Hepatology, Stanford University School of Medicine, Stanford, United States*
Email: harel.dahari@gmail.com

Background and aims: We recently reported that Lambda InterFeron combination Therapy (LIFT) is safe and tolerable for up to 6 months in most patients with HDV. The goal of the current study was to characterize HDV RNA, HBV DNA, HBsAg and ALT kinetics during and after lonafarnib (LNF) and pegylated IFN-λ (Lambda) combination therapy.

Method: Twenty-six chronic HDV infected patients participated in a randomized, open-label Phase 2a clinical study of oral LNF 50 mg plus

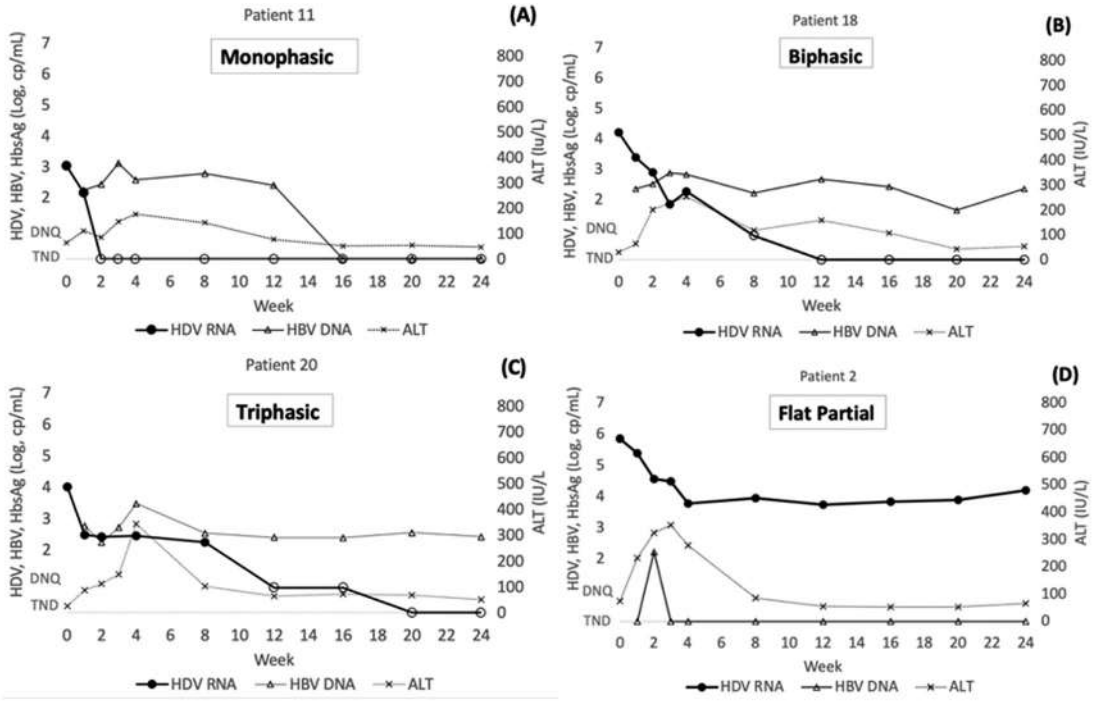

Figure 1. Kinetic characterization categories under Lambda and LNF therapy. (A) Monophasic (n=9) with ALT flare at week 16, and HBV increase at week 12. (B) Biphasic (n=11) with ALT flare at week 4, and HBV fluctuations throughout treatment. (C) Triphasic/Transient (n=2) with ALT flare at week 4 and high HBV viral level maintained throughout treatment. (D) Flat partial response (n=4) with ALT flare at week 3.

Figure: (abstract: OS092)

ritonavir (RTV) 100 mg twice daily and subcutaneous Lambda 180 mcg weekly for 24 weeks, followed by per-protocol post-therapy monitoring for 24 weeks. Three patients completed <24 weeks (12, 16, and 20 weeks). All participants were started on tenofovir or entecavir prior to therapy. Kinetic data were obtained weekly for the first four weeks, and then every four weeks during and post treatment. HDV kinetic phase changes were defined as a 2-fold change in slope. HDV RNA was measured by Robogene 2.0 (limit of quantification, LoQ = 14 cp/ml).

Results: Mean pretreatment HDV RNA, ALT, and HBsAg were 4.9 log IU/ml [IQR 1.6], 80 U/L [IQR 45], and 3.8 log cp/ml [IQR 0.5], respectively. Fourteen (54%) patients had pretreatment HBV DNA target not detected (TND) and 12 patients had mean HBV DNA 2.6 log IU/ml [IQR 0.38]. During therapy, patients fit into 4 HDV kinetic patterns (Fig. 1): monophasic, MP (n = 9, Fig. 1A), biphasic, BP (n = 11, Fig. 1B), triphasic/transient, TP (n = 2, Fig. 1C), and flat-partial response, FPR (n = 4, Fig. 1D). HBsAg remained at pretreatment level in all patients (not shown). All patients had a transient ALT increase during therapy (mean 6-fold [IQR 4] from upper limit of normal (40 IU/ml). Six (of 14) patients maintained HBV serum levels at TND, while the other 8 had transient increases or fluctuations from baseline TND. Of the 12 patients with high baseline HBV DNA levels, 8 maintained high levels throughout treatment, and 4 dropped to TND. A 2 log decline (or LoQ, n = 15) from pre-treatment HDV levels at end of therapy (EOT) was seen in 23 (88%) patients: 9/9 MP, 11/11 BP, 2/2 TP, 1/4 FPR. Mean ALT level at EOT was 94 IU/ml [IQR 31], similar to pretreatment levels. At end of follow-up (EFU), 5 (4 MP and 1 BP) out of 15 patients who had HDV LoQ at EOT remained LoQ (Fig. 1A and B), and the remaining had rebound (from EOT) with a mean value of 4.83 log IU/ml [IQR 1.9]. Eleven (42%) patients achieved ALT normalization at EFU.

Conclusion: We previously reported in the LIMT-1 study (The Liver Meeting, AASLD 2019 #LP12) 5 HDV kinetic patterns under Lambda monotherapy: MP (19%), BP (22%), FPR (19%), and triphasic/staircase (40%). Compared to Lambda monotherapy, including LNF significantly (p = 0.009) diminished the HDV triphasic/staircase kinetic patterns to 8%, suggesting that LNF reduces intracellular HDV production. The LIMT-1 study saw successful HDV viral decline in only 45% of patients, while the present study showed 88% success in reducing HDV by more than 2 log.

OS093

Real life study of bulevirtide in chronic hepatitis delta: preliminary results of the ANRS HD EP01 BuleDelta prospective cohort

Email: helene.fontaine@aphp.fr

Background and aims: About 5 % of positive-HBsAg patients are infected with the hepatitis Delta virus (HDV), leading to an increase of 2 to 5-fold of cirrhosis and hepatocellular carcinoma, and a higher mortality in comparison with chronic hepatitis B alone. The management of chronic hepatitis delta (CHD) has improved recently in France, with the availability of bulevirtide (BLV) within an early access program in September 2019 and thanks to a conditional marketing authorization since September 2020.
Method: The aim of the BuleDelta cohort, a French multicenter ANRS |MIE observatory is to analyze the efficacy and the safety of BLV in patients treated since September 2019. This preliminary analysis has been performed in patients treated for at least 24 weeks (W24). The biological response was defined as a normalization of ALT, the virologic response as a decrease of HDV RNA of at least 2 log IU/ml or HDV RNA undetectability, the combined response as the association of both.
Results: as of October 1st, 2021, 138 patients have been included in the BuleDelta cohort: 66% were male, mean ± SD age of 42 ± 11 years; 54 % were of European or Asian origin and 44 % from Sub-Saharan Africa, 12 % presented HIV coinfection, 73% were treated with nucleo (s)tides analogs (NUC) and 42% with pegylated interferon-α (Peg-IFN).
At baseline (D0), the mean HDV RNA was 6.1 ± 1.4 log IU/ml; HBV DNA was above quantification threshold in 38 patients (mean 2.6 ± 1.6 log IU/ml).
The preliminary analysis included the 98 out of 138 patients with available data at W24 in whom 54 (55%) were treated with BLV only, and 44 (45 %) in association with peg-IFN. Overall 74 (76 %) were concomitantly treated with NUC. The mean decrease of HDV RNA at W24 was of 1.9 ± 1.4 log IU/ml (2.6 and 1.6 log IU/ml with and without peg-IFN, respectively). The virologic response at W24 was observed in 55 (56%) patients (80% and 37%, with and without peg-IFN, respectively). Among these 55 patients, the virologic response was observed in 8 (15%) patients at W4, in 26 (47%) at W8 and in 38 (69%) at W12. The biological response was observed in 36 out of 98 (37%) patients at W24 (34% and 40%, with and without peg-IFN, respectively) and the combined response in 25 (26%) patients at W24 (36% and 17%, with and without peg-IFN, respectively).
In the 43 patients without virologic response at W24, Figure 1 presents which therapeutic strategy was adopted. No patient had Peg-IFN add-on.

	Treatment decision		
HDV viral load at W24	Treatment continuation	Increase of BLV from 2 to 10 mg/d	BLV interruption
Quantifiable (n = 34)	26 (76.5%)	6 (17.6%)	2 (5.9%)
Detectable below quantification limit (n = 9)	8 (88.9%)	0 (0%)	1 (11.1%)

Conclusion: In this first real life study, a decrease of HDV viremia greater than 2 log IU/ml after 24 weeks of treatment of BLV was observed in more than half of patients with CHD and was associated with a normalization of ALT in half of them. Updated results will be presented at the meeting.

OS094

Therapeutic vaccine JNJ-0535 induces a strong HBV-specific T-cell response in healthy adults and a modest response in chronic HBV-infected patients

An De Creus[1], Leen Slaets[1], Bart Fevery[1], Ellen Van Gulck[1], Linghua Zhou[1], Tim Van De Parre[1], Celine Van Den Broeke[1], Dessislava Dimitrova[2], Isabelle Lonjon-Domanec[1], David Blue, Jr[3], Pieter Van Remoortere[2], Stefan Bourgeois[4], Patrick Kennedy[5], Sandra De Meyer[1]. *[1]Janssen Research and Development, Belgium; [2]Janssen Research and Development, United States; [3]Janssen Biopharma, Inc.; [4]Hospital Network Antwerp (ZNA), Belgium; [5]Barts and The London School of Medicine and Dentistry, United Kingdom*
Email: adecreus@its.jnj.com

Background and aims: JNJ-0535 is a hepatitis B virus (HBV)-specific therapeutic DNA vaccine administered via electroporation (EP)-mediated intramuscular injection. JNJ-0535 comprises 2 plasmids encoding either HBV core or polymerase (pol) proteins. Induction of functional core and pol-specific T cells was evaluated in healthy and chronic HBV (CHB)-infected individuals.
Method: First in human (FIH) study 64300535HPB1001 evaluated total doses of 0.25 mg (n = 6), 1 mg (n = 7) or 6 mg (n = 10) JNJ-0535 (containing equal quantities of the 2 plasmids) or placebo (n = 7) delivered by intramuscular electroporation with TDS-IM v2.0 in CHB patients who were virologically suppressed, HBeAg- and on stable nucleos (t)ide therapy. Study 64300535HPB1003 evaluates the 6 mg dose of JNJ-0535 in healthy volunteers (HVs) (n = 12). PBMCs collected at baseline, during the vaccination period (10–14 days after the 3 vaccinations, and during follow-up were evaluated for T cell responses against core and pol using ex vivo IFNγ ELISpot and intracellular cytokine staining (ICS). Results of the vaccination period will be presented for both studies comparing the 6 mg dose.
Results: A ≥3-fold increase in ELISpot responses over baseline to core and/or pol was observed in 5/10 CHB patients (50%) and in 11/12 HVs (91.7%) at 6 mg JNJ-0535. Six (50%) HV responded to both antigens whereas no CHB patients responded to both antigens. JNJ-0535 vaccination induced a higher median (interquartile range) maximum fold-increase in T cell responses from baseline in HV (24.4 [10.1–51]) compared to CHB patients (4.8 [4.4–10]). Overall, vaccine-induced core-specific CD4+ T cells were polyfunctional in both HV and CHB patients for ELISpot responses ≥150 SFU/million PBMC. Polyfunctional core-specific CD8+ T cells were only induced in HV. No safety issues have been identified for JNJ-0535 vaccine delivered by intramuscular electroporation.

Conclusion: T cell responses induced in HV were superior to those in CHB patients at a JNJ-0535 dose of 6 mg in terms of the proportion of responders, the magnitude of fold-increase from baseline, the breadth (number of antigens) and CD4+ and CD8+ core-specific T cell polyfunctionality. This supports the hypothesis that CHB infection negatively impacts the ability of patients to induce T cells in response to therapeutic vaccination.

OS095

Sustained 12 week off treatment antiviral efficacy of ATI-2173, a novel active site polymerase inhibitor nucleotide, combined with tenofovir disoproxil fumarate in chronic hepatitis B patients, a phase 2a clinical trial

Myreen Tomas[1], Alina Jucov[2,3], Igor Anastasiy[4], Lauren Ogilvie[1], Karen Fusaro[1], Katherine Squires[1], Douglas Mayers[1]. Email: mtomas@antiostherapeutics.com

Background and aims: ATI-2173 is a novel phosphoramidate liver-targeted prodrug of clevudine that functions as an active site polymerase inhibitor nucleotide (ASPIN). In Phase 1, ATI-2173 demonstrated potent hepatitis B virus (HBV) activity with sustained off-treatment responses 4 to 24 weeks after discontinuation. The SAVE-1 Phase 2a trial evaluated the efficacy of ATI-2173 + tenofovir disoproxil fumarate (TDF) in treatment-naive chronic HBV-infected (CHB) patients.
Method: A randomized, double-blind, placebo-controlled trial (NCT04847440) was conducted at sites in Moldova and Ukraine. Each cohort had 10 CHB patients randomized 8:2 to receive either 25 mg or 50 mg of ATI-2173 + TDF or placebo (PBO) + TDF daily for 90 days. HBV DNA and HBV RNA were measured using a Roche cobas 6800 (lower limit of quantification; LLOQ = 10 IU/ml, and 10 copies/ml respectively). The Roche RNA assay is investigational use only. Hepatitis B surface antigen (HBsAg) was measured using a Roche Elecsys (LLOQ = 0.05 IU/ml).
Results: Most patients were hepatitis B e antigen-negative (90%). Change from baseline virologic responses (HBV DNA) at the end of treatment for TDF alone (N = 4), 25 mg (N = 8) and 50 mg ATI-2173 + TDF (N = 8) were −3.53, −3.72, and −3.54 $\log_{10}$ IU/ml, respectively. No changes in HBsAg were observed. HBV RNA mirrored the HBV DNA responses on treatment. At 12 weeks off treatment, viral load response in the TDF arm was −0.66, while the 25 mg and 50 mg arms had maintained suppression of −3.20 and −3.50 $\log_{10}$ IU/ml, respectively (Figure). 0/4 in the TDF alone, 3/8 in the 25 mg cohort and 3/8 in the 50 mg cohort had HBV DNA below the limit of quantification <10 IU/ml at 12 weeks off treatment. By the week 12 visit, none of the 16 subjects in the ATI-2173 +TDF arms restarted TDF compared to 1 of 4 in the TDF alone arm who restarted TDF at week 8 due to virologic relapse (HBV DNA >2000 IU/ml). An off-treatment alanine aminotransferase (ALT) flare was observed in the TDF arm but not in the ATI-2173 arms.

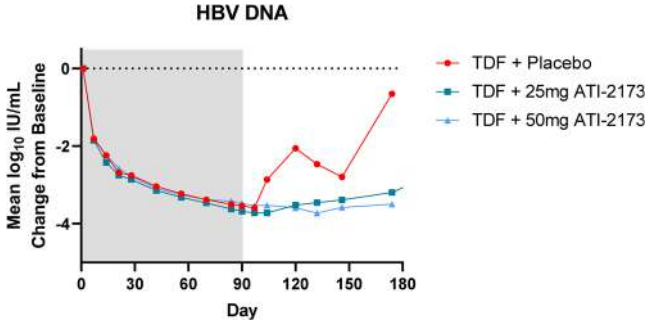

Figure: Mean HBV DNA change from baseline across arms.

Conclusion: Similar on- and off-treatment HBV DNA antiviral activity was observed between 25 mg and 50 mg cohorts of ATI-2173 + TDF. In the off-treatment period, ATI-2173 + TDF provided prolonged HBV DNA suppression, longer time to rebound, and absence of ALT flares compared to TDF alone. 24-week off-treatment data will be presented at the conference.

NAFLD: Diagnostics and non-invasive assessment

OS096

Impact of type 2 diabetes on the accuracy of non-invasive tests of liver fibrosis: a comprehensive analysis of 1, 051 biopsy proven NAFLD patients showing clinical implications

Jerome Boursier[1], Clémence M. Canivet[1], Charlotte Costentin[2], Adrien Lannes[3], Adele Delamarre[4], Nathalie Sturm[5], Brigitte Le Bail[6], Sophie Michalak[7], Frédéric Oberti[3], Marie-Noëlle Hilleret[2], Marie Irles-Depe[4], Isabelle Fouchard[3], Paul Hermabessière[4], Justine Barthemon[2], Bertrand Cariou[8], Victor de Lédinghen[4], Marine Roux[1]. Email: jeboursier@chu-angers.fr

Background and aims: It has been suggested that non-invasive tests (NITs) of liver fibrosis are less accurate in type 2 diabetes (T2D). We aimed to compare the diagnostic accuracy of six NITs between patients with and without T2D, to explain the observed differences, and to adapt diagnostic algorithms for clinical practice accordingly.
Method: 1, 051 patients with non-alcoholic fatty liver disease (NAFLD), liver biopsy, blood fibrosis tests (NAFLD fibrosis score, FIB4, Fibrotest, FibroMeterV2G), vibration controlled transient elastography (VCTE), and the combinatory elasto-blood test FibroMeterVCTE were included. The study end point was advanced fibrosis (NASH CRN staging) on liver biopsy.
Results: The difference in result for NAFLD fibrosis score was highly significant between patients with and without T2D, T2D being included in the test formula. Consequently, only 11% of the patients with T2D were included in the rule-out zone of the NAFLD fibrosis score. AUROCs of the five other NITs were significantly lower in patients with T2D, mostly because of a decrease in specificity. The decrease of FIB4 specificity was explained by the significantly higher age of patients with T2D. After adjustment for age, there was no longer significant difference in FIB4 accuracy between patients with and without T2D. The decrease of specificity observed for Fibrotest, FibroMeterV2G, and FibroMeterVCTE was explained by age but also by higher alpha2macroglobulin level which is known to increase in T2D. Sensitivity of NITs was not affected by T2D but, because of the twofold higher prevalence of advanced fibrosis in this group, it masked a doubled raw number of false negatives in T2D. The sequential algorithm FIB4-VCTE had 90.3% diagnostic accuracy in patients without T2D versus only 79.0% in T2D ($p < 0.001$). To maintain rates of false-positives and false-negatives in a similar range than obtained with the FIB4-VCTE algorithm in patients without T2D, diagnostic algorithms in patients with T2D required specialized tests (first-line VCTE or FibroMeterV2G, then second-line FibroMeterVCTE).
Conclusion: The diagnostic accuracy of NITs is different between patients with and without T2D because of the different prevalence of advanced fibrosis in these two populations, but also because T2D

itself modifies the level of some biomarkers. The diagnosis of advanced liver fibrosis in T2D should use first-line specialized tests.

OS097

Machine learning algorithms identify novel biomarker combinations for NAFLD

Jenny Lee[1], Max Westphal[2], Yasaman Vali[1], Yu Chen[3], Leigh Alexander[4], Jerome Boursier[5], Quentin Anstee[6], Aeilko Zwinderman[1], Patrick Bossuyt[1]. *[1]Amsterdam UMC, Locatie AMC, Department of Epidemiology and Data Science, Amsterdam, Netherlands; [2]Fraunhofer MEVIS, Data Science and Biostatistics, Bremen, Germany; [3]Eli Lilly and Company Ltd, Lilly Research Laboratories, Indianapolis, United States; [4]SomaLogic Inc, Boulder, United States; [5]Angers University Hospital, Hepatology Department, Angers, France; [6]Newcastle University, Translational and Clinical Research Institute, Newcastle upon Tyne, United Kingdom*
Email: j.a.lee@amsterdamumc.nl

Background and aims: Application of machine learning algorithms for developing diagnostic tests (or NITs) has grown across multiple disciplines, with models achieving promising classification performance levels. For non-alcoholic fatty liver disease (NAFLD), detection of non-alcoholic steatohepatitis (NASH) and advanced fibrosis remains challenging. We aimed to develop classifiers by applying machine learning algorithms to stage NAFLD patients.
Method: Data from the LITMUS Metacohort, which includes adults with biopsy-proven NAFLD were analyzed for NASH (NAS≥4) and advanced fibrosis (F≥3), staged according to the NASH-CRN scale. Thirty-three predictors (clinical characteristics, serum biomarkers and FibroScan-VCTE) were included in the analysis. Any missing data were handled by multiple imputation. Data were randomly split (75/25) into training and validation sets. Gradient boosting method (GBM) was applied to develop a classifier for each component of NASH (ballooning, inflammation, steatosis) and for advanced fibrosis, with repeated 10-fold cross-validation to tune hyperparameters. Class predictions for each component of NASH were aggregated to obtain a total NASH probability. Area under the receiver operating characteristic (AUC) curve was used to evaluate performance.
Results: Data from 720 NAFLD adults were analyzed (training set: 540, validation set: 180), of which 53% had NASH and 26% advanced fibrosis (including 7% cirrhotics). The AUCs for each component of NASH in the training/validation sets were: steatosis (0.68/0.66), inflammation (0.72/0.80), and ballooning (0.66/0.69). The aggregate GBM model for NASH achieved an AUC of 0.79 in the training and 0.74 in the validation set. For the GBM model for advanced fibrosis, the AUC was 0.90 and 0.84 in the training and validation sets, respectively. Different predictors were selected as most informative for the NASH components and fibrosis models (Table 1).

Table 1: Top five predictors for NASH components and fibrosis models

	Steatosis	Inflammation	Ballooning	Fibrosis
1	Body mass index (BMI)	Hemoglobin	BMI	Liver stiffness measurement-VCTE
2	Cytokeratin-18 (CK-18) M30 antigen	Age	Alkaline phosphatase	CK-18 M30 antigen
3	Age	Hyaluronic acid	Systolic blood pressure	Hyaluronic acid
4	Procollagen III peptide (P3NP)	P3NP	N-terminal type III collagen propeptide (PRO-C3)	PRO-C3
5	Alanine transaminase	Tissue inhibitor matrix metalloproteinase 1 (TIMP1)	Aspartate aminotransferase	Haemoglobin A1c

Conclusion: The GBM algorithm produced a high performing model for detecting advanced fibrosis, performance was less impressive for the NASH models. Better predictors, with understood associations to steatosis, inflammation and ballooning, are needed to develop more robust models for detecting NASH. Validation of the models in the prospective LITMUS cohort is underway.

OS098

Head to head comparison of MEFIB, MAST, and FAST for detecting candidates with stage 2 fibrosis or higher among patients with NAFLD

Beom Kyung Kim[1,2], Nobuharu Tamaki[1,3], Jinho Jung[1], Claude Sirlin[1], Atsushi Nakajima[4], Rohit Loomba[1]. *[1]University of California San Diego, La Jolla, United States; [2]Yonsei University College of Medicine, Korea, Rep. of South; [3]Musashino Red Cross Hospital, Tokyo, Japan; [4]Yokohama City University Graduate School of Medicine, Kanagawa, Japan*
Email: roloomba@ucsd.edu

Background and aims: Non-alcoholic fatty liver disease (NAFLD) patients with significant fibrosis (fibrosis stage≥2) are candidates for pharmacological trials. Here, we compared head-to-head the diagnostic accuracies of non-invasive models, MEFIB (magnetic resonance elastography [MRE] plus FIB-4), MAST (magnetic resonance imaging-aspartate aminotransferase [AST]), and FAST (FibroScan-AST) for detecting significant fibrosis.
Method: This prospective study included 563 biopsy-proven NAFLD patients undergoing contemporaneous MRE, MRI proton density fat fraction (MRI-PDFF), and FibroScan from two prospective cohorts. Each model was categorized into three classes as rule-in, indeterminate, and rule-out, using rule-in/-out criteria. Diagnostic performances of models were evaluated by area under the receiver operating characteristic (AUROC).
Results: The mean age was 56.5 years and 49% were male. Significant fibrosis was observed in 51.2%. To predict significant fibrosis, MEFIB outperformed both MAST and FAST (both $p < 0.001$); AUROCs (95% confidence interval) for MEFIB, MAST, and FAST as categorical variables were 0.901 (0.875–0.928), 0.770 (0.730–0.810), and 0.725 (0.683–0.767), respectively. Using rule-in criteria, positive predictive value of MEFIB (95.3%) was higher than FAST (83.5%, $p = 0.001$), but similar to MAST (90.0%, $p = 0.056$). Notably, MEFIB's rule-in criteria covered more of the study population than MAST (34.1% vs. 26.6%; $p = 0.006$). Using rule-out criteria, negative predictive value of MEFIB (90.1%) was higher than either MAST (69.6%) or FAST (71.8%) (both $p < 0.001$).
Conclusion: MEFIB showed the reliability of rule-in/-out, with a better predictive performance compared to MAST and FAST. Thus, a two-step strategy by MEFIB (FIB-4 followed by MRE), may be used to identify ≥2 stage fibrosis.
Key words: NAFLD, significant fibrosis, MEFIB, FAST, MAST, diagnosis, validation

OS099

Validation of the new 2021 EASL algorithm for the non-invasive diagnosis of advanced liver fibrosis in non-alcoholic fatty liver disease

Clémence M. Canivet[1,2], Adrien Lannes[1,2], Charlotte Costentin[3], Adele Delamarre[4], Nathalie Sturm[3], Frédéric Oberti[1,2], Thomas Decaens[3], Marie Irles-Depe[3], Isabelle Fouchard[1,2], Paul Hermabessière[4], Justine Barthemon[3], Victor de Lédinghen[4], Jerome Boursier[1,2]. *[1]Angers University Hospital Center, Angers, France; [2]Université d'Angers, HIFIH, UPRES EA3859, Angers, France; [3]Centre Hospitalier Universitaire de Grenoble, La Tronche, France; [4]Chu Haut Leveque, Pessac, France*
Email: clemence.canivet@chu-angers.fr

Background and aims: EASL recently proposed in its 2021 guidelines an algorithm for the diagnosis of advanced liver fibrosis (AF) in patients with non-alcoholic fatty liver disease (NAFLD). This original algorithm is based on the sequential use of FIB4, then vibration controlled transient elastography (VCTE) and, innovatively, on the use of patented serum tests as third-line procedure. Our objective was to evaluate the diagnostic accuracy of this algorithm (FIB4/VCTE/patented serum test) in a large cohort of NAFLD patients.

Method: 1, 051 NAFLD patients with liver biopsy were included in three tertiaries centres. Four non-invasive fibrosis tests were available: FIB4, VCTE, FibroMeter and Fibrotest. The ELF score was available in a subgroup of 396 patients. AF was defined on liver biopsy as fibrosis ≥F3 according to the NASH-CRN classification
Results: The median age was 58.1 years, half of the patients were diabetic, and 60% were male. The prevalence of AF was 39.5%. Agreement between two non-invasive fibrosis tests (FIB4 then VCTE, VCTE then patented serum test) increased specificity and positive predictive value to respectively 83–89% and 79–85%, versus 58–75% and 56–65% with single fibrosis tests. Within the EASL algorithm, the third line testing with a patented serum test allowed to correctly reclassify 29% (FibroMeter), 42% (Fibrotest) and 65% (ELF) of the false positive results following the FIB4 then VCTE sequence. All these results justified the sequential use of NITs proposed by the EASL algorithm. Accuracy of the EASL algorithm for the diagnosis of AF is detailed in the Table. In the whole study population, both FIB4/VCTE/FibroMeter and FIB4/VCTE/Fibrotest algorithms performed similarly. Same results were obtained in the subgroup of 396 patients where the FIB4/VCTE/ELF algorithm was available. In the whole population, 28.7% of F3-F4 patients were false negatives, among whom only 18.5% had cirrhosis. The EASL algorithm provided 85% sensitivity for the diagnosis of cirrhosis.
Conclusion: Our study validates the algorithm proposed by the EASL in its latest 2021 guidelines for the diagnosis of AF in NAFLD.

Figure: Accuracy of the 2021 EASL algorithm for the diagnosis of AF

	Whole study population (n = 1, 051)		ELF group (n = 396)

OS101

Utility of FIB-4 thresholds to identify patients with at-risk F2-F3 NASH based on screening data from a 2000 patient biopsy confirmed cohort of resmetirom Phase 3 clinical trial, MAESTRO-NASH

Jörn Schattenberg[1], Naim Alkhouri[2], Rebecca Taub[3], Jim Hennan[4], Mazen Noureddin[5], Stephen Harrison[6]. *[1]Johannes Gutenberg-University Mainz; [2]Arizona Liver Institute; [3]Madrigal Pharmaceuticals, Conshohocken, United States; [4]Madrigal Pharmaceuticals; [5]Cedar Sinai Medical Center; [6]Pinnacle Research, United States*
Email: rebeccataub@yahoo.com

Background and aims: MAESTRO-NASH NCT03900429 is a 52-week Phase 3 registrational double blind placebo controlled NASH clinical trial to study the effect of resmetirom in patients with NASH and significant liver fibrosis. Eligibility requires at least three metabolic risk factors, fibroscan VCTE kPa ≥8.5 and biopsy-proven NASH with fibrosis stage 1B, 2, or 3 (or 1A/C with PRO-C3≥14), and NAFLD activity score (NAS) ≥4 with at least 1 in each NAS component. FIB-4 of ≥1.3 is frequently used to identify potential at-risk NASH patients and patients with FIB-4 <1.3 may be considered low risk.
Method: FIB-4 cutoff values of 1.3 and 1.0 were applied to ~2000 patients who screened for MAESTRO-NASH with screening labs, fibroscan, MRE, MRI-PDFF and a screening liver biopsy. Relationships between screening FIB-4 ≥1.0 and ≥1.3 and liver biopsy NAS and fibrosis stage were assessed.
Results: 56.9% F2, 40.3% F3, 24.4% F4 biopsy confirmed patients had FIB-4 < 1.3 and, 46.4% of patients with active NASH (NAS≥4) fibrosis F2/F3 had FIB-4 < 1.3 (Table). 32.6% of F2 and 18.0% of F3 subjects had FIB-4 < 1.0. In patients with active NASH (NAS≥4), 41.7% of F2 and 17.3% of F3 subjects had FIB-4 < 1.0. NAS ≥ 4 F2-F3 patients with FIB-4 ≥ 1.3 had mean age 61.1 while NAS ≥ 4 F2-F3 patients with FIB-4 < 1.3 had mean age 52.2 (p < 0.001); those with FIB-4 ≥ 1.0 had mean age 59.9; NASH patients with FIB-4 < 1.0, had mean age 47.6 (p < 0.001). More low risk NAFLD patients (F0, F1A/C) had FIB-4 < 1.3 than FIB-4 < 1.0 (F0, 84.3% versus 58.1%, respectively). Absolute values of AST (p < 0.0001), ALT (p < 0.0001), PRO-C3 (p < 0.0001), HbA1c (p = 0.0001), GGT (p < 0.0001) and MRE (p < 0.0001) showed statistically significant differences between low risk (F0) and high risk (F2–F3) NASH patients and could be used to further stratify risk.
Conclusion: Based on a large Phase 3 data set of biopsy confirmed NASH patients, FIB-4 ≥ 1.3 lacks the sensitivity to accurately identify patients with at-risk F2–F3 NASH. The influence of age on FIB-4 may require an age adjustment to ensure younger patients are not removed from consideration for therapy.

Radiomic model based on contrast-enhanced CT imaging to predict early recurrence for patients with hepatocellular carcinoma after radical resection

Liying Ren[1], Dongbo Chen[2], Tingfeng Xu[1], Pu Chen[2], Bigeng Zhao[1], Hongsong Chen[2], Weijia Liao[1]. *[1]Affiliated Hospital of Guilin Medical University, Laboratory of Hepatobiliary and Pancreatic Surgery; [2]Peking University People's Hospital, Peking University Hepatology Institute, Beijing Key Laboratory of Hepatitis C and Immunotherapy for Liver Disease, China*
Email: liaoweijia288@163.com

Background and aims: Radical resection remains an effective strategy for patients with hepatocellular carcinoma (HCC), unfortunately, the postoperative early recurrence (recurrence within 2 years) rate is still high. Therefore, we developed a radiomic model based on preoperative contrast-enhanced CT (ce-CT) to evaluate the early recurrence for patients with a single tumor.
Method: We enrolled a total of 422 patients from two centers who were diagnosed with single HCC and received radical resection. At first, the features from venous and arterial phase of ce-CT were extracted based on the region of interest (ROI), and the early recurrence related radiomic features were selected via the Least

Absolute Shrinkage and Selection Operator proportional hazards model (LASSO Cox) model and determined radiomic scores for each patient. Then the clinicopathologic data were combined to develop a model to predict early recurrence by Cox regression. Last we evaluated the prediction effect of this model by multiple methods.

Results: A total 1915 radiomic features were extracted from ce-CT images, and 31 of them were used to determine the radiomic scores, which showed significant difference between early recurrence and non-early recurrence groups. Univariate and multivariate Cox regression analyses result showed radiomic scores and serum AFP were independent indicators and were used to develop a combined model to predict early recurrence. The area under the receiver operating characteristic curve (AUC) were 0.77 and 0.74, while C-indexes were 0.712 and 0.674, respectively in the training and validation cohorts. The calibration curves and decision curve analysis showed satisfactory accuracy and clinical utilities, as well. Kaplan-Meier curves based on the recurrence-free survival (RFS) and overall survival (OS) showed significant differences.

Conclusion: The preoperative radiomic model showed value to predict early recurrence for patients with single HCC.

Background and aims: Cholangiocarcinomas (CCAs), heterogeneous biliary tumors with dismal prognosis, lack accurate early-diagnostic methods, especially important for individuals at high-risk (*i.e.* primary sclerosing cholangitis (PSC)). Here, we aimed to identify precise non-invasive CCA biomarkers.

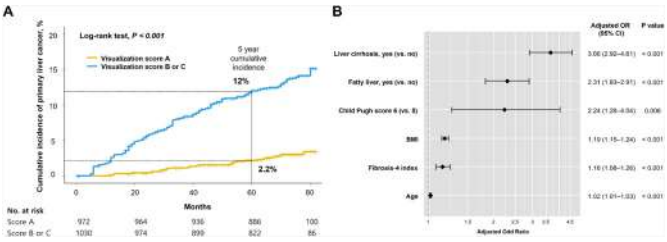
Method: Serum extracellular vesicles (EVs) from patients with: *i*) isolated PSC (n = 39); *ii*) PSC without clinical evidences of malignancy at sampling who developed CCA overtime (PSC to CCA; n = 10); *iii*) concomitant PSC-CCA (n = 14); *iv*) CCAs from non-PSC etiology (n = 26); and *v*) healthy individuals (n = 41) were analyzed by mass-spectrometry. Diagnostic biomarkers of PSC-CCA, non-PSC CCA or CCAs regardless etiology (pan-CCAs) were defined, and their expression evaluated in human multi-organs and within CCA tumors at single-cell level. Prognostic EV-biomarkers for CCA were described.

Results: High-throughput proteomics identified candidate diagnostic biomarkers for PSC-CCA, non-PSC CCA or pan-CCA, independent to sex, age and CCA subtype. Machine learning logit modelling disclosed PLCH1/FGL1 algorithm with diagnostic value of AUC = 0.903 and OR = 27.8 for early-stage PSC-CCA *vs* isolated PSC, overpowering CA19–9 (AUC = 0.608, OR = 2.0). An algorithm combining SAMP/A1AT allowed the diagnosis of early-stage non-PSC CCAs compared to healthy individuals (AUC = 0.863, OR = 18.5). Noteworthy, the levels of 6 proteins (ALBU;FIBB;FLG1;IGHA1;TLN1;IMA8) showed predictive value for CCA development in patients with PSC before clinical evidences of malignancy. Multi-organ transcriptomic analysis revealed that serum EV-biomarkers were mostly expressed in hepatobiliary tissues and scRNA-seq analysis of CCA tumors indicated that some biomarkers -including PIGR, FGG, SERPINA1, FGL1- were mainly expressed in malignant cholangiocytes. Multivariable analysis revealed EV-prognostic biomarkers independent to clinical features,

with FCN2/SDPR/FA9 panel being strongly associated to patients' survival.
Conclusion: Serum EVs contain etiology-specific protein biomarkers for the prediction, early diagnosis and prognosis estimation of CCA, representing a novel tumor cell-derived liquid biopsy for personalized medicine.

OS104
Evaluation of the effectiveness of surveillance according to the ultrasound liver imaging reporting and data system (US LI-RADS) visualization score in patients with chronic hepatitis B
Min Kyung Park[1], Yun Bin Lee[1], Yoon Jun Kim[1], Jung-Hwan Yoon[1], Dong Ho Lee[2], Jeong-Hoon Lee[1]. *[1]Seoul National University College of Medicine, Department of Internal Medicine and Liver Research Institute, Seoul, Korea, Rep. of South; [2]Seoul National University College of Medicine, Department of Radiology, Seoul, Korea, Rep. of South*
Email: pindra@empas.com

Background and aims: Ultrasonography (US) is a standard surveillance tool of hepatocellular carcinoma (HCC) in the high-risk group. This study evaluated the detection power of the US and the occurrence of primary liver cancer (PLC) according to the US Liver Imaging Reporting and Data System (LI-RADS) visualization score.
Method: Consecutive patients with chronic hepatitis B undergoing regular HCC surveillance were included in this cohort study. Outcomes of interest included cumulative incidence of PLC and false-negative rate of US (defined as no HCC on US conducted within 3 months prior to PLC diagnosis) according to baseline LI-RADS visualization scores (A vs B/C). Risk factors associated with poor visualization score were also analyzed.
Results: A total of 2, 002 patients were included in this study: 972 were classified as visualization score A and 1, 030 as either visualization score B or C (score B, 1, 003; score C, 27). During a median follow-up of 75 months (interquartile range, 69–77 months), 166 patients developed PLC (HCC, 158; others, 8). Patients with poor visualization score (visualization score B or C) has significantly higher risk of PLC than those with visualization score A (2.41%/year vs. 0.50%/year: hazard ratio, 4.83; 95% confidence interval, 3.24–7.21; $p < 0.001$ by log-rank test) (Figure 1A). Higher false-negative rate of US was observed in the poor visualization group than visualization score A (43.5% vs. 20.0%). Furthermore, among 51.2% (85 of 166) patients diagnosed as very early-stage PLC, merely 13.9% (10 of 72) of patients with visualization score B/C were detected with US, while in 53.8% (7 of 13) among patients with visualization score A. Poor visualization score was independently associated with the presence of liver cirrhosis (adjusted odds ratio [aOR], 3.66) or fatty liver (aOR, 2.31), high body mass index (aOR, 1.19), high FIB-4 score (aOR, 1.16), and Child-Pugh score 6 (vs score 5: aOR, 2.24) (Figure 1B).



Conclusion: Chronic hepatitis B patients with US LI-RADS visualization score B/C had a higher risk of PLC as well as false-negative rate of US than those with score A. Surveillance using alternative computed tomography or magnetic resonance imaging might be highly recommended for patients with US LI-RADS visualization score B or C.

Email: wkseto@hku.hk

Background and aims: Liver cancer ranks second globally in cancer death and has a high case-fatality rate. The Liver Imaging Reporting and Data System (LIRADS) categorizes liver observations on cross-sectional imaging based on hepatocellular carcinoma (HCC) risk. Intermediate-risk observations require repeated scans making an early diagnosis of HCC difficult. It remains uncertain if artificial intelligence can improve the diagnostic performance of computed tomography (CT) for HCC.
Method: We retrospectively collected archived thin-cut (<1.25 mm slice thickness) contrast triphasic CT images in raw DICOM format and relevant clinical information. CT observations were contoured and categorized via LIRADS, with ground truth diagnosis of HCC established via AASLD recommendations and validated by a clinical composite reference standard based on subsequent 12-month outcomes. We constructed several deep learning algorithms (NVIDIA Tesla V100 GPUs, Dell Technologies), including the multiscale three-dimensional convolutional network (MS3DCN, Figure 1) model which uniquely considers the multi-phasic nature of CT, and followed the Checklist for AI in Medical Imaging (CLAIM) framework for algorithm training, validation and testing.

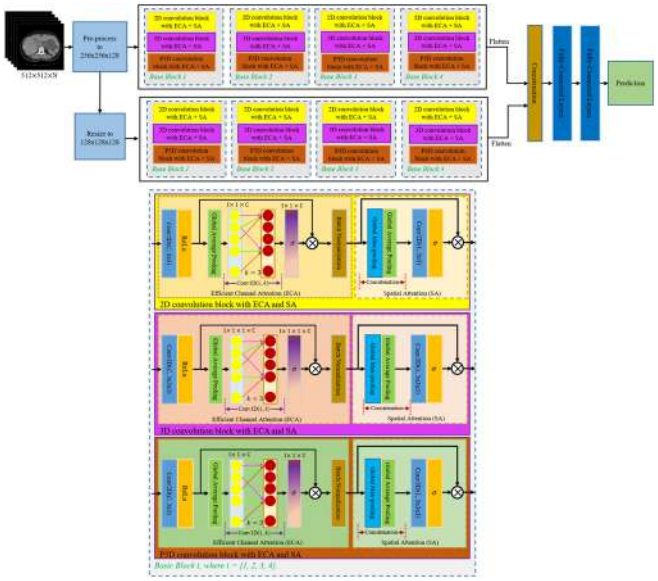

Figure 1. Model architecture of the MS3DCN deep learning algorithm to achieve an accurate diagnosis of HCC

Results: Among 2, 796 retrieved scans, 2, 281 were included with 3, 620 liver observations contoured. The cohort's mean age was 58.4 ± 14.2 years, 61.0% male, with 1, 214 (53.2%) at-risk for HCC. Median observation size was 21.0 (IQR 12.6–41.3) mm; 793 (21.9%) had a ground truth diagnosis of HCC. After randomly dividing observations into training and validation sets in a 7:3 ratio, MS3DCN was the best-performing algorithm at observation level for diagnosing HCC, achieving an AUC of 96.9% (95%CI 95.3%–98.2%), sensitivity 95.9%, specificity 98.1%, positive predictive value (PPV) 93.7%, and negative predictive value (NPV) 98.8%; compared to AUC 85.3% (95%CI 82.4%–88.1%), sensitivity 71.3%, specificity 99.3%, PPV 96.7% and NPV 91.9% for LIRADS. Sensitivity analysis found MS3DCN's diagnostic performance to remain robust, achieving an AUC of 96.3% (95%CI 95.8%–97.6%) at patient level and 97.1% (95%CI 95.3%–98.6%) in the at-risk cohort. In external testing of an independent cohort of 551 scans and 780 observations, MS3DCN achieved an AUC of 98.0% (95%CI 96.8%–99.0%) and 97.6% (95%CI 96.0%–98.9%) at observation and patient level respectively.

Conclusion: The MS3DCN deep learning model deployed to triphasic CT was highly and robustly accurate in diagnosing HCC, superior to LIRADS, with performance validated via internal validation and external testing. Artificial intelligence-based technologies can facilitate precise establishment of diagnosis and improve clinical outcomes. *Supported by the Innovation and Technology Fund, the Government of the HKSAR; and United Ally Research Limited, a subsidiary of Hong Kong Sanatorium and Hospital Limited.*

OS106

Lifestyle factors and population attributable risk of hepatocellular carcinoma in lean vs non-lean populations

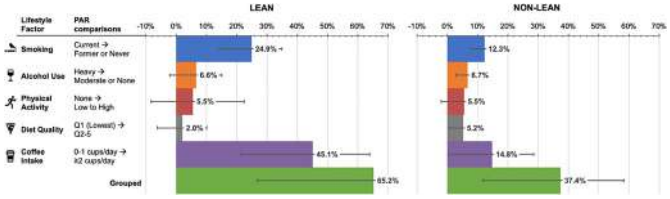
Kali Zhou[1], Tiffany Lim[1], Jennifer Dodge[1], Norah Terrault[1], Veronica Setiawan[1]. [1]*University of Southern California, Los Angeles, United States*
Email: kalizhou@usc.edu

Background and aims: Several lifestyle factors are associated with risk of hepatocellular carcinoma (HCC), but actual impact may differ in individuals with normal (lean) vs elevated (non-lean) body mass index (BMI) due to differential prevalence. We aim to estimate the population attributable risk (PAR) of modifiable lifestyle factors to HCC burden in lean vs non-lean populations to prioritize these factors for patient-level counseling and population-level cancer prevention.

Method: We conducted prospective analysis using data from the Multiethnic Cohort (MEC), a large diverse cohort in Los Angeles County/Hawaii with >20 years of follow-up. Incident HCC was identified via cancer registry linkage. Lifestyle factors were obtained from baseline questionnaire: smoking (never/former/current), alcohol (none/low/heavy), diet quality (alternate Mediterranean diet (aMED) score: Q1 = lowest to Q5 = highest adherence), physical activity (none/low/high), and coffee intake (0, 1, ≥2 cups per day). Lean was defined as BMI <23 kg/m^2 for Asians and <25 kg/m^2 for non-Asians. BMI-stratified multivariable Cox models examined association of each factor with HCC adjusted for age, sex, race/ethnicity, diabetes, and hypertension, followed by calculation of PAR (%).

Results: Of 181, 346 at risk participants, 753 developed HCC during an average follow-up of 19.8 years. 23.1% of cases vs 35.0% of non-cases were lean. At baseline, prevalence of current smoking was higher in lean vs non-lean cases (33.2% vs 21.8%); 23.1% in both groups reported heavy alcohol use. No physical activity was reported in 50.3% of lean vs 45.0% non-lean cases, while 76.4% vs 84.6% had suboptimal adherence to aMED diet (Q1–4). ≥2 cups/day of coffee was reported by 14.2% of lean vs 22.0% of non-lean cases. Smoking (former vs. never: HR = 2.08, 95% CI 1.39–3.09; current vs. never: HR = 4.41, 2.85–6.81) and coffee (≥2 vs 0 cups/day: HR = 0.47, 0.29–0.77) were associated with developing HCC for lean participants, compared to smoking (former: HR = 1.55, 1.26–1.89; current: HR = 2.62, 2.04–3.35), diet quality (Q5 vs Q1: HR = 0.61, 0.46–0.80), and coffee (≥2 vs 0 cups/day: HR = 0.77, 0.60–0.98) for non-lean participants. Alcohol use approached significance in the non-lean group (heavy vs none: HR 1.22, 0.98–1.53) while physical activity was not significant for either group. Overall, the combined PAR for lifestyle factors was 65.2% in lean compared to 37.4% in non-lean. The lifestyle factor with highest PAR for both was coffee (45.1% lean, 14.8% non-lean), followed by smoking (24.9% lean, 12.3% no-lean). All other lifestyle factors had PAR <10%.

Conclusion: HCC burden can be substantially reduced through modifiable lifestyle factors, more prominently for lean compared to non-lean populations. Drinking ≥2 cups of coffee per day could reduce up to 45% of HCC burden among lean individuals. Diet and lifestyle counselling are critical to HCC prevention.



OS107

Validation of the prognostic role of a new distinct assessment of liver function in non surgical HCC patients

Bernardo Stefanini[1], Benedetta Stefanini[2], Andrea De Sinno[3], Francesco Tovoli[4], Franco Trevisani[5], Fabio Piscaglia[4]. [1]*Division of Internal Medicine, Hepatobiliary and Immunoallergic Diseases, IRCCS Azienda Ospedaliero-Universitaria di Bologna, Bologna, Italy;* [2]*Semeiotica Medica, Azienda Ospedaliero-Universitaria di Bologna, Bologna, Italy;* [3]*Alma Mater Studiorum-University of Bologna, Bologna, Italy;* [4]*Division of Internal Medicine, Hepatobiliary and Immunoallergic Diseases, IRCCS Azienda Ospedaliero-Universitaria di Bologna, Department of Medical and Surgical Sciences (DIMEC), University of Bologna, Bologna, Italy;* [5]*Semeiotica Medica, Azienda Ospedaliero-Universitaria di Bologna, Department of Medical and Surgical Sciences (DIMEC), University of Bologna, Bologna, Italy*
Email: bernardo.stefanini@gmail.com

Background and aims: While the role of distinct HCC tumor burdens is quite consolidated, new insights about the impact of more granular assessment of liver function in the prognosis of HCC patients are emerging.

A very recent review published in Journal of Hepatology described the prognostic relevance of liver functional reserve across the various non-surgical HCC treatments. Based on their experience, the authors proposed a new staging algorithm combining liver functional reserve and tumor bulk separating patients even within the Child-Pugh A and B classes. The present study aims to validate the prognostic role of such system.

Method: We retrospectively evaluated all patients with HCC who were not surgically treated in two large Italian centers between 2010 and 2021. A Kaplan-Meier survival analysis was carried out classifying patients according to the new classification proposed by D'avola, Piscaglia et al. which identifies four different subclasses considering the liver functional reserve:

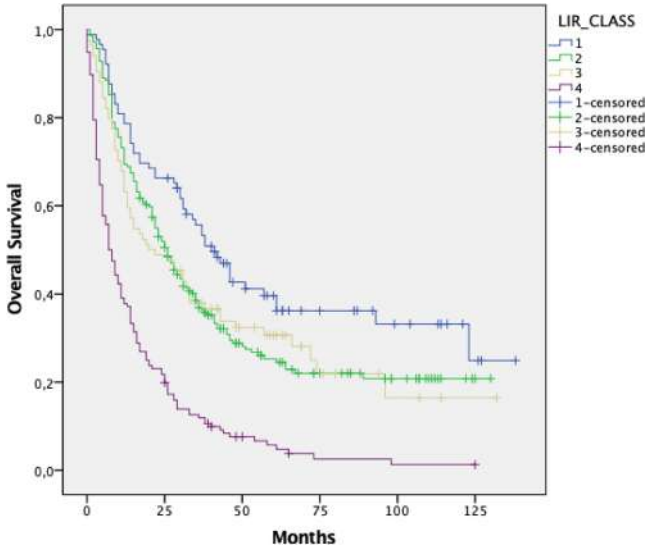
LIR 1 (optimal) includes CPT class A patients with CPT score A5 and with no previous hepatic decompensation, no high risk varices, tumor related performance status (PS) ≤1 and ALBI grade = 1.

LIR 2 (suboptimal) includes CPT class A patients with ALBI grade ≤2 and PS≤1 and either CPT score A5 but with a history of previous hepatic decompensation or score A6 (regardless of previous history of decompensation).

LIR 3 (intermediate) includes CPT class B patients with a CPT score of B7 and PS≤1 regardless of any previous decompensation.

LIR 4 (poor) includes decompensated CPT B or C cirrhotic patients with a PS≥2.

Results: A total of 538 patients were analyzed. Median overall survival was 41 months in LIR 1 (89 pts), 26 months in LIR 2 (209 pts), 20 months jn LIR 3 (84 pts) and 16 months in LIR 4 (156 pts). Interestingly, LIR 1 median OS was significantly higher than LIR 2 subgroup ($p < 0.05$), despite both including only CPT class A patients. LIR 2 OS which instead was closer to that of LIR 3 subgroup suggesting an important prognostic role for ALBI grade and past episodes of hepatic decompensation even for patients within the Child-Pugh A class. Additionally within the CPT B/C classes, a current decompensation must be kept separated from CPT B7 patients.



Conclusion: This new classification based on more granular assessment of liver functional reserve confirms its significant prognostic impact with significant differences even within the same Child-Pugh class.

Structured early detection of compensated advanced chronic liver disease-results of the SEAL program

Christian Labenz[1], Anita Arslanow[1], Michael Nagel[2], Marc Nguyen-Tat[3], Marcus-Alexander Wörns[2], Matthias Reichert[4], Franz Josef Heil[5], Dagmar Mainz[5], Gudula Zimper[6], Barbara Römer[7], Johannes Jäger[8], Erik Farin-Glattacker[9], Urs Fichtner[9], Harald Binder[9], Erika Graf[9], Dominikus Stelzer[9], Reyn van Ewijk[10], Julia Ortne[10], Louis Velthuis[10], Frank Lammert[8,11], Peter Galle[1]. *[1]University Medical Center Mainz, Germany; [2]Dortmund Hospital; [3]Allgäu Hospital Group; [4]Saarland University Medical Center; [5]German Gastroenterology Association; [6]General Practitioners' Association Saarland; [7]General Practitioners' Association Rhineland-Palatinate; [8]Saarland University; [9]University of Freiburg; [10]Johannes Gutenberg University Mainz; [11]Hannover Medical School*
Email: anita.arslanow@uni-mainz.de

Background and aims: Detection of patients with compensated advanced chronic liver disease (cACLD) is of pivotal importance to prevent the occurrence of complications and improve prognosis. However, a structured screening program to detect patients with cACLD has not been implemented into daily routine. Therefore, it was the aim of the SEAL (structured detection of early liver cirrhosis) program to evaluate the usefulness of a structured screening program to detect cACLD.

Method: SEAL was a prospective cohort study conducted in two states in Germany, Rhineland-Palatinate and Saarland, between 01/2018 and 02/2021. Patients participating in a precautionary program (Check-up 35) with their primary care physician were offered additional testing of liver function tests (AST and ALT). If AST/ALT levels were elevated, the APRI score was calculated, and patients with a score >0.5 were referred to a gastroenterologist/hepatologist for more detailed evaluation of their liver disease. The primary end point of this study was the diagnostic rate of cACLD (F3 and F4) compared to a retrospective cohort (ICD-10 codes) of patients attending check-up 35 in the two states during 2016–2017 (n = 349, 570).
Results: In total, 11, 859 patients were enrolled into the SEAL program. Slightly more women (54.5%) than men participated in the program, and the mean age of the cohort was 60 years. Elevated LFTs were found in 737 patients (6.1%). The most frequent aetiology of liver disease was non-alcoholic fatty liver disease (59%) followed by chronic alcohol abuse (18%). cACLD was detected in 45 patients. The standardized incidence of cACLD in the SEAL cohort was slightly higher than in controls (3.832‰, 95% CI 2.475, 5.188 vs. 3.358‰, 95% CI 3.136, 3.580). In logistic regression analyses, SEAL was not associated with a higher detection rate of cACLD after adjusting for age and gender (OR 1.141, one-sided 95% CI 0.801, +Inf). When patients with decompensated cirrhosis at diagnosis were excluded from the control cohort, SEAL was associated with a higher detection rate of cACLD on logistic regression analysis (OR 1.586, one-sided 95% CI 1.056, +Inf).
Conclusion: The implementation of a structured screening program may increase the detection rate of cACLD in the general population. In this context, the SEAL program may serve as a feasible concept.

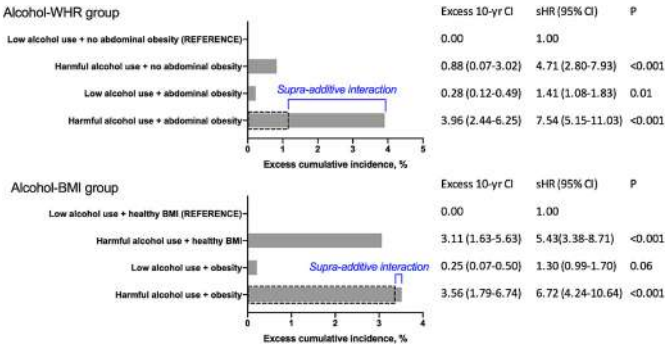
OS109

Abdominal obesity is key when evaluating interactions between alcohol use and obesity for liver disease

Fredrik Åberg[1], Veikko Salomaa[2], Martti Färkkilä[3], Antti Jula[2], Satu Männistö[2], Markus Perola[2], Annamari Lundqvist[2], Ville Tapio Männistö[4]. *[1]Helsinki University Hospital and University of Helsinki, Transplantation and Liver Surgery, Helsinki, Finland; [2]Finnish Institute for Health and Welfare, Helsinki, Finland; [3]Helsinki University Hospital and University of Helsinki, Department of Gastroenterology, Helsinki, Finland; [4]University of Eastern Finland and Kuopio University Hospital, Departments of Medicine, Kuopio, Finland*
Email: fredrik.aberg@helsinki.fi

Background and aims: Alcohol use and obesity are independent risk factors for chronic liver disease, but controversy exists regarding possible interaction effects between alcohol and obesity for incident liver disease, and regarding the best obesity measure to predict future liver disease. The waist-hip ratio (WHR) as a measure of abdominal obesity has been suggested to better reflect the metabolic risks associated with obesity and the risk for incident liver disease compared to body mass index (BMI), but population-based studies are scarce. In a large population cohort, we compared the predictive performance of BMI and WHR for incident liver disease, and their interaction with alcohol use.
Method: Data from the Finnish health-examination survey (FINRISK 1992–2012 and Health 2000) were linked with national healthcare registers for hospitalization, cancer and death related to liver disease. Subjects with baseline liver disease were excluded. Predictive performance was assessed by Harrell's C. Cumulative 10-year incidence according to alcohol use (low use: men <176 g/wk; women <120 g/wk; harmful use: men >392 g/wk, women >280 g/wk) and waist-hip ratio (WHR) (reference: lowest sex-specific tertile; abdominal obesity: highest sex-specific tertile), and alcohol and BMI (healthy: BMI 20–25 kg/m^2; obesity: BMI >30 kg/m^2), were calculated by the Aalen-Johansen and Fine-Gray competing-risk methods (subdistribution HRs adjusted for age, sex, education level, employment and marital status). Excess cumulative incidence was calculated

by subtracting the cumulative incidence observed in a specific group from the cumulative incidence in the reference group.
Results: Study comprised 40923 adults: 47% men, mean age 50 years (SD 14), 21% with BMI >30 kg/m^2, mean WHR 0.96 (men)/0.83 (women) (SD 0.07), and 82% with low alcohol use. There were 355 liver-related events during a median 12.9-year follow-up (IQR 7.8–17.8).
C-statistic in predicting liver outcomes was 0.58 (95% CI 0.55–0.62) for BMI and 0.72 (95% CI 0.68–0.75) for WHR. Supra-additive interaction between harmful alcohol use and BMI for liver outcomes was minimal, while the interaction between harmful alcohol use and WHR was considerable (excess 10-year cumulative incidence due to interaction: 3.96–0.28–0.88 = 2.8%, Figure).



Conclusion: WHR is superior to BMI in predicting incident liver disease in the general population. WHR shows profound interaction effect with high alcohol use for incident liver disease, which is not seen with BMI.

OS110

The number of public health policies reduces the burden and mortality of alcohol-associated liver disease worldwide: a call for action

Background and aims: Harmful alcohol consumption cause a significant burden of disease worldwide. To date, the impact of alcohol-related public health policies (PHP) in alcohol-associated liver disease (ALD) has not been adequately addressed. We aimed to assess the association between alcohol-related PHP and ALD mortality worldwide.
Method: We performed an ecological multi-national study including 193 countries. We recorded socio-demographic data from the World Bank Open Data source. We registered the presence of alcohol-related PHP in each country from the WHO GISAH (in 2016). Data on alcohol consumption measures and their harmful health consequences were collected from the WHO Global Information System of Alcohol and Health (GISAH) and the Global Burden of Disease (GBD) databases (updated to 2019). We constructed generalized linear models (GLM) with a Poisson family distribution, logit link, and a robust variance estimator to assess the association between the number of PHP and disease burden outcomes. The models were adjusted by population size and population structure.
Results: We included 193 countries (7, 626, 289, 120 inhabitants); the median number of PHP was 7 [6–8]. The most developed categories were drink-driving policies and countermeasures (92.2%), tax regulations (87%), limiting drinking age (84.5%), and restrictions to alcohol access (81.9%). Other categories were national license, production, and selling control (81.9%), government monitoring systems and community support (74.1%), control over advertising and promotion (70.5%), and presence of a national plan (50.3%). Importantly, as higher number of PHP was associated with lower mortality due to cirrhosis (all causes) (prevalence ratio [PR]:0.78 95% CI: 0.67–0.90; p = 0.001), mortality due to ALD (RP:0.81 95%CI: 0.68–0.98; p = 0.029), cardiovascular mortality (PR:0.81 95%CI: 0.67–0.98; p = 0.029), and alcohol use disorder (AUD) (PR:0.80 95%CI: 0.63–0.99; p = 0.046) (Figure). The association between PHP on alcohol consumption and burden of disease was significantly higher in Africa, the Americas, and Asia.

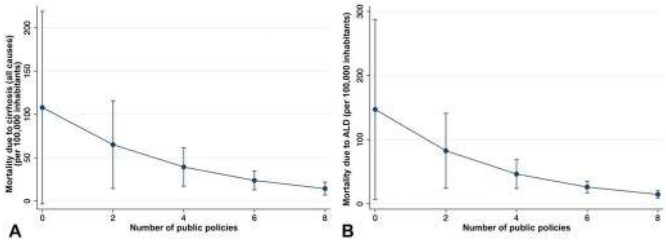

Figure: Relationship between alcohol-related public health policies and (A) deaths due to cirrhosis (all causes), and (B) deaths due to alcohol-associated liver disease (ALD) in 2019.

Conclusion: Those countries with a higher number of PHP had lower mortality due to cirrhosis (all causes), mortality due to ALD, cardiovascular mortality, and AUD. Our results strongly encourage the development and implementation of PHP on alcohol consumption worldwide.

Smoking, alcohol consumption and combined association risk for developing liver cancer in chronic hepatitis B: a prospective study

Cao Maomao[1], Wanqing Chen[1]. [1]*National Cancer Center/National Clinical Research Center for Cancer/Cancer Hospital, Chinese Academy of Medical Sciences and Peking Union Medical College, Office of Cancer Screening, Beijing, China*
Email: chenwq@cicams.ac.cn

Background and aims: Evidence of liver cancer with tobacco smoking and alcohol consumption remains controversial. We aimed to investigate associations between liver cancer risk and alcohol consumption, smoking, and the combined interaction between these two risk factors in this prospective study.
Method: Baseline smoking and alcohol consumption were collected from all subjects in a population-based prospective cohort. Cox proportional hazard regression models were used to estimate hazard ratios (HRs) and 95% confidence intervals (CIs) adjusting for potential confounders. The population attributable fractions (PAFs) were estimated. The cumulative incidences of liver cancer were generated with the use of Kaplan-Meier methods and compared based on the log-rank test.
Results: A total of 4003 participants were included in this study up to 3 years of follow-up, 72 liver cancer cases were identified. Alcohol consumption was found to increase the risk of liver cancer with a non-significant difference (Adjusted HR = 1.19, 95% CI = 0.66–2.16, PAF = 3.83%). Smoking increased the risk of liver cancer in men (HR = 1.59, 95% CI = 1.22–2.06, PAF = 26.69%). A dose-responsive pattern between the duration and intensity of smoking and the risk of liver cancer was noted. Similar results were also observed in men. Further statistical analysis revealed interactions between the effect of smoking and alcohol consumption on the risk of liver cancer, contributing to 11.12% of liver cancer cases in our cohort.
Conclusion: The findings further support smoking is an independent risk of liver cancer with a clear dose-and duration-dependent relation. We also showed the combined effect of alcohol consumption and smoking on the development of liver cancer.

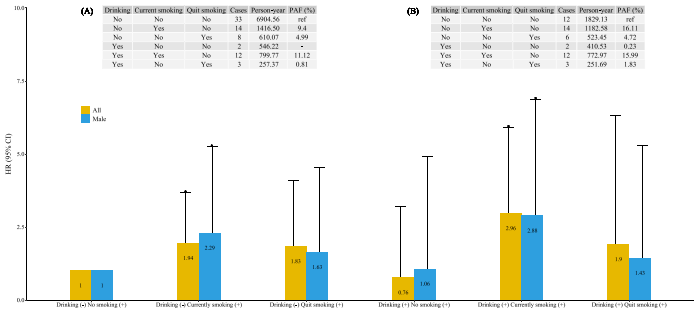

Figure 1: The synergistic effect of smoking and alcohol contributed to liver cancer risk (A. All population; B Male sex).

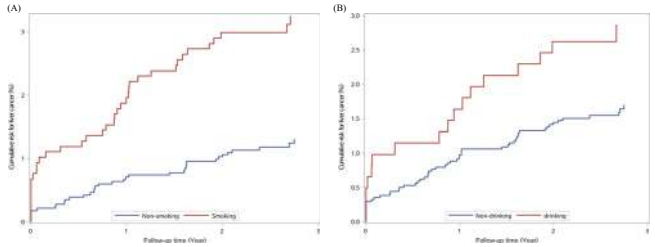

Figure 2: The cumulative incidence of liver cancer by drinking and smoking status (A. Smoking; B. Drinking).

Email: patrik.nasr@liu.se

Background and aims: Chronic liver diseases affects approximately 844 million individuals and causes an estimated two million deaths per year. The most common causes are chronic viral hepatitis, alcohol-related liver disease and non-alcoholic fatty liver disease. With the availability of curative treatments and effective vaccines for viral hepatitis and increasing prevalence of metabolic syndrome-the landscape of liver diseases is shifting. In this study, we aimed to describe the incidence and prevalence of a wide range of chronic liver diseases as well as their role in mortality in Sweden.
Method: In this register-based, nationwide cohort study, aggregated statistics, stratified on categories of age, sex and geographical locations, on all adult Swedish inhabitants with a diagnosis of liver disease during 2005 to 2019 were obtained from National registers.
Results: During 2005 to 2019, there were substantial changes in the epidemiology of liver diseases in Sweden. The incidence of alcohol-related cirrhosis increased by 18% annually (incidence rate 13.1/100, 000 in 2019). The incidence rate of non-alcoholic fatty liver disease and cirrhosis with unspecified etiology increased by 14% and 20% annually respectively (incidence rate 15.2 and 18.7/100, 000). Furthermore, incidence rates of chronic hepatitis C steeply declined, while autoimmune hepatitis increased (3.4/100, 000). In parallel with the increasing incidence of liver cirrhosis, liver malignancies have become more common.
The most common causes of liver related mortality were alcohol-related disease without a code for cirrhosis, alcohol-related cirrhosis, and unspecified liver disease with mortality rates of 4.1, 2.9, and 2.8/100, 000. Most liver diseases were more frequent amongst men. Furthermore, varying differences was seen in the incidence rate between regions, with some etiologies (*e.g.* autoimmune liver diseases) being more common in rural areas.
Conclusion: The incidence rates of non-alcoholic fatty liver disease, alcohol-related cirrhosis, unspecified liver cirrhosis has increased during the last 15 years, in parallel with a decreasing incidence of viral hepatitis. The incidence of AIH and hepatobiliary malignancies is also increasing. Worryingly, mortality in several liver diseases increased, likely reflecting the increasing incidence of cirrhosis. Significant disparities of liver diseases exist across sex and geographical regions, which needs to be considered when allocating healthcare resources.

Email: kabbani.abdul-rahman@mh-hannover.de

Background and aims: Systemic inflammation has been associated with an increased risk for cardiovascular events. Liver cirrhosis is associated with both systemic inflammation and endothelial dysfunction. However, a possible link between liver cirrhosis and cardiovascular diseases remains poorly investigated. We here aimed to analyze the risk of cardiovascular events (myocardial infarction and stroke) in patients with liver cirrhosis compared to non-cirrhotic patients in a population-based study from Northern Germany.
Method: Analysis was based on administrative data from one large German public health insurance fund. All adult individuals continuously insured until death or the end of observation period (2010–2019) were included. We used a pre-observation period (2010–2012) to exclude individuals with cardiovascular events prior to the start of observation in 2013. The presence of liver cirrhosis and cardiovascular risk factors were identified using ICD-10 codes. Myocardial infarction and stroke were analyzed as a composite and as individual end points. To determine the risk of cardiovascular events in patients with liver cirrhosis we used a multivariable Cox regression adjusted for age, gender and selected cardiovascular risk factors (hypertension, heart failure, atherosclerosis, chronic ischemic heart disease, obesity, nicotine abuse, dyslipidemia, diabetes, alcohol abuse and chronic renal failure with dialysis).
Results: A number of 1.29 million patients were included. Liver cirrhosis was present in 6, 517 individuals (0.51%) at the start of the observation in 2013. Individuals with liver cirrhosis were older (62.8 vs. 55.9 yr), more often male (60.4% vs. 44.6%) and had more comorbidities (e.g. alcohol abuse 39.5% vs. 2.3% or atherosclerosis 11.3% vs. 5.4%). Overall incidence of cardiovascular events was significantly higher among patients with cirrhosis (7.7% vs 5.9%, $p < 0.001$). This difference was also documented when limiting the analysis to the incidence of strokes (5.1% vs 3.5%, $p < 0.001$). In contrast, myocardial infarctions occurred with a similar frequency in cirrhotic and non-cirrhotic individuals (2.8% vs 2.6%, $p = 0.327$). After adjusting for potential confounders in the multivariable cox regression analysis liver cirrhosis was associated with a 20.9% and 37.3% higher risk of overall cardiovascular events ($p < 0.001$) and strokes in particular, respectively, while there was no risk difference with regard to myocardial infarction ($p = 0.703$).
Conclusion: Liver cirrhosis is associated with a higher risk of stroke. Importantly, this link is independent from other established cardiovascular risk factors. A correspondingly higher risk of myocardial infarction could not be demonstrated.

Background and aims: The liver, an immune privileged organ, is a sanctuary for acute and chronic infections and a frequent site for metastasis due to its immunosuppressive environment. Chronic liver inflammation is a major risk factor for primary liver cancer. Hepatocellular carcinoma (HCC) is the fourth leading cause of cancer related death, and metastatic liver cancer occurs even more often. Fatty liver is apparent in 30% of the western world due to western diet and lifestyle, increasing the risk of non-alcoholic steatohepatitis (NASH). NASH fuels chronic inflammation which could progress to cirrhosis and HCC.
Method: MicroRNA-122 (miR-122), the liver specific microRNA, plays important roles in regulating several liver-specific processes and was reported to be significantly down-regulated in HCC. Our group has shown that: Inflammatory mediators regulate miR-122 expression and secretion i.e. TNFα (Rivkin M et al Gastroenterology 2016). In NASH, miR-122 is decreased in livers with increased inflammation, steatosis and fibrosis. Upon increasing miR-122 expression the NASH pathologies reverse (Chai C et al Gastroenterology 2020). MiR-122 functions as a hormone, it is produced in hepatocytes and affects remote tissue (Chai C et al Gastroenterology 2017). Concurring with previous studies, we have shown that miR-122 has tumor suppressive effects through numerous mechanisms (Simerzin A et al Hepatology 2016).

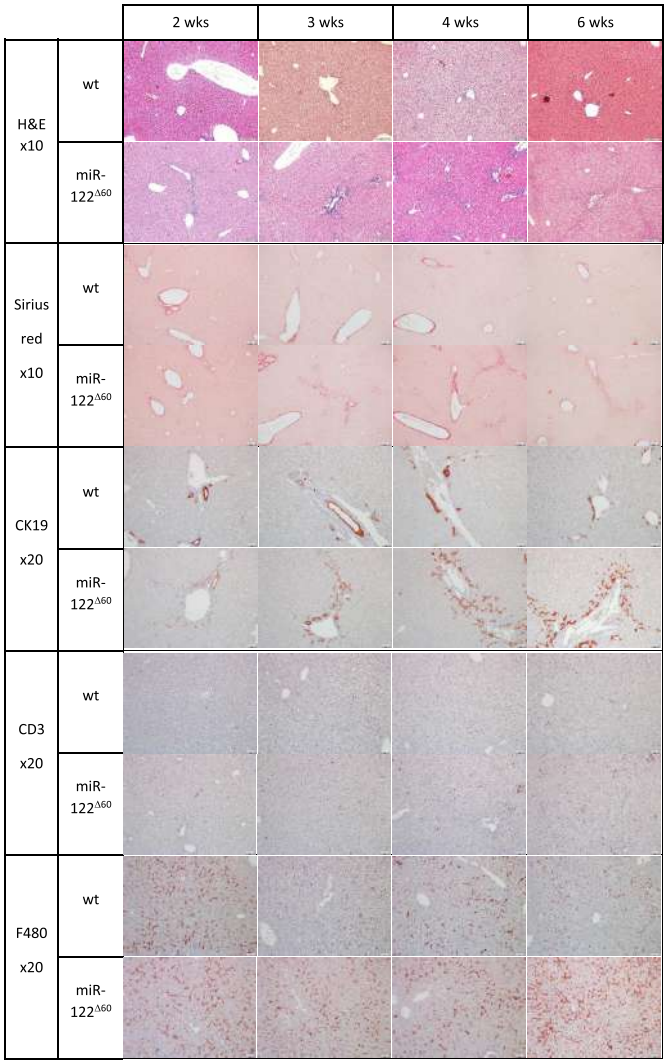

Figure: MiR-122 null mice develop fibrosis and ductular proliferation as well as initiation of an inflammatory response. Liver sections from miR-122 null mice (null) and wild type (WT) controls were obtained at the indicated ages (weeks). Staining for haematoxylin eosin (H&E) and fibrosis (Sirius red). Immunohistochemical staining for cholangiocytes (CK19), T cells (CD3) and Kupffer cells (F480).

Results: We generated a genetically modified mouse model by deleting 60nt of miR-122, (miR-122$^{\Delta 60}$). The miR-122$^{\Delta 60}$ mice develop fibrosis and ductular proliferation as well as initiation of an inflammatory response already by the age of 3 weeks progressing with age. At a later age these mice develop NASH and HCC (age 40–80 weeks old). In a model of metastasis to the liver, miR-122$^{\Delta 60}$ develop significantly more secondary tumors in the liver with an aggressive phenotype. RNA-seq analysis revealed enhanced epithelial-to-mesenchymal transmission (EMT). This was associated with an increase in ADAM17 expression, a known target of miR-122, which we have collaboratively shown, induces necroptosis of endothelial cells and cause enhanced tumor cell invasion into parenchyma (Bolik J et al, J Exp Med paper *in press*). All these results teach to the pivotal role of miR-122 in liver tolerance, inflammation and tumorigenesis.
Conclusion: Overall, miR-122 is on the one hand "anti-inflammatory" and on the other hand a "tumor suppressor." Understanding the regulation of miR-122 and its downstream effects could shed light on mechanisms of the diseased liver and potentially identify disease biomarkers and lead to therapeutic strategies.

OS115

The role of OFD1 and loss of primary cilia in cholangiocarcinoma: a novel promising therapeutic target

Massimiliano Salati[1], Anna Barbato[2], Francesco Caputo[1], Andrea Spallanzani[1], Fabio Gelsomino[1], Betrice Ricco'[1], Gabriele Luppi[1], Luigi Ferrante[2], Roberta Biondi[2], Francesco Massaro[2], Antonella Iuliano[2], Gennaro Gambardella[2], Fabiola Piscopo[2], Pasquale Pisapia[3], Antonino Iaccarino[3], Maria Salatiello[3], Giancarlo Troncone[3], Luca Reggiani-Bonetti[1], Massimo Dominici[1], Brunella Franco[2], Pietro Carotenuto[2]. *[1]University of Modena and Reggio Emilia, Modena, Italy; [2]Tigem, Pozzuoli, Italy; [3]University of Naples Federico II, Napoli, Italy*
Email: p.carotenuto@tigem.it

Background and aims: CCA is a highly lethal primary liver cancer with an increasing incidence and limited therapeutic options. The primary cilium has been postulated to have a tumor-suppressor role in the biliary tract being involved in several cancer-related pathways including WNT, Hedgehog and NOTCH. Here, we aimed at identifying and functionally characterizing primary cilium-associated genes with translational relevance for CCA prognostication and treatment.
Method: Whole-transcriptome profiling was performed with RNA-Seq on laser micro-dissected FFPE resected tissue specimens. Knocking-down of OFD1 showed was performed using siRNA interference transfections of CCA cells. Immunofluorescence staining of cilia markers was used to analyze and count cilia.
Results: Overall, 70 CCA patients were included, 51% (36) had intrahepatic and 49% (34) had extrahepatic CCA. Among 3392 and 6315 differentially expressed genes between tumour and normal tissue and tumour and stroma, OFD1 was the top-ranked cilium-associated gene (fold-change≥2.5, $p < 0.01$). siRNA-mediated depletion of OFD1 induced ciliogenesis and suppresses tumour growth *in vitro* in normal cholangiocyte and 4 different CCA cell lines. In the Western blot, OFD1 knockdown significantly increase the expression of ciliary proteins such as PCM1, ARL13B and Acetylated Tubulin, while OFD1 overexpression reduced their expression. When assessing the impact of OFD1 on prognosis, higher expression of OFD1 was significantly associated with a worse overall survival in resected CCA patients (10 vs 39 months; HR 2.33, 95%CI 1, 01–5, 31, $p = 0.03$).
Conclusion: We demonstrated that OFD1 acts as an oncogene in CCA and experimentally-induced depletion of OFD1 stimulated ciliogenesis and suppressed tumour growth in vitro. Interestingly, higher OFD1 expression adversely impacted survival of CCA patients undergoing curative-intent resection. This work identifies the primary cilium-associated gene OFD1 as a novel promising therapeutic target and prompts ciliotherapy development in CCA.

OS116

Human antigen R (HuR) is a master regulator of hepatic glucose metabolism

Sofia Lachiondo-Ortega[1], Miren Bravo[1], Irene González-Recio[1], María J. González Rellán[2], Jorge Simón Espinosa[1,3], Naroa Goikoetxea[1], Petar Petrov[1,3], Rubén Rodríguez Agudo[1], Arantza Sanz-Parra[1], Begoña Rodriguez Iruretagoyena[1], Teresa Cardoso Delgado[1], Dan A. Dixon[4], Myriam Gorospe[5], Ruben Nogueiras[2,6], María Luz Martínez-Chantar[1,3]. *[1]Center for Cooperative Research in Biosciences (CIC bioGUNE), Liver Disease Lab, Spain; [2]Center for Research in Molecular Medicine and Chronic Diseases (CIMUS), Department of Physiology, Spain; [3]Centro de Investigación Biomédica en Red de Enfermedades Hepáticas y Digestivas (CIBERehd); [4]University of Kansas, Department of Molecular Biosciences, United States; [5]National Institute on Aging (NIA), National Institutes of Health (NIH), Laboratory of Genetics and Genomics, United States; [6]Centro de Investigación Biomédica en Red de Fisiopatología de la Obesidad y Nutrición (CIBERobn), Spain*
Email: mlmartinez@cicbiogune.es

Background and aims: Human antigen R (HuR) or Embryonic Lethal Abnormal Vision-Like 1 (ELAVL1) is a ubiquitous member of the ELAV/

Hu family of RNA-binding proteins (RBPs). Under normal physiological conditions HuR is primarily nuclear. However, upon specific stimuli, *e.g.* stress signals, HuR translocates to the cytoplasm where it functions as a potent regulator of the stabilization and translation of target mRNAs. By binding to U/AU-rich elements (AREs) typically present in the 3′-untranslated region (UTR) of mRNAs, HuR post-transcriptionally controls the expression of many proteins and hence governs diverse molecular and cellular functions. Thus, in addition to its implication in disease, HuR is involved in physiological processes, *e.g.* adipogenesis, myogenesis, senescence, and immune response. However, the role of HuR in hepatic glucose metabolism remains to be addressed and constitutes the main aim of the present work.

Method: HuR expression was modulated in cultured primary mouse hepatocytes and in the THLE-2 human liver cell line stimulated with glucagon, glucose or insulin, as well as in mice fed a high-fat diet (HFD) during 4 days or subjected to glucagon administration for 30 min. Next, changes in glucose levels, RNA and protein expression, HuR localization, fluxomic analysis with ^{13}C-uniformly labelled glucose, RNA and RNA immunoprecipitation (RIP) and sequencing (Seq) assays were performed.

Results: Hepatic HuR expression was increased after intraperitoneal administration of glucagon in mice, while it remained unchanged in the glucagon receptor *knockout* animal model. Conversely, HuR expression decreased in mice upon insulin injection into the inferior cava vein. Importantly, HuR expression was significantly upregulated in the liver of a cohort of type II diabetes mellitus (T2DM) patients and in the insulin resistance *in vivo* model consisting of mice fed a HFD during 4 days. HuR was mainly located in the nucleus upon glucose and insulin stimuli, whereas it translocated to the cytoplasm after glucagon administration. Silencing the expression of HuR in the HFD mouse model sensitized the liver to insulin-mediated glucose uptake and subsequent glycolysis, while its gluconeogenic capacity was reduced. Importantly, ablating hepatic HuR expression resulted in a two-fold reduction of subcutaneous white adipose tissue weight due to increased lipolysis. Moreover, RNA-Seq analysis revealed different expression signatures of RNAs involved in glucose metabolism upon modulation of HuR expression. Finally, RIP-Seq experiments identified a panel of HuR-interacting mRNAs encoding proteins with molecular functions that helped explain how HuR controls liver glucose homeostasis.

Conclusion: Given that HuR appears to be a master regulator of glucose metabolism, we propose that HuR ought to be considered as a potential pharmacological target for the clinical management of T2DM.

OS117

Primary cilia in biliary regeneration-a potential approach to improve outcomes in liver transplantation

Hannah Esser[1], Sofia Ferreira-Gonzalez[1], Tak Yung Man[1], Alastair Kilpatrick[1], Daniel Rodrigo Torres[1], Rhona E. Aird[1], Candice Ashmore-Harris[1], Kayleigh Thirlwell[2], Benjamin J. Dwyer[3], Gabriel Oniscu[4], Stefan Schneeberger[5], Luke Boulter[6], Stuart Forbes[1]. *[1]University of Edinburgh, Centre for Regenerative Medicine, Institute for Regeneration and Repair, Edinburgh, United Kingdom; [2]Tissues, Cells and Advanced Therapeutics Scottish National Blood and Transfusion Service (SNBTS), Edinburgh, United Kingdom; [3]Curtin University, Curtin Medical School, Curtin Health Innovation Research Institute, Perth, Australia; [4]Transplant Unit, Royal Infirmary of Edinburgh, Edinburgh, United Kingdom; [5]Innsbruck Medical University, Department of Visceral, Transplant and Thoracic Surgery, Center of Operative Medicine, Innsbruck, Austria; [6]University of Edinburgh, The Institute of Genetics and Molecular Medicine (IGMM), Edinburgh, United Kingdom*
Email: stuart.forbes@ed.ac.uk

Background and aims: Biliary complications (BC) are one of the most common complications after orthotopic liver transplantation. Up to 25% of liver transplant recipients will develop BC, a major factor determining long term patient survival. BC have been associated with pre-transplant cold storage conditions, hypoxia and insufficient regeneration of biliary epithelial cells (BEC) following transplantation. BEC have primary cilia (PC), a unique organelle that is crucial to sense the extracellular environment and regulate cell proliferation. In this study we investigate the impact of PC and regeneration in the setting of BC arising post liver transplantation.

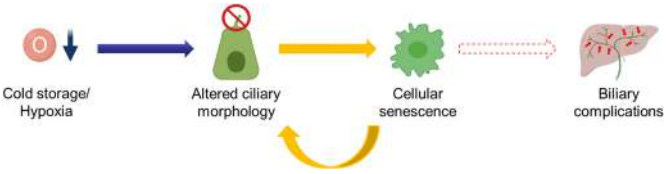
Method: Human biopsies were used to study the structure/function of PC in liver transplant recipients with ($N = 7$) and without BC ($N = 12$). We developed novel murine models of liver pre-transplantation stages, where we can study the role of PC in BEC, using conditional ablation of PC ($K19CreER^{T}$ $KIF3A^{flox/flox}$ mouse model). Lastly, Tubastatin A was used to stabilise PC and promote BEC regeneration, in a combination of *in vitro* and *in vivo* models of cold storage.

Results: BEC's PC are shortened prior to transplantation in livers that later develop BC ($p = 0.006$). We identify hypoxia as the main molecular mechanism responsible of this damage during cold storage conditions.

Hypoxia induced shortening/loss of PC triggers the onset of cellular senescence, impairing the regenerative capacity of BEC *in vitro* and *in vivo*. We also explore how hypoxia-independent genetic ablation of PC induces cellular senescence, indicating the presence of a feedback loop that negatively impacts the regenerative response of BEC after liver transplantation.

Inhibition of cellular senescence (using $p21^{-/-}$ mice or by administration of senolytics) preserves PC during cold storage ($p = 0.0004$), improving BEC regeneration. We finally show how stabilisation of PC during cold storage improves BEC proliferation *in vitro* ($p = 0.0005$).

Conclusion: pre-transplantation hypoxic conditions trigger the loss of PC in BEC, impairing biliary regeneration through cellular senescence. Our results indicate that PC represent a potential novel therapeutic target to improve biliary regeneration and prevent BC development during liver transplantation.



OS118

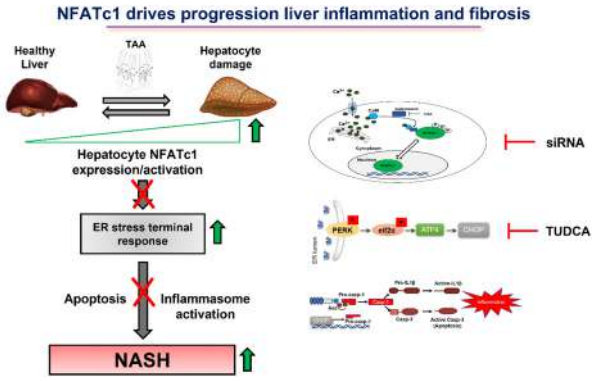
NFATc1 drives progressive liver inflammation and fibrosis by regulating pro-apoptotic stress responses

Muhammad Umair Latif[1], Geske Schmidt[2], Sercan Mercan[2], Kristina Reutlinger[2], Elisabeth Hessmann[2], Shiv Kumar Singh[2], Philipp Ströbel[3], Volker Ellenrieder[2]. *[1]University Medical center Göttingen, Department of Gastroenterology, Gastrointestinal Oncology and Endocrinology, Göttingen, Germany; [2]University Medical center Göttingen, Department of Gastroenterology, Gastrointestinal Oncology and Endocrinology, Göttingen, Germany; [3]University Medical center Göttingen, Institute for Pathology, Göttingen, Germany*
Email: umair.latif@med.uni-goettingen.de

Background and aims: Chronic liver inflammation lead to fibrosis and cirrhosis, which is the 12th leading cause of death in the world. Many acute and chronic liver disorders including hepatic inflammation originate from stress conditions followed by some complex inter cellular processes. Progression of the disease can progress to distinctive cirrhosis and hepatocellular carcinoma development. Here, we describe a key role of NFATc1 in liver damage, inflammation, and fibrosis. NFATc1, beside its well-established role in inflammatory diseases and inflammation-associated tumors, has not been comprehensively studied in liver diseases. This project aimed to characterize the functional implications of NFATc1 and its therapeutic potential in inflammatory liver diseases.

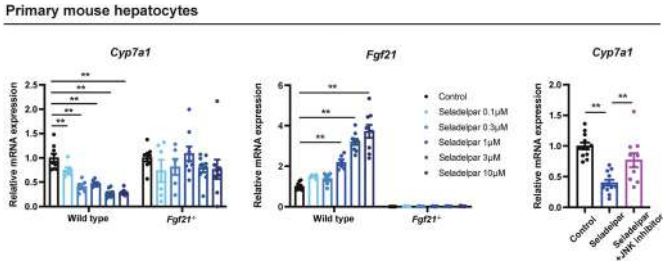
Method: To address this, we analyzed NFATc1 activation in patients with inflammation/fibrosis, cell lines and mice tissues, pretreated

with Thioacetamide (TAA), using immunoblot, RT-PCR and immunohistochemistry. Liver tissues from vehicle and TAA treated *NFATc1*^{wt}, *NFATC1*$^{c.a.}$ and *NFATc1*$^{fl/fl}$ mice were examined for NFATc1 dependent morphological changes by analyzing inflammation, and fibrosis. RNA-seq analysis in AML12 cells was performed to identify NFATc1 regulated gene signatures and signaling mechanisms. We further highlighted the therapeutic potential of NFATc1 dependent signaling mechanisms by their inhibition, both *in-vivo* and *in-vitro*.
Results: Liver biopsies from patients with inflammation/fiborsis revealed increased NFATc1 expression and nuclear localization in hepatocytes. Moreover, TAA induced NFATc1 activation resulted in progressive inflammation, fibrosis and cirrhosis whereas hepatocyte-specific depletion of the transcription factor prevented mice from liver damage. Mechanistically, hepatocyte specific NFATc1 activation drives chronic ER stress-responses and promotes apoptosis (cleaved Caspase-3) and pro-inflammatory signaling cascades through PERK-CHOP-mediated NLRP3 inflammasome activation. Finally, TUDCA mediated inhibition of NFATc1-driven signaling prevented hepatocyte damage and subsequent inflammation/fibrosis.
Conclusion: Together, our study successfully established the role of NFATc1 in liver inflammation and fibrosis through terminal ER-stress signalling and subsequent NLRP3 inflammasome activation in hepatocytes. This study also highlighted the therapeutic potential of ER-stress inhibition by TUDCA. In fact, TUDCA application resulted in strikingly lower liver damage and fibrosis in mice.



OS119
The selective PPAR-delta agonist seladelpar suppresses bile acid synthesis by reducing hepatocyte CYP7A1 through the FGF21 pathway
Tetsuya Kouno[1], Xiao Liu[2], Tatiana Kisseleva[2], Edward Cable[3], Bernd Schnabl[1]. [1]*University of California San Diego, Department of Medicine, La Jolla, United States;* [2]*University of California San Diego, Department of Surgery, La Jolla, United States;* [3]*CymaBay Therapeutics, Newark, United States*
Email: beschnabl@ucsd.edu

Background and aims: PPAR-delta agonists exert beneficial effects in liver disease and reduce total bile acid levels. Since little is known about the mechanism whereby PPAR-delta agonism reduces bile acid levels, the aim of the current study was to investigate the molecular pathways responsible for reducing bile acid synthesis in hepatocytes following treatment of the selective PPAR-delta agonist, seladelpar.
Method: Wild type C57BL/6 mice were gavaged with vehicle (PBS) or seladelpar (10 mg/kg body weight), and gene expression in the liver and ileum was examined 6 hours later by qPCR. For mechanistic studies, primary mouse hepatocytes isolated from wild type C57BL/6 mice, Ppar-alpha-/- mice, or Fgf21-/- mice were treated with seladelpar for 48 hours, and gene expression analysis was performed. The effect of seladelpar on bile acid regulation was also investigated in primary human hepatocytes.
Results: Administration of seladelpar to wild type mice repressed the liver expression of cholesterol 7 alpha-hydroxylase (Cyp7a1), a rate limiting enzyme for bile acid synthesis, and decreased plasma 7α-hydroxy-4-cholesten-3-one (C4), the freely diffusible metabolite downstream of Cyp7a1, without affecting Farnesoid X receptor pathway in the liver or ileum. In primary mouse hepatocytes, seladelpar significantly reduced the expression of Cyp7a1 and upregulated fibroblast growth factor 21 (Fgf21). The effect of seladelpar on the expression of Cyp7a1 and Fgf21 was observed in the hepatocytes isolated from Ppar-alpha-/- mice, confirming the effect of seladelpar is not based on PPAR-alpha activation. Recombinant Fgf21 protein repressed Cyp7a1 gene expression via an activation of the JNK signaling pathway in primary mouse hepatocytes. The suppressive effect of seladelpar on Cyp7a1 expression was blocked by both a JNK inhibitor and in the absence of Fgf21, indicating that Fgf21 plays an indispensable role in PPAR-delta-mediated downregulation of Cyp7a1. Reduction of CYP7A1 expression by seladelpar was confirmed in primary human hepatocytes.
Conclusion: Seladelpar reduces bile acid synthesis via an FGF21-dependent mechanism that signals, at least partially through JNK, to repress Cyp7a1.



NAFLD Therapy

Dissecting the effects and mechanism-of-action of statin use on fatty liver disease: a multidimensional study
Ibrahim Ayada[1,2], Laurens van Kleef[3], Huai Zhang[4], Pengfei Li[3], Kuan Liu[1], Ling Wang[3], Marla Lavrijsen[3], Mohsen Ghanbari[2], Luc J.W. Van Der Laan[5], Maikel Peppelenbosch[3], Ming-Hua Zheng[6], Robert De Knegt[3], Qiuwei Pan[3]. [1]*Erasmus MC, Gastroenterology and Hepatology, Rotterdam, Netherlands;* [2]*Erasmus MC, Department of Epidemiology;* [3]*Erasmus MC, Gastroenterology and Hepatology;* [4]*Medical Quality Management Office, the First Affiliated Hospital of Wenzhou Medical University, Wenzhou, China, Department of Biostatistics and Records Room;* [5]*Erasmus MC, Department of Surgery;* [6]*The First Affiliated Hospital of Wenzhou Medical University*
Email: ibrahimayada653@hotmail.com

Background and aims: Statins are widely used for the prevention of cardiovascular events and treatment of dyslipidemia. Previous studies have suggested potential beneficial effects of statin use on fatty liver disease, but the evidence is segmented and inconclusive. This study aims to comprehensively investigate the epidemiological and clinical evidence in this respect, and to understand the mechanism-of-action in experimental models.
Method: The association between statin use and fatty liver disease (FLD) was investigated in the Rotterdam Study (a population-based prospective cohort), a biopsy proven FLD cohort and lastly in meta-analysis of published clinical trials and cohort studies. The effect of simvastatin and lovastatin on lipid accumulation was investigated in

3D cultured human liver organoids fed with lactate, pyruvate and octanoic acid to mimic steatosis. Since macrophages are the key drivers of inflammation in FLD, human THP-1 macrophage cell line was used to study inflammatory gene expression.

Results: In the Rotterdam Study cohort (n = 4352 participants), statin use among participants with the metabolic syndrome (n = 1700) was associated with decreased risk for steatosis (OR 0.45, 95%CI 0.33–0.60, p <0.001) and fibrosis (OR 0.51, 95%CI 0.26–0.90, p = 0.031). In the biopsy proven patient cohort (n = 569), statin use in a subpopulation with the metabolic syndrome (n = 266) was associated with decreased risk for non-alcoholic steatohepatitis (OR 0.49, 95%CI 0.25–0.98, p = 0.04). In meta-analysis, lower levels of AST (mean difference: −0.74 U/L) and ALT (mean difference: −0.87 U/L) were observed in fatty liver disease patients using statins. Pooled odds ratio of 0.65 (95%CI 0.35–1.07) was estimated on the association of statin use and FLD development. In liver organoids model of steatosis, we found treatment with statins significantly inhibited the number of formed lipid droplets, although the effect was prominent only at relatively high concentration (10 microM). Our preliminary results suggest that statin inhibits the expression of inflammatory genes, including IL-1beta, IL-6, TNF-alpha and IL-8, but these results require further confirmation.

Conclusion: Our epidemiological and clinical evidence strongly supports the beneficial effects of statin use on multiple stages of fatty liver disease; steatosis, fibrosis and steatohepatitis. This is likely attributed to multiple mechanisms, including inhibition of steatosis and inflammatory response.

OS121

Biomarkers, imaging and safety in a well-compensated NASH cirrhotic cohort treated with resmetirom, a thyroid hormone receptor beta agonist, for 52 weeks

Stephen Harrison[1], Kris Kowdley[2], Rebecca Taub[3], Naim Alkhouri[4], Guy Neff[5]. *[1]Pinnacle Research; [2]Liver Institute Northwest, Seattle, United States; [3]Madrigal Pharmaceuticals, RandD, Conshohocken, United States; [4]Arizona Liver Institute, Chandler, United States; [5]Covenant Research, Sarasota, United States*
Email: rebeccataub@yahoo.com

Background and aims: MAESTRO-NAFLD-1 is a 52-week >1200 patient Phase 3 randomized double blind placebo controlled NASH clinical trial to study safety and biomarker effects of resmetirom, a selective thyroid hormone receptor beta agonist, in NASH patients with F1-F4 fibrosis identified using non-invasive biomarkers and imaging (NCT04197479). A goal of this "real life" NASH study is to identify non-invasive markers that correlate with individual patient response to resmetirom treatment. The study includes an open label active resmetirom treatment arm in well-compensated NASH cirrhotic patients.

Method: Eligibility required at least 3 metabolic risk factors (metabolic syndrome), and NASH cirrhosis diagnosed on liver biopsy or according to accepted criteria. The primary and key secondary end points of the cirrhotic arm include safety, relative percent reduction of MRI-PDFF (week 16), LDL cholesterol (LDL-C) (week 24), Apolipoprotein B and triglycerides, and markers of fibrosis. Patients received 80–100 mg daily dose of resmetirom for 52 weeks.

Results: 105 well-compensated NASH cirrhotic patients were enrolled in the open label arm, 2/3 confirmed by liver biopsy. 60% had completed Week 52 at the time of this abstract (all will complete by EASL 2022). Demographics include mean age 62.7 (9.0 (SD)), female 64%, BMI 35.4 (7.4), diabetes 70%, hypertension 77%, dyslipidemia >70%, mean ASCVD score 16.1%, hypothyroid 32.4%, 51% on statins. MRE kPa, 5.7 (2.1); fibroscan kPa, 24.6 (14.9), CAP, 318 (59) and mean MRI-PDFF, 8.1% (5). Stage of cirrhosis was inversely correlated with baseline PDFF. At week 52 resmetirom lowered fibroscan CAP (-42 units (p < 0.0001) and kPa (−7.6 kPa, p = 0.02). In patients with baseline PDFF >5% (5% = UL normal), resmetirom lowered PDFF by 37% (p < 0.0057). Resmetirom lowered MRE by 0.68 kPa at week 52, and 34% had an MRE reduction of ≥15%. GGT, −27%, p = 0.04 and ALP −18%, p = 0.04 were reduced. Liver volume (LV), which was elevated in NASH cirrhosis patients at baseline, was reduced −15.9% (7.7%) at week 16 (p < 0.0001) independent of baseline PDFF (week 52 LV, pending). LV reduction was correlated with reduction in MRE, MRI-PDFF, TIMP, P3NP, and the SHBG responses to resmetirom (Table). Resmetirom reduced LDL-C (20%), triglycerides (21%), ApoB (20%), Lp (a) (30%), independent of cirrhosis stage. BP was reduced by 4–5 mm. Resmetirom was safe and well-tolerated.

Conclusion: Resmetirom treatment of patients with NASH cirrhosis for up to 52 weeks was safe and effective at lowering markers of CV risk and NASH fibrosis.

Magnesium modulation by CNNM4 silencing in DIAMOND mice via GalNAc-siRNA therapy: a new and effective therapeutic approach against MAFLD

Rubén Rodríguez Agudo[1], Naroa Goikoetxea[1], Miren Bravo[1], Sofia Lachiondo-Ortega[1], Marina Serrano-Macia[1], Maria Mercado-Gómez[1], Marcos Fernandez Fondevila[2], Teresa Cardoso Delgado[1], Luis Alfonso Martinez-Cruz[1], Franz Martin-Bermudo[3], Ruben Nogueiras[2], Cesar Augusto Martín[4], Ute Schaeper[5,6], Daniela Buccella[7], Jorge Simón[1,8], María Luz Martínez-Chantar[1,8]. *[1]Liver Disease Laboratory, CIC bioGUNE; [2]Molecular Metabolism Lab, CIMUS; [3]CABIMER, UPO; [4]Instituto Biofisika (UPV/EHU); [5]Silence Therapeutics GmbH; [6]Silence Therapeutics GmbH, Berlin, Germany; [7]Department of Chemistry, NYU; [8]CIBER Enfermedades Hepáticas y Digestivas (CIBERehd)*
Email: jsimon@cicbiogune.es

Background and aims: There is mounting evidence that metabolic alterations play an important role in non-alcoholic fatty liver disease (NAFLD), which led to the notion to be renamed metabolic associated fatty liver disease (MAFLD). When extending the focus of the studies to systemic physiology, there are relevant comorbidities that commonly appear with MAFLD such as obesity, insulin resistance or cardiovascular diseases. Magnesium perturbations have been characterized in steatohepatitis and associated comorbidities, together with the role of Cyclin M4 (CNNM4) in modulating magnesium homeostasis. Based on these results, we evaluated the disease-modifying effects of a GalNAc-siRNA therapy targeting CNNM4 in a MAFLD animal model with obesity and insulin resistance.

Method: In vitro: Primary hepatocytes were stimulated with 400 μM oleic acid (OA) for a MAFLD phenotype. In vivo: DIAMONDTM mice were fed a high-fat sugar western diet (HFS-WD) for 25 weeks. Mice were treated twice, at weeks 17 and 21, with either 1 mg/kg or 5 mg/kg CNNM4-targeting GalNAc siRNA . Insulin resistance was characterized by intraperitoneal glucose (IPGTT) and insulin (ITT) tolerance tests and histopathological characterization of NASH was assessed by determining steatosis, inflammation and fibrosis development.

Results: Treatment of primary hepatocytes with GalNAc siRNA targeting CNNM4 reduced the lipid accumulation induced by OA stimulation. In the in vivo Diamond mouse model, at 17th week, when GalNAc siRNA treatment was initiated, DIAMONDTM mice had already developed insulin resistance. siRNA treatment did not affect weight gain or food consumption pattern. Hepatomegaly induced by HFS-WD was partially controlled by GalNAc CNNM4-targeting siRNA, while serum transaminases tended to decrease in treated mice. Histopathological characterization showed a significant reduction in steatosis and fibrosis development, together with a tendency of reduced inflammation.
Conclusion: GalNAc CNNM4-targeting siRNA-based treatment appears to reduce steatosis, inflammation and fibrosis in a MAFLD animal model, in which mice develop comorbidities, such as insulin resistance or obesity. Ongoing studies will characterize the effect on systemic alterations in MAFLD such as cardiovascular risk or pancreas and kidney functionality.

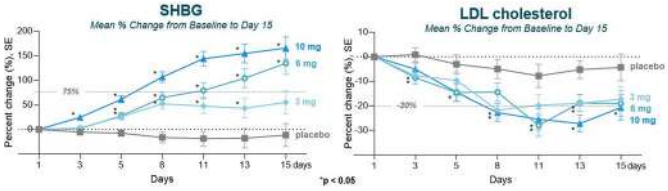
Multiple doses of thyroid hormone receptor-beta agonist TERN-501 were well-tolerated and resulted in significant dose-dependent changes in serum lipids and sex hormone binding globulin in a first-in-human clinical study

Cara H. Nelson[1], Christopher Jones[1], Lois Lee[1], Tonya Marmon[1], Diana Chung[1], Kevin Klucher[1], Yizhao Li[1], Erin Quirk[1], Daria Crittenden[1]. [1]*Terns Pharmaceuticals, Foster City, United States*
Email: cnelson@ternspharma.com

Background and aims: Thyroid hormone receptor-beta (THR-beta) agonists reduce low-density lipoprotein cholesterol (LDL-c), decrease liver fat, and improve liver histology in patients with non-alcoholic steatohepatitis (NASH). TERN-501 is a novel, metabolically stable, highly selective THR-beta agonist. In a first-in-human (FIH) study, single doses of TERN-501 were well-tolerated with significant changes in LDL-c, apolipoprotein B (Apo B), and sex hormone binding globulin (SHBG). Here we describe multiple ascending dose results from the TERN-501 FIH study.
Method: Healthy participants (n = 8/cohort) with mildly elevated LDL-c were randomized 3:1 to receive TERN-501 (3, 6, or 10 mg) or placebo once daily for 14 days in 3 cohorts. Intensive PK was assessed on Days 1 and 14, and pharmacodynamic markers were measured pre-dose on Days 1, 3, 5, 8, 11, and 13, and on Days 15, 17, and follow-up. Safety assessments were performed throughout the study.
Results: All 24 subjects completed the study without study drug discontinuations. All adverse events (AEs) were mild (Grade 1); no AEs by preferred term occurred in >1 subject. Vital signs and electrocardiograms remained stable. Transaminase changes in TERN-501 groups compared to placebo were unremarkable. Dose-dependent declines in free thyroxine were observed without clear changes in thyroid stimulating hormone or signs or symptoms of hyper/hypothyroidism. TERN-501 plasma exposures were dose-proportional with low variability. Median half-life was >15 h in all cohorts. SHBG increased dose-dependently with least squares mean (LSM) changes from baseline of 55%, 134%, and 166% on Day 15 in TERN-501 3, 6, and 10 mg groups, respectively (−12% in placebo; see Figure). Statistically significant dose-dependent LSM reductions in Apo B of −18%, −23% and -28% in the 3, 6, and 10 mg groups, respectively, were observed on Day 15 (−6% in placebo). Total cholesterol was reduced in all TERN-501 groups and maximum LSM LDL-c decreases during dosing were −22%, −28%, and −27% for 3, 6, and 10 mg (−8% in placebo; see figure).



Conclusion: Once daily TERN-501 at 3, 6, and 10 mg for 14 days was overall safe and well-tolerated. TERN-501 increased SHBG, a key marker of hepatic THR-beta engagement, in a dose-dependent fashion. Significant reductions in atherogenic serum lipids with favorable PK observed in this study support further investigation of TERN-501 for NASH treatment alone or in combination with other agents.

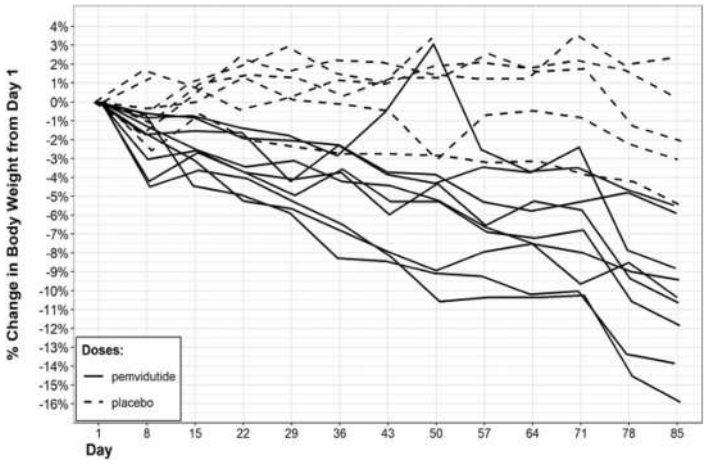
OS124

Pemvidutide (ALT-801), a novel GLP-1/glucagon dual receptor agonist, achieves rapid and potent reductions in body weight and liver fat: results of a placebo-controlled, double-blind, first-in-human (FIH) clinical trial

Stephen Harrison[1], John Nestor[2], Sarah Browne[3], Jacques Payne[4], Staci Steele[5], Robert Casper[5], Anvar Suyundikov[6], Vyjayanthi Krishnan[7], Scot Roberts[8], Joyce James[9], M. Scott Harris[10]. [1]*Pinnacle Research, Research, San Antonio, United States;* [2]*Spitfire Pharma, South San Francisco, United States;* [3]*Altimmune, Inc., Clinical Development, Gaithersburg, United States;* [4]*Altimmune, Inc., Clinical Operations, Gaithersburg, United States;* [5]*Altimmune, Inc., Clinical Operations, Gaithersburg, United States;* [6]*Altimmune, Inc., Biostatistics, Gaithersburg, United States;* [7]*Altimmune, Inc., Product Development, Gaithersburg, United States;* [8]*Altimmune, Inc., Research, Gaithersburg, United States;* [9]*Corvid LLC, Pharmacokinetics, Oakland, United States;* [10]*Altimmune, Inc., Medical, Gaithersburg, United States*
Email: sharris@altimmune.com

Background and aims: Pemvidutide (ALT-801) is a GLP-1/glucagon dual receptor agonist under development for the treatment of NASH and obesity. It combines the reduced caloric intake effects of GLP-1 receptor agonists with the increased energy expenditure and lipometabolic effects of glucagon receptor agonists on the liver. The 1:1 ratio of GLP-1 and glucagon agonism within pemvidutide is hypothesized to provide the optimal balance of efficacy and tolerability. The aim of the current study was to assess the safety and pharmacokinetics (PK) of pemvidutide and to evaluate its effects on weight loss and liver fat content (LFC), both important attributes in the treatment of NASH.
Method: This was a placebo-controlled, double-blind, first-in-human trial comprised of single ascending dose (SAD) cohorts of 0.4, 1.2, 2.4, 3.6 and 4.8 mg and multiple ascending dose (MAD) cohorts of 1.2, 1.8, and 2.4 mg administered weekly by subcutaneous (SC) injection for 12 weeks, without use of dose titration. Overweight and obese but otherwise healthy subjects (BMI 25–40 kg/m^2) were randomized 3:1 and 4:1 in SAD and MAD cohorts to pemvidutide or placebo, respectively, with placebos pooled for analyses. The primary end point of the study was safety and tolerability. Secondary end points included change in body weight and PK; change in LFC by MRI-PDFF was evaluated in exploratory analyses.
Results: 36 subjects across SAD cohorts and 34 subjects across MAD cohorts received 1 or more doses of study drug. Pemvidutide was well-tolerated to single doses of 3.6 mg. Nausea was the most frequently reported adverse event (AE), most being mild in severity. No subjects experienced diarrhea at 1.2 and 1.8 mg, and no study discontinuations due to AEs were reported at any dose. One subject receiving pemvidutide 1.8 mg and 1 placebo experienced 3–5x elevations of ALT without other significant findings. Time to peak drug concentration was slow at 70 hrs; $t_{1/2}$ was extended at 110 hours, compatible with weekly dosing. Weight loss occurred rapidly and consistently across study weeks. By Week 12, subjects receiving

pemvidutide achieved mean weight losses of 4.9%, 10.3%, and 9.0% at the 1.2 mg, 1.8 mg**, and 2.4 mg* doses, respectively, vs. 1.6% for subjects receiving placebo (*p < 0.01, **p < 0.005 vs. placebo); subject plots at 1.8 mg (Figure) suggested sustained effects over time. MRI-PDFF analyses following 6 weeks of treatment revealed all 5 subjects with fatty liver (≥5%) at baseline, including some as high as 19.5%, receiving 1.8 mg or 2.4 mg pemvidutide had reductions in LFC to undetectable levels (limit of detection 1.5%), a >90% mean reduction.



Conclusion: The rapid and potent reductions in body weight and LFC, including double-digit weight loss in 12 weeks and decreases in LFC to levels below the limit of detection, without the need for dose titration, suggest pemvidutide could be a promising new agent for treatment of NASH and its co-morbidities.

OS125

Safety, pharmacokinetics and efficacy of the novel pan-phosphodiesterase inhibitor ZSP1601 in 36 NASH patients: a double-blinded, placebo-controlled, multiple-dose escalation phase Ib study

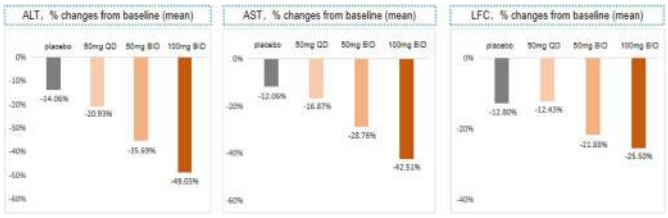
Yue Hu[1], Hai Jun Li[2], Hong Zhang[1], Jinjun Chen[3], Zhongyuan Xu[3], Hong You[4], Ruihua Dong[4], Xiaoxue Zhu[1], Hong Chen[1], Yun Peng[2], Jing Li[2], Xiaojiao Li[1], Lei Zhang[5], Di Cao[4], He Jin[4], Dongdong Qiu[5], Aruhan Yang[1], Jingrui Liu[1], Haiyan Jia[1], Jinfeng Lou[1], Junqi Niu[6], Yanhua Ding[1]. *[1]The First Hospital of Jilin University, Phase I Clinical Research Center, Changchun, China; [2]Guangdong Raynovent Biotech Co., Ltd, Guangzhou, China; [3]Nanfang Hospital, Nanfang Medical University, Guangzhou, China; [4]Beijing Friendship Hospital, Capital Medical University, Beijing, China; [5]The First Hospital of Jilin University, Radiology, Changchun, China; [6]The First Hospital of Jilin University, Hepatology, Changchun, China*
Email: dingyanhua2003@126.com

Background and aims: NASH is a serious healthcare burden. Although there has been steady progress in advancing drug development, no new drug is approved yet for this condition. The primary aim of this clinical trial is to evaluate the safety, pharmacokinetics, and efficacy of ZSP1601 that is a pan-phosphodiesterase (PDE) inhibitor to decrease producting TNF-α to reduce liver inflammation in NASH patients.

Method: This is a double-blind and randomized phase Ib study in 36 NASH patients (aged 18–65 years), the study is consisted of three dose cohorts (50 mg QD, 50 mg BID, 100 mg BID), 12 patients were enrolled for every cohorts of which 9 received ZSP1601 and 3 received placebo orally for 28 days.The patients who were diagnosed by liver biopsy or met clinical features that contains the following two criteria: ALT≥1.5 × ULN (male 75 U/L, female 60 U/L) for two examinations within 28 days with an interval greater than 7 days; BMI≥25 kg/m^2 and a baseline MRI-PDFF of liver ≥10% were enrolled.

Results: A total of 36 NASH patients were enrolled and completed the study. After the consecutive administration of ZSP1601 50 mg QD, 50 mg BID or 100 mg BID for 28 days, the plasma concentration reached steady state on the third day. The AUC increased gradually with increasing dose. There is a relatively lower accumulation of ZSP1601. MRI-PDFF was measured at baseline and day 29. The patients received ZSP1601 50 mg QD or BID or 100 mg BID or placebo had a mean relative reduction from baseline in MRI-PDFF of 12.43%, 21.88%, 25.50% and 12.80%. ≥30% reduction in MRI-PDFF relative to baseline was measured in 7 patients received ZSP1601 and 1 patient received placebo. The mean reduction of ALT from baseline were 24.8 U/L, 38.94 U/L, 55.06 U/L and13.55 U/L. The ALT of 8 patients decrease to normal, including 1 patient in 50 mg QD cohort, 2 patients in 50 mg BID cohort, 4 patients in 100 mg BID cohort and 1 patient in placebo cohort. And the AST of patients in ZSP1601 cohorts also showed obvious change from baseline. In addition, the Cap, HOMA-IR, FIB4, APRI and CK-18 decreased in ZSP1601 cohort.18 of 36 (50%) patients experienced at least one mild or moderate adverse event (AE), and the incidence rates of AEs were 77.8% and 66.7% in ZSP161 cohorts and placebo cohort, respectively. No serious adverse event. ZSP1601 was well-tolerated in this study. The most frequent AEs were adaptive headaches, creatinine slightly transiently elevated, diarrhoea and indigestion.

Conclusion: The results of this clinical trial showed that a significant reduction in liver fat by MRI-PDFF and ALT level of NASH patients enrolled after 28-days treatment. The phase 1b study suggested that ZSP1601 is safe and effective. The efficacy of 50 mg BID and 100 mg BID cohort were better than the 50 mg QD cohort and placebo cohort. Comparing with the results of other new drugs treating for NASH clinical study, the efficacy of ZSP1601 are inspiring. (This trial registered number is NCT04140123).



Cirrhosis and its complications: Portal Hypertension

The association between proton pump inhibitor exposure and key liver-related outcomes in patients with cirrhosis: a veterans affairs cohort study

Nadim Mahmud[1], Marina Serper[1], Tamar Taddei[2], David Kaplan[1]. *[1]Hospital of the University of Pennsylvania, Gastroenterology, Philadelphia, United States; [2]Yale University, New Haven, United States*
Email: nadim.mahmud@gmail.com

Background and aims: The impact of proton pump inhibitor (PPI) use on infection, decompensation, and mortality remains a point of controversy in patients with cirrhosis. We aimed to explore these associations in a large U.S. dataset while accounting for complex confounding relationships.

Method: This was a retrospective cohort study of patients with compensated cirrhosis in the Veterans Health Administration (VHA). We identified all PPI prescriptions in the VHA and time-updated PPI exposure every 30 days, including PPI dose which was normalized to omeprazole equivalents. Inverse probability treatment weighting

(IPTW) and Cox regression analysis adjusted for time-updated cardiovascular comorbidities, statin medications, antiplatelet medications, and hospitalized gastrointestinal bleed (GIB) were constructed for outcomes of infection, decompensation, and all-cause mortality.

Results: A total 76, 251 patients were included, 23, 628 (21.0%) of whom were on PPI at baseline. Patients on baseline PPI were more often white (64.4% vs. 60.0%, p < 0.001), had higher body mass index (median 29.3 vs. 28.3, p < 0.001), and had more cardiovascular and metabolic comorbidities. In IPTW Cox regression, there was a significant interaction between hospitalized GIB and PPI exposure such that there was no association between PPI use and all-cause mortality in patients without hospitalized GIB (hazard ratio [HR] 0.99, 95% confidence interval [CI] 0.97–1.02, p = 0.58), but PPIs were associated with reduced hazard of mortality in those who experienced hospitalized GIB (HR 0.88, 95% CI 0.84–0.92, p < 0.001). PPI exposure was associated with increased hazard of cirrhosis decompensation (HR 1.64, 95% CI 1.61–1.68, p < 0.001) and severe infection (HR 1.21, 95% CI 1.18–1.24, p < 0.001), with increased hazard with higher dose exposure (each p < 0.001). Among infection types, the strongest observed association was with spontaneous bacterial peritonitis, where PPI exposure conferred a 77% increased hazard (HR 1.77, 95% CI 1.66–1.88, p < 0.001).

Conclusion: PPI exposure was associated with an increased risk of severe infection, in particular SBP, as well as cirrhosis decompensation. Regarding all-cause mortality, PPI usage had a protective association in patients with prior hospitalized GIB, but no association with mortality apart from this population. These findings suggest that PPIs should not be avoided in patients with cirrhosis in the setting of an appropriate indication.

Background and aims: Non-invasive tests (NIT) for clinically significant portal hypertension (CSPH; hepatic venous pressure gradient [HVPG] ≥10mmHg) have predominantly been studied in patients with active HCV-infection, while investigations after HCV-cure are limited and yielded conflicting results. Thus, we conducted an individual patient data meta-analysis.

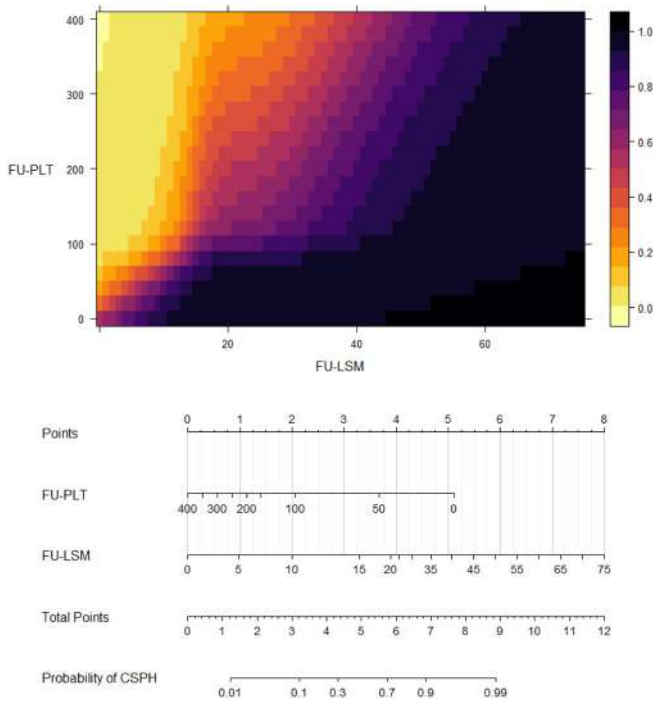
Method: 418 patients with pre-treatment HVPG ≥ 6 mmHg who achieved sustained virological response (SVR) and underwent post-treatment HVPG-measurement. Paired data on pre-/post-treatment liver stiffness-measurement (LSM)/platelet count (PLT) was available in 324 patients.

The derived non-invasive criteria were validated against the direct end point hepatic decompensation in 470 compensated advanced chronic liver disease (cACLD) patients with SVR.

Results: At a median of 28.4 (IQR: 24–44) weeks post-treatment, HVPG decreased in 79.7%, remained unchanged in 5.5%, and increased in 14.8%; median relative difference: −18.8 (IQR: −32.8–[−4.8])%. Among patients with pre-treatment CSPH (84.4%), HVPG-decreases ≥10% were observed in 208 (64.2%).

In cACLD patients with paired NIT, the correlation between LSM/HVPG was significantly stronger post- vs. pre-treatment (Spearman's ρ = 0.68 vs. 0.53; $P < 0.001$), while that of PLT/HVPG remained unchanged. HVPG tended to be lower post- vs. pre-treatment for any given LSM/PLT-value within the range relevant for clinical decision-making, indicating the need for dedicated algorithms after HCV-cure.

A non-linear model combining post-treatment (FU-)LSM/PLT yielded a high diagnostic accuracy (AUC: 0.89 [95%CI: 0.85–0.93]) for post-treatment CSPH in cACLD and can be used to estimate the probability of CSPH in an individual patient (Figure). Post-treatment LSM <12 kPa and PLT >150 G/L excluded CSPH (sensitivity: 99.2%), while LSM ≥25 kPa was highly specific (93.6%) for CSPH.



The LSM <12 kPa and PLT >150 G/L-criterion was achieved in 185/470 (39.4%) cACLD patients and their 3-year decompensation risk was 0%. In patients with post-treatment LSM ≥25 kPa (77/470 [16.4%]), 3-year decompensation risk was 14.2%, while it was 1.3% in those (208/470 [44.3%]) meeting none of the above criteria.

Conclusion: NIT can exclude/rule-in CSPH after HCV-cure and predict clinical outcomes. Based on these findings, Baveno VII recommends that patients with LSM <12 kPa and PLT >150 G/L (CSPH excluded; no decompensation risk) may be discharged from portal hypertension surveillance (NIT ± endoscopy), if no co-factors are present, while continuation of carvedilol is warranted in those with LSM ≥25 kPa (CSPH ruled-in; increased decompensation risk). In patients not meeting these criteria, the presence of post-treatment CSPH can be estimated by the provided 3-D plot/nomogram or determined by HVPG-measurement.

Carvedilol plus Simvastatin modulates systemic inflammation in cirrhosis with portal hypertension and non-response to B-blockers: randomised double-blind study

Edilmar Alvarado-Tapias[1,2], Rosa Montañés[1], Anna Brujats[1], Berta Cuyas[1], Marta García Guix[1], Claudia Pujol[1], Marianette Murzi-Pulgar[1], Maria Poca[1,2], Isabel Graupera[2,3], Oana Pavel[4], Alba Ardevol[1], Xavier Torras[1,2,5], Paula Bufi Roig[1], Àngels Escorsell[1,2], Silvia Vidal[1], Càndid Villanueva[1,2]. *[1]Hospital de la Santa Creu i Sant Pau. Email: cvillanueva@santpau.cat

Background and aims: Carvedilol (Cv) has greater reducing effect on portal hypertension than propranolol and has antioxidant and anti-inflammatory properties. Statins reduce intrahepatic vascular resistance. Some proinflammatory cytokines such as IL-6 have been involved in the progression of cirrhosis. The effect of Cv on systemic inflammation is unclear and whether combination with simvastatin may modulate this effect in patients with clinically-significant portal-hypertension (CSPH).

Method: Patients with cirrhosis and high-risk varices wereconsecutively included. The hepatic venous pressure gradient (HVPG) was measured before and after propranolol i.v. and non-responders (i.e. HVPG-decrease≤20%) were treated with Cv and randomized to receive simvastatin (Sv) (40 mg/d) or placebo (Pb), under double-blind conditions. One month later, the chronic hemodynamic response was assessed. Plasma was obtained in each hemodynamic study to determine proinflammatory cytokines (IL-6, TNF-α, IL-1ß, MCP-1) and oxidative stress markers (NO, MDA, FvW).

Results: We included 82 patients, 41 treated with Cv + Sv 41 with Cv + Pb. Baseline clinical and hemodynamic characteristics, and cytokine levels were similar. The inflammatory cytokines IL-6, MCP-1, and MDA decreased significantly ($p < 0.05$) in both groups, but sucha decrease was greater with Cv + Sv ($p < 0.01$). No significant changes were observed in the other markers. HVPG decreased significantly with both, Cv+Pb (19 ± 3 mmHg to 17 ± 3 mmHg, $p < 0.001$) and Cv + Sv (19 ± 4 mmHg to 16 ± 4 mmHg, $p < 0.001$). The decrease was greater with Cv + Sv (−17 ± 12% vs −11 ± 8%, $p = 0.05$). In patients with chronic decrease in HVPG >20%, Δ% IL-6 was significantly higher with Cv + Sb (−30 ± 6 vs −11 ± 2, $p = 0.04$). Significant correlation was observed between IL-6 and HVPG at follow-up ($r = 0.52$, $p < 0.001$).

Conclusion: In patients with cirrhosis and CSPH, carvedilol achieves a significant reduction in proinflammatory cytokines and oxidative stress mediators and improves the portal hypertension. All these changes are significantly increased by adding simvastatin. This suggests that the addition of simvastatin to carvedilol may improve clinical efficacy.

Non-invasive diagnosis of clinically significant portal hypertension and treatment with non-selective beta-blockers: a new paradigm

Elton Dajti[1], Federico Ravaioli[1], Giovanni Marasco[2], Vanessa Alemanni[3], Luigi Colecchia[4], Alberto Ferrarese[5], Caterina Cusumano[5], Stefano Gemini[5], Amanda Vestito[3], Matteo Renzulli[3], Rita Golfieri[2], Davide Festi[4], Antonio Colecchia[5]. *[1]IRCCS S. Orsola Hospital, Bologna, Italy; Department of Medical and Surgical Sciences, University of Bologna, Bologna, Italy; [2]IRCCS S. Orsola Hospital, Bologna, Italy, University of Bologna, Bologna, Italy; [3]IRCCS S. Orsola Hospital, Bologna, Italy, Bologna, Italy; [4]University of Bologna, Bologna, Italy; [5]Borgo Trento University Hospital of Verona, Verona, Italy*
Email: e_dajti17@hotmail.com

Background and aims: Non-selective beta-blockers (NSBB) may reduce the risk of decompensation in patients with clinically significant portal hypertension (CSPH). We aimed to improve the available algorithms for the non-invasive diagnosis of CSPH by evaluating spleen stiffness measurement (SSM) in patients with compensated advanced chronic liver disease (cACLD).

Method: This is a retrospective study in patients with liver stiffness measurement (LSM) ≥10 kPa, no previous decompensation, and available measurements of hepatic venous pressure gradient (HVPG), LSM and SSM referring to our tertiary center in Bologna. The diagnostic algorithms were adequate if negative (NPV) and positive predictive value (PPV) >90% when ruling-out and in CSPH, respectively; these models were validated in a cohort from Verona. The 5-year decompensation rate was reported in each risk group.

Results: One-hundred-ten patients were included in the derivation cohort (CSPH prevalence 58.6%). Available algorithms based on LSM and platelet count (PLT) (LSM >25 kPa or LSM >20 kPa and PLT <150.000/mm^3 for ruling-in CSPH and LSM ≤15 kPa or LSM ≤20 kPa and PLT ≥150.000/mm^3 for ruling out-CSPH) were validated. However, a large number of patients (38–59%) remained in the grey zone with indeterminate results for CSPH presence. The application of SSM cut-off 40 kPa and PLT 150.000/mm^3 in the "grey zone" patients allowed to significantly reduce the rate of indeterminate

results to 16–23%, maintaining adequate NPV and PPV (above 90%) (Figure 1A). The combined algorithms were validated in an independent (Verona) cohort of eighty-one patients. A nomogram based on LSM, SSM and PLT was developed to predict the individual probability of CSPH presence (AUROC = 0.966) (Figure 1B); the model performed significantly better than the Anticipate model ($p < 0.05$). During follow-up, 21–63% of first decompensation events occurred in the patients within the "grey zone" according to the models based only on LSM and PLT, whereas almost all decompensation events occurred in the "rule-in" zone defined by the models including SSM.

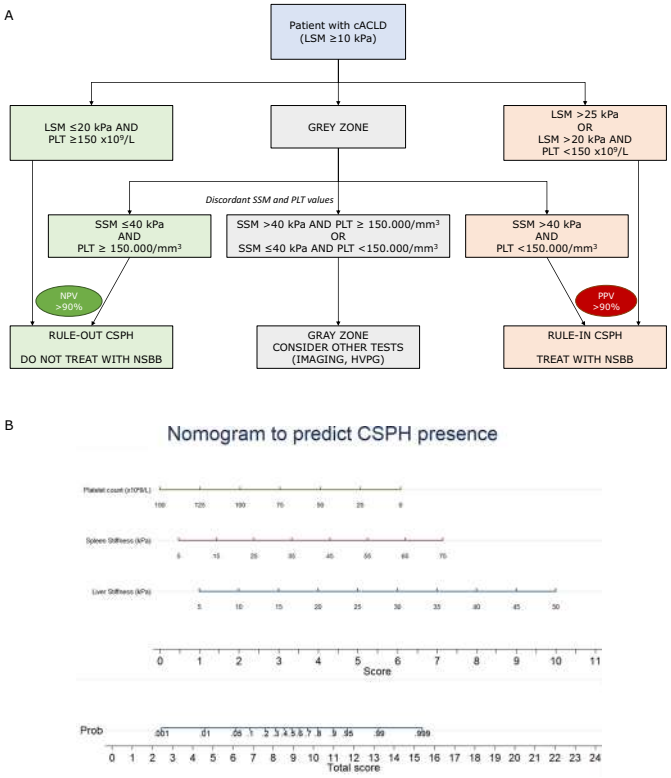

Figure 1 (A) Proposed algorithm based on liver stiffness, platelet count and spleen stiffness for the diagnosis of CSPH in cACLD patients; (B) A newly proposed nomogram based on liver stiffness, platelet count and spleen stiffness to predict the presence of CSPH.

Conclusion: The addition of SSM significantly improves the clinical applicability of the algorithms based on LSM and platelet count for CSPH diagnosis. Our models can be used to non-invasively identify candidates for NSBB treatment and patients at high-risk of decompensation.

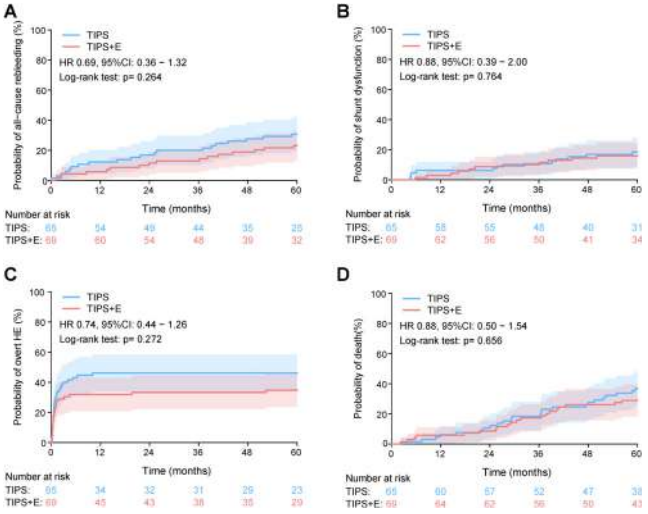
TIPS with versus without variceal embolization for the prevention of variceal rebleeding: a randomized controlled trial

Yong Lv[1], Hui Chen[1], Bohan Luo[1,2], Wei Bai[1,2], Kai Li[1], Zhengyu Wang[1,2], Dongdong Xia[1,2], Wengang Guo[1,2], Xiaomei Li[1,2], Jie Yuan[1,2], Zhanxin Yin[1,2], Daiming Fan[1], Guohong Han[1,2]. *[1]National Clinical Research Center for Digestive Diseases and Xijing Hospital of Digestive Diseases, Fourth Military Medical University, Department of Liver Diseases and Digestive Interventional Radiology, Xi'an; [2]Xi'an International Medical Center Hospital of Digestive Diseases, Department of Liver Diseases and Digestive Interventional Radiology, Xi'an, China*
Email: 13991969930@126.com

Background and aims: The role of variceal embolization at the time of transjugular intrahepatic portosystemic shunt (TIPS) creation for the prevention of variceal rebleeding remains controversial. This study aimed to evaluate whether adding variceal embolization to TIPS placement could further reduce the incidence of post-TIPS variceal rebleeding in patients with cirrhosis.
Method: From June 2014 to February 2016, 134 consecutive cirrhotic patients who had variceal bleeding in the past 6 weeks were randomly assigned (1:1) to receive TIPS alone (TIPS group, n = 65) or TIPS plus variceal embolization (TIPS + E group, n = 69) to prevent variceal rebleeding. The primary end point was all-cause rebleeding.
Results: TIPS placement and variceal embolization was successful in all patients. During a median follow-up of 63.1 months in the TIPS group and 61.8 months in the TIPS + E group, the primary end point was met in 21 patients (32.3%) in the TIPS group and 16 patients (23.2%) in the TIPS + E group ($p = 0.324$). The 2-year cumulative incidence of all-cause rebleeding was not significantly between the two groups (TIPS + E vs TIPS: 11.6 % vs 16.9%; HR: 0.69, 95%CI, 0.36 to 1.32; $p = 0.264$). Neither the incidence of shunt dysfunction (15.9% vs 18.5%, $p = 0.875$), overt hepatic encephalopathy (36.2% vs 46.2%, $p = 0.322$), death (34.8% vs 38.5%, $p = 0.807$) nor other adverse events was significantly different between the two groups.



Conclusion: In patients with cirrhosis, adding variceal embolization to TIPS did not confer further benefit for the prevention of variceal rebleeding. Our study did not support concomitant variceal embolization during TIPS for the prevention of variceal rebleeding.

Clinical course of cirrhotic patients developing ascites as the single first decompensation

Lorenz Balcar[1,2], Marta Tonon[3], Georg Semmler[1,2], Katharina Pomej[1,2], Valeria Calvino[3], Bernhard Scheiner[1,2], Simone Incicco[3], Rafael Paternostro[1,2], Carmine Gabriele Gambino[3], David JM Bauer[1,2], Antonio Accetta[3], Lukas Hartl[1,2], Alessandra Brocca[3], Mathias Jachs[1,2], Paolo Angeli[3], Michael Trauner[1], Mattias Mandorfer[1,2,4], Salvatore Piano[3,4], Thomas Reiberger[1,2,4]. *[1]Medical University of Vienna, Division of Gastroenterology and Hepatology, Department of Internal Medicine III, Vienna, Austria; [2]Medical University of Vienna, Vienna Hepatic Hemodynamic Lab, Division of Gastroenterology and Hepatology, Department of Internal Medicine III, Vienna, Austria; [3]University of Padova, Unit of Internal Medicine and Hepatology, Department of Medicine, Padova, Italy; [4]Baveno faculty, Baveno cooperation, an EASL consortium, Bologna, Italy*
Email: thomas.reiberger@meduniwien.ac.at

Background and aims: While ascites is the most frequent first decompensating event in cirrhosis, the clinical course of patients with ascites as the index decompensation is not well defined, in particular regarding the occurrence of further decompensation. The aim of this multicenter study was to investigate (i) the clinical course and (ii) the incidence and type of further decompensation in patients with isolated ascites as the first decompensating event.
Method: 622 patients with cirrhosis presenting with ascites (grade II or III) as the single index decompensating event at the University Hospital of Padova (Italy) or the Vienna General Hospital (Austria) between 2003 and 2021 were included. Patients with concomitant decompensating event (s) were excluded. Death and transplantation were considered as competing risks.
Results: Mean age was 57 ± 11 years and most patients were male (n = 423, 68%). 323 (52%) patients presented with grade II and 299 (48%) with grade III ascites. Median Child score was 8 (IQR: 7–10) and mean MELD was 15 ± 6.
During a median follow-up period of 82 months, 350 (56%) patients progressed to further decompensation: refractory ascites (n = 204; 33%), hepatic encephalopathy (n = 183; 29%), spontaneous bacterial peritonitis (n = 105; 17%), HRS-AKI (n = 81; 13%) and variceal bleeding (n = 54;9%). Median time to further decompensation was 27 months. Variceal bleeding as an isolated further decompensation was rare (n = 18; 3%), while non-bleeding further decompensation (n = 161; 26%) and ≥2 further decompensation events (n = 171; 27%) were common. Further decompensation occurred more frequently in patients with grade III ascites at index decompensation (75% vs. 33% in grade II ascites; p < 0.001; A).
Stratifying patients according to MELD revealed patients with distinct risks of further decompensation after 5 years: <10: 38% vs. 10–14: 56% vs. ≥15: 67% (p < 0.001; B). In patients with grade II ascites, MELD<15 identified patients with intermediate risks (<10: 27%; 10–14: 34%; p = 0.510), whereas MELD≥15 identified patients with high risks for further decompensation after 5 years (53%; p < 0.001).
Median transplant-free survival was 65 months. Higher MELD translated into an increased risk of liver-related death. Patients with ascites grade II at index decompensation had increased risk of liver-related mortality in case of impaired liver function (C). In patients with ascites grade III at index decompensation, the incidence of further decompensation and liver-related mortality was similarly high, regardless of liver function (i.e., MELD; D).
Conclusion: Further decompensation is frequent in patients with ascites as a single index decompensation and only rarely due to bleeding. Since further decompensation depends on ascites severity and MELD at index decompensation, risk stratification must consider both initial grade of ascites and hepatic function.

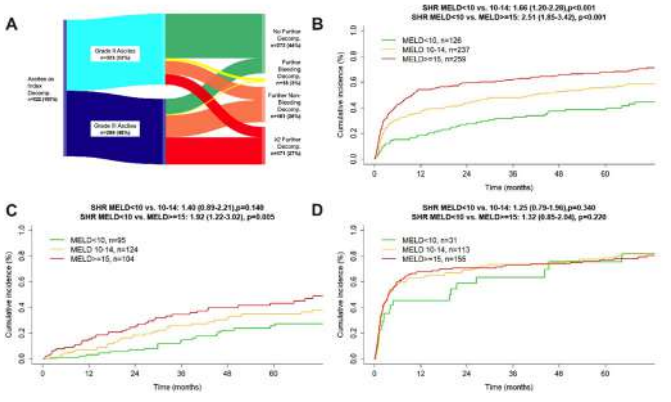

Figure. A Sankey plot for further decompensation, **B** further decompensation according to MELD-strata, **C** liver-related death according to MELD-strata in patients with grade II ascites, **D** further decompensation according to MELD-strata in patients with grade III ascites.

Email: ana.lleo@humanitas.it

Background and aims: Autoimmune Hepatitis (AIH) is a rare disease characterized by circulating autoantibodies, hypergammaglobulinemia and interface hepatitis on histology. Survival is impaired due to the potential evolution to cirrhosis with its complications, including hepatocellular carcinoma (HCC). Risk assessment of HCC in AIH still remains a challenge and available data derive mainly from small cohorts and single-center studies. Our aim was to investigate the risk of HCC across a global AIH cohort and identify predictive factors and potential stratification elements.
Method: We performed a retrospective, observational, and multicentric study of data collected within the International Autoimmune Hepatitis Group Retrospective Registry. The registry is an ongoing, non-interventional, international, and multicenter study. All patients with regular and complete follow-up for AIH were included. Demographic, clinical, biochemical and treatment data were collected both at baseline and during follow-up. Outcomes considered were HCC development, liver transplantation and death.
Results: 1210 patients from 21 centers were included, with a median follow-up of 12.3 years. 74.7 % of them were female (905/1210), with 61.7 % of the cohort being over 40 years of age. 36.2 % of patients were overweight or obese (245/1210 and 196/1210, respectively). Most of the patients did not have a significant alcohol consumption. 21.2 % of patients were already cirrhotic at diagnosis (257/1210), with

splenomegaly reported in 116 patients (9.6 %). PBC and PSC overlap syndromes were observed in 9.7 % and 7.5 % of the cohort. Treatment at baseline included the use of prednisone in 83.5 % of patients (1010/1210). 22 patients developed HCC during follow-up (22/1210, 1.8 %). Cumulative incidence of HCC of the whole cohort was 0.7% (0.3–1.4) at 5 and 10-year (95 % CI), 2.6% (1.4–4.4) at 20 years and 5.7 % (2.5–10.9) at 30-years of follow-up. The risk of HCC after cirrhosis development increases proportionally to years from the onset of the disease. Age>40 years (HR 5.99, p = 0.02), BMI>30 kg/m^2 (HR 4.11, p = 0.02), splenomegaly (HR 4.03, p = 0.03), and PSC overlap syndrome (HR 8.63, p < 0.001) resulted independent risk factors for HCC development at multivariate analysis balanced by sex. No association was observed between tumor formation and type of treatment, nor activity on liver histology resulted to have any prognostic value.
Conclusion: The incidence of HCC in AIH is lower than reported to other chronic liver diseases even after cirrhosis development. Age more than 40 years, obesity, splenomegaly and PSC variant syndrome represent risk factors for HCC development, but further studies are needed to identify predictive tools for stratification of the at-risk population.

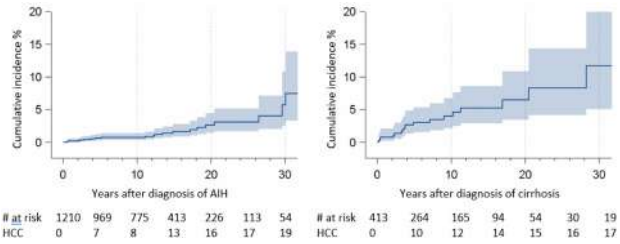

Figure: Development of HCC after diagnosis of AIH and after cirrhosis development in AIH.

OS133

Recurring intrahepatic cholestasis of pregnancy presents with distinct changes in the gut microbiota

Hanns-Ulrich Marschall[1], Peidi Liu[2], Sara Malcus[2], Mattias Bergentall[2], Tanweer Khan[2], Anita Lövgren-Sandblom[3], Peter Malcus[4], Gun Lindell[4], Fredrik Backhed[1], Ewa Wiberg-Itzel[5], Helena Strevens[4]. *[1]Gothenburg University, Department of Molecular and Clinical Medicine/Wallenberg Laboratory, Gothenburg, Sweden; [2]Metabogen AB, AZ BioVentureHub, HF3, Mölndal, Sweden; [3]Karolinska University Hospital Huddinge, Department of Clinical Chemistry C1-62, Stockholm, Sweden; [4]Skåne University Hospital Lund, Department of Gynaecology and Obstetrics, Lund, Sweden; [5]Södersjukhuset, Department of Gynaecology and Obstetrics, Stockholm, Sweden*
Email: hanns-ulrich.marschall@gu.se

Background and aims: Intrahepatic cholestasis of pregnancy (ICP) is the most common pregnancy-related liver disease with a high recurrence risk (rICP). We aimed to prospectively define distinct metagenomics and metabolite patterns in rICP and non-recurring ICP (n-rICP).
Method: Women with a history of ICP (n = 50) were screened at 9–19 weeks of gestation (Visit 1, V1) and 1:1 matched to pregnant women without a history of ICP (controls, C). Visits 2, 3 and 4 were performed at gestational weeks 28 ± 2 and 36 ± 2, and 6 ± 2 weeks postpartum. ICP was defined as otherwise unexplained pruritus and total BA ≥ 10 mmol/L at any time from V2 to delivery, with normalization at V4. Blood samples were taken at each visit for targeted metabolomics, i.e. bile acid (BA) and sulfated progesterone metabolite (PMxS) profiles and C4, while fecal samples were collected for shot-gun metagenomics.
Results: Out of 50 women with a history of ICP, 17 (34%) developed rICP. Ten of these (59%) were treated with UDCA. Demographics at inclusion were not different between groups. In rICP, BA metabolites and mono- and disulfated PMxS-diols were significantly higher as compared to n-rICP and C. Of note, also in n-rICP, PM2DiS and PM3DiS were significantly increased both at V2 and V3. In rICP, the relative abundance of a specific bacterium with 7-beta-hydroxysteroid dehydrogenase (7β-HSDH) activity was decreased by 95% at V1 but the abundance became increased at V3 in UDCA-treated rICP. In contrast, at V2 the relative abundance of *Faecalibacterium prausnitzii* was decreased by 40% which was negatively correlated (p < 0.01) with PM4S and PM5S.
Conclusion: Recurring ICP presents a distinct metagenome with significant decreases of specific bacteria before the development of the ICP phenotype, which is associated with ICP-predictive increases in sulfated progesterone metabolites and elevated bile acid levels. Bacterial species were identified as potential targets for microbiome-based interventions for the prevention and/or treatment of ICP.

OS134

Quality of life outcomes in patients with primary biliary cholangitis treated with setanaxib: post-hoc results from a phase 2 randomised, placebo-controlled trial

David Jones[1], Marco Carbone[2,3], Pietro Invernizzi[2,3], Frederik Nevens[4], Mark G. Swain[5], Philippe Wiesel[6], Cynthia Levy[7]. *[1]Newcastle University Medical School, Newcastle upon Tyne, United Kingdom; [2]University of Milano-Bicocca, Division of Gastroenterology, Centre for Autoimmune Liver Diseases, Department of Medicine and Surgery, Monza, Italy; [3]San Gerardo Hospital, European Reference Network on Hepatological Diseases (ERN RARE-LIVER), Monza, Italy; [4]University Hospital KU Leuven, Department of Gastroenterology and Hepatology, Leuven, Belgium; [5]University of Calgary, Calgary, Canada; [6]Genkyotex, Geneva, Switzerland; [7]University of Miami, Schiff Center for Liver Diseases, United States*
Email: david.jones@newcastle.ac.uk

Background and aims: Primary biliary cholangitis (PBC) is an autoimmune cholestatic liver disease.[1] Fatigue substantially impacts quality of life of patients with PBC, and remains an unmet need with currently available treatments.[2] We present quality of life results from a phase 2, double-blind, randomised trial of setanaxib in patients with PBC.
Method: This trial (NCT03226067) randomised patients with PBC and inadequate response or intolerance to ursodeoxycholic acid (UDCA) at baseline (serum alkaline phosphatase and gamma-glutamyl transferase ≥1.5× upper limit of normal) 1:1:1 to setanaxib 400 mg once/twice daily (OD/BID) or placebo for 24 weeks.[3] Quality of life was assessed using the PBC-40 questionnaire (reported as mean [standard deviation] scores). Patients from the intention-to-treat (ITT) population were stratified post-hoc by baseline fatigue score (mild, moderate or severe) using published PBC-40 fatigue domain cut-offs.[4] Moderate and severe patients were grouped. Correlations between change in fatigue and quality of life domains from baseline were made.
Results: Of 111 patients (placebo: 37; setanaxib 400 mg OD: 38; setanaxib 400 mg BID: 36), 92 had mild and 19 had moderate-to-severe fatigue at baseline. The ITT group had a baseline fatigue score of 17.2 (11.3) (placebo: 17.4 [12.1]; setanaxib 400 mg OD: 15.7 [10.7]; setanaxib 400 mg BID: 18.5 [11.3]). The moderate-to-severe subgroup had higher PBC-40 social, emotional and cognitive domain scores vs the mild subgroup (social: 30.6 [8.8] vs 19.1 [8.0]; emotional: 11.3 [2.8] vs 6.8 [3.1]; cognitive: 18.3 [6.9] vs 11.3 [5.1]). At Week 24, patients treated with setanaxib 400 mg BID had greater reductions from baseline in mean fatigue scores vs patients treated with placebo or setanaxib 400 mg OD (Figure). Similar observations were made in

social, emotional, cognitive and symptom domains. Patients with moderate-to-severe fatigue had larger changes in mean fatigue scores from baseline at Week 24 vs patients with mild fatigue; these changes were greatest amongst setanaxib 400 mg BID patients (−11.0 [11.5; n = 5]; vs setanaxib 400 mg OD: −7.5 [5.3; n = 4], placebo: 0.1 [5.7; n = 7]). Fewer patients reported "most of the time" or "always" for all PBC-40 fatigue items at Week 24 vs baseline. Improvements in fatigue from baseline at Week 24 in patients with moderate-to-severe fatigue correlated with improved social, emotional, symptom (all r = 0.5) and cognitive (r = 0.4) measures.

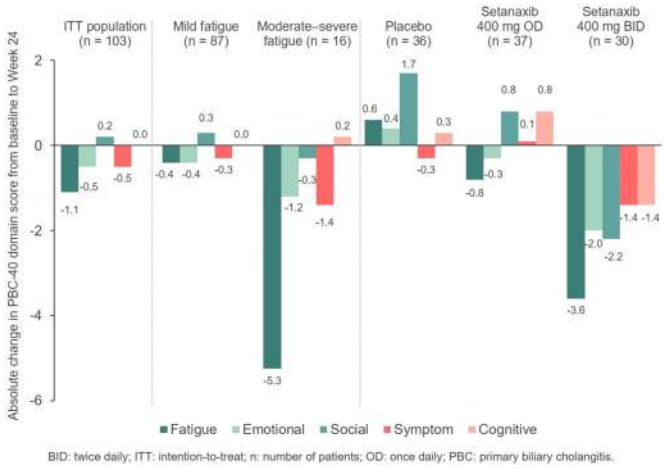

Figure: Summary of absolute score changes from baseline to Week 24 of the PBC-40 domains.

Conclusion: Setanaxib 400 mg BID, in addition to UDCA, is a promising treatment for reducing fatigue in patients with PBC and enhancing quality of life by improving social, emotional and cognitive function.

Quantitative magnetic resonance cholangiopancreatography outperforms Mayo risk score in predicting clinical outcomes in primary sclerosing cholangitis

Raj Vuppalanchi[1], Vijay Are[1], Sofia Mouchti[2], Carla Kettler[1], Mark Gromski[1], Sarah Finnegan[2], Fatih Akisik[1]. [1]*Indiana University School of Medicine, Indianapolis;* [2]*Perspectum Ltd, Oxford, United Kingdom*
Email: sarah.finnegan@perspectum.com

Background and aims: Magnetic resonance cholangiopancreatography (MRCP) is a non-invasive imaging technique commonly used to evaluate biliary diseases. Despite its widespread use, MRCP relies on subjective assessments, lacks quantitative metrics and cannot predict the onset of liver-related events. Quantitative MRCP (MRCP+™) is a novel technique that automatically segments biliary anatomy and provides quantitative biliary tree metrics. This study sought to understand the utility of MRCP+ in predicting clinical outcomes for primary sclerosing cholangitis (PSC).
Method: Patients with PSC underwent standardized MRCP imaging post-processed with MRCP+ software, which, via artificial intelligence (AI) driven pathfinding algorithms, enhanced tubular biliary structures to quantify biliary tree volume and dilated and strictured regions of the biliary tree. The duration (in years) between the MRCP scan and clinical event (liver transplantation or death) was calculated. Survival analysis was performed, and a stepwise Cox regression was used to investigate the optimal combination of MRCP+ metrics for predicting clinical outcomes. The resulting risk score was compared to the Mayo risk score using the Akaike Information Criterion (AIC) and expressed as a hazard ratio (HR).
Results: In this retrospective study of 149 PSC patients [32% male; 83% Caucasian; median age 47 years (31.0–61.2)], 29 patients reached clinical outcomes over the course of the study (18 underwent liver transplantation and 11 died). Eight quantitative MRCP+ metrics (M) and total bilirubin (B) were associated with the probability of a clinical event. When combined as a risk score, the overall discriminative performance of the MRCP+ composite biomarker (M+B) was excellent for predicting clinical outcomes with at AUC of 0.87 (95% 0.81, 0.94) and a hazard ratio (HR) of 21.1. (95% 6.4, 70.1) This was superior to the Mayo risk score with AUC of 79 (95% 0.69, 0.89) and HR of 7.2 (95% 3.24, 16.17).

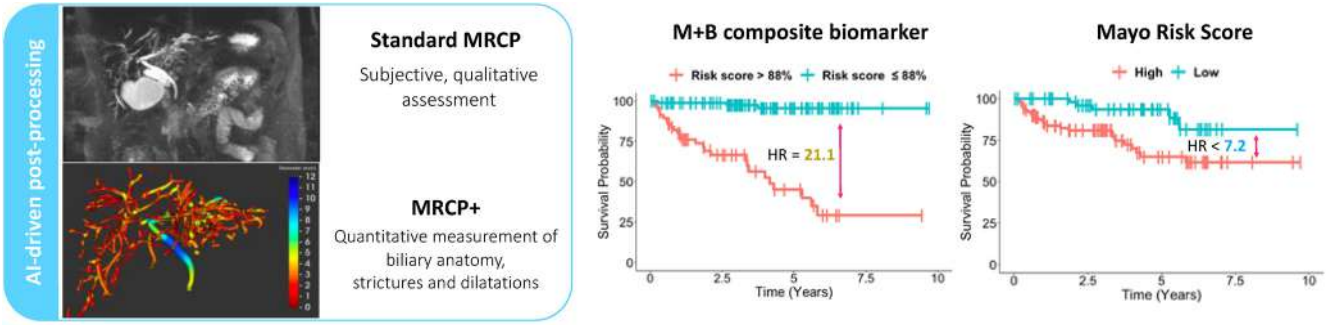

Figure 1: A standard MRCP image (top left), novel MRCP+ quantitative image (bottom left). Kaplan-Meier curves when adjusting for the composite biomarker M+B risk classifier (middle) binary Mayo risk score classified with 'intermediate' is redefined as 'low' (right) to predict a clinical event within 3-years of entering the study.

Figure: (abstract: OS135)

Conclusion: A composite score of MRCP+ metrics and total bilirubin outperformed Mayo risk score for identifying patients with PSC who were at the highest risk of liver failure and death.

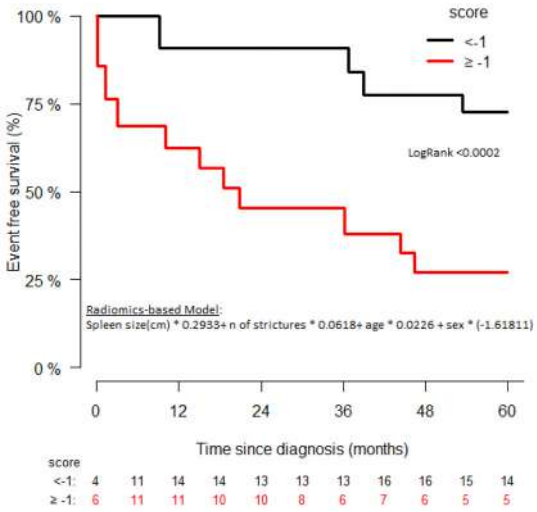
Email: l.cristoferi@campus.unimib.it

Background and aims: Magnetic resonance cholangiopancreatography (MRCP) is the gold standard for diagnosis and follow-up of patients with primary sclerosing cholangitis (PSC). The semi-quantitative MRCP-derived ANALI score, while performant in risk stratification, has poor-to-moderate inter-reader agreement. We aimed to evaluate the prognostic performance of novel quantitative MRCP in PSC.
Method: This is a retrospective study of PSC patients with at least one MRCP available from 2012 to 2019. Images have been analysed using MRCP+ software (Perspectum Ltd, Oxford) which, using AI-driven pathfinding algorithms to enhance biliary structures, provides quantitative metrics of the bile ducts (number, length and severity of strictures and dilations, and biliary tree volume). The prognostic value of radiomic biomarkers has been assessed towards both soft (hepatic decompensation, variceal bleeding, bacterial cholangitis, and hepatobiliary cancer) and hard end points (death or liver transplantation [LT]). Left truncated Cox regression model was used to account for MRCPs performed later than PSC diagnosis. The multivariate model was internally validated using k-fold cross-validation.
Results: 115 PSC patients with MRCP were evaluated; 90 MRCP passed the quality control. Median age was 41 (IQR 26–51) years, 61% were male, with a follow-up from MRCP to event/censoring of 242 patient-years. An adverse outcome occurred in 28 (25%) patients (8 LT, 3 liver-related death, 5 liver decompensation, 10 bacterial cholangitis, 2 cholangiocarcinoma). Univariate analysis showed a good prognostic performance of all radiomics features evaluated. At multivariable analysis, adjusted for age and sex, the number of strictures and the spleen length were independently associated with the occurrence of adverse event with a HR of 1.06 (per unit, CI 95% 1.03–1.09, $p < 0.0001$) and 1.34 (per cm, CI 95% 1.11–1.6, $p = 0.002$), respectively and a C-statistic of 0.81. The model was internally validated and outperformed the ANALI score in our cohort (C-statistic of 0.72 vs 0.6). The radiomics-based model, using the mean value as cut-off (−1), enabled risk-stratification of PSC patients (Fig).



Conclusion: A radiomics-based model, which includes the number of strictures and the spleen length, can identify PSC patients at higher risk of adverse outcome and outperforms the available radiological scores. MRCP+ features represent a novel biomarker for disease monitoring and a potential surrogate end point for clinical trials.

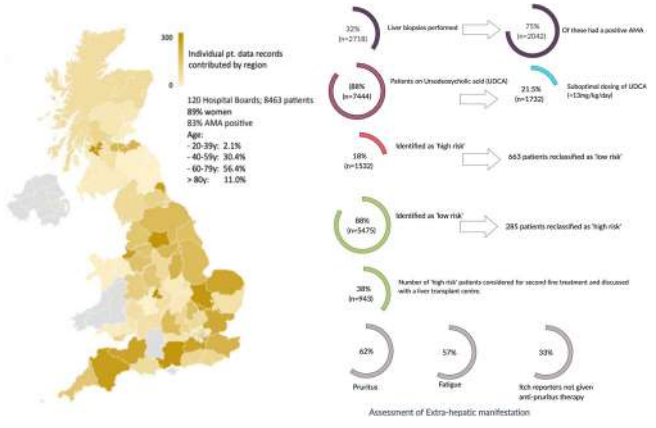
Jones[6], Joanna Leithead[7], Douglas Thorburn[8], Conor Braniff[9], Michael Heneghan[10], Andrew Yeoman[11], Collette Thain[12], Chris Mitchell[12], Robert Mitchell-Thain[12], David Jones[13], Palak Trivedi[1,2,14], George Mells[3], Laith Al-Rubaiy[15,16] and UK-PBC Consortium[17]. *[1]University of Birmingham, Institute of Immunology and Immunotherapy, Birmingham, United Kingdom; [2]University of Birmingham, United Kingdom; [3]Cambridge University Hospitals NHS Foundation Trust, United Kingdom; [4]University of Cambridge, United Kingdom; [5]Portsmouth Hospitals NHS Trust, United Kingdom; [6]Leeds Teaching Hospitals NHS Trust, United Kingdom; [7]Forth Valley Royal Hospital, United Kingdom; [8]Royal Free Hospital, United Kingdom; [9]Belfast Health and Social Care Trust, Northern Ireland; [10]Institute of Liver Studies, King's College Hospital, United Kingdom; [11]Aneurin Bevan University Health Board, United Kingdom; [12]PBC Foundation, United Kingdom; [13]Newcastle University, United Kingdom; [14]University of Birmingham, Institute of Biomedical Research, United Kingdom; [15]St Mark's Hospital and Academic Institute, United Kingdom; [16]Imperial College School of Medicine, United Kingdom; [17]UK-PBC Consortium, United Kingdom*
Email: nadir.abbas@uhb.nhs.uk

Background and aims: Herein, we present the first population-based, nationwide evaluation of healthcare delivery in primary biliary cholangitis (PBC) since publication of the European (EASL) and British guidelines (BSG). Our aim was to assess adherence to guideline recommendations and identify gaps in service provision.
Method: This was a cross-sectional study conducted between 01/21 and 01/22. All 154 hospital boards across England, Scotland, Wales, and Northern Ireland were invited to participate. Data was accrued through the REDcap™ platform, accumulating parameters relating diagnosis, treatment pathways, symptoms, risk stratification and clinical end points.
Results: In entirety, data was returned from 120 hospital boards, with data capture from 8461 pts across the UK. The majority (n = 7084; 83%) tested positive for anti-mitochondrial antibodies (AMA, Figure), with 2718 (32%) of the latter subgroup also undergoing liver biopsies. Ursodeoxycholic acid (UDCA) was used as first-line treatment in 7444

patients (88%) but sub-optimally dosed (<13 mg/kg/day) in 1732 (21.5%). Only 197 pts who were under-dosed were documented to have intolerance to higher dosing. Of individuals who were not taking UDCA, only 214 (23%) were referred for alternative/second-line therapy. Of pts taking UDCA for >12 months (n = 7007), 5475 (78%) and 1532 (22%) were classified as low-risk and high risk, respectively, by the contributing hospital. However, on applying the POISE criteria, 663 and 285 patients could be reclassified as 'low-risk and high risk' respectively. Among all who were deemed high-risk with regards disease progression (n = 2476; 29%), 1228 (49.5%) commenced second-line therapy (inc. 551 obeticholic acid; 468 bezafibrate; 68 fenofibrate; 76 combination therapy) and 35 referred directly to a transplant centre. In all, 1831 pts were identified as having cirrhosis (22%), of which 1304 (71%) participated in hepatocellular carcinoma surveillance. Features of decompensated liver disease were identified in 272 pts, of which only 46% (n = 67) were discussed with a transplant centre. With regards symptoms/extrahepatic manifestations, n = 3237 and 3690 pts did not undergo any assessment of pruritus (38%) or fatigue (44%) in the 24 months prior to data collection. 1803 pts reported ongoing pruritus at the time of assessment, of whom only 1205 (67%) were receiving anti-pruritus therapy.



Conclusion: Our study of real-world practice identifies significant gaps in clinical care across the UK PBC population. Potential future strategies to maximise adherence to guideline standards include the implementation of an integrated care pathway, along with key performance indicators, and development of a centralised referral network, allowing equitable and virtual access to specialists for all those living with PBC.

A genome-wide CRISPR/Cas9 screen identifies Rab5A as host factor of the hepatitis E virus life cycle

Noémie Oechslin[1], Nathalie Da Silva[1], Maliki Ankavay[1], Darius Moradpour[1], Jérôme Gouttenoire[1]. [1]*Service of Gastroenterology and Hepatology, Lausanne, Switzerland*
Email: noemie.oechslin@chuv.ch

Background and aims: Hepatitis E virus (HEV) is a major cause of acute hepatitis worldwide. Current understanding of the molecular mechanisms allowing for productive HEV infection is limited, especially with respect to host factors required for the viral life cycle. Hence, our study aims at identifying host factors required for HEV replication.

Method: A genome-wide CRISPR/Cas9 screen was performed in permissive human cell lines harboring newly developed subgenomic HEV replicons allowing for positive and negative selection, followed by next-generation sequencing and bioinformatic analyses. Candidates were validated by siRNA-mediated gene silencing and CRISPR/Cas9-mediated gene knockout in cells transfected with subgenomic HEV replicons or infected with cell culture-derived HEV.
Results: The newly developed replicons and a library of 120, 000 unique guide RNAs were employed in two separate screens, identifying 20 top host factor candidates. Validation yielded five host factors, including GBF1, which had been identified previously by a directed approach, and the Ras-related early endosomal protein Rab5A. The expression level and functional activity of Rab5A and of well-characterized mutants thereof were found to modulate HEV RNA replication. Colocalization studies revealed close proximity to the HEV replicase of Rab5A and other endosomal components.
Conclusion: We describe an innovative approach exploiting CRISPR/Cas9 to identify host factors of a noncytolytic virus. Future studies shall address the mechanisms by which Rab5A modulates HEV RNA replication and define the role of early endosomes in the establishment of a functional replication complex. Altogether, this work yields new insights into the HEV life cycle and the virus-host interactions required for productive infection.

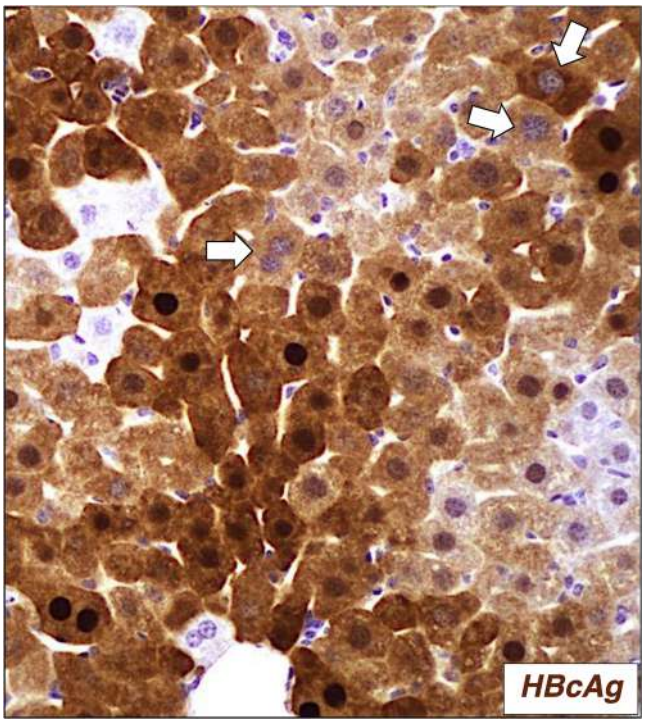
Email: guidotti.luca@hsr.it

Background and aims: ATI-1428 is a sub-nM active class II capsid assembly modulator (CAM) that safely and durably blocks hepatitis B virus (HBV) replication in immunocompetent transgenic (HBV Tg) mice. Different from other CAMs, ATI-1428 induced no *in vivo* abnormal accumulation of hepatitis B core antigen (HBcAg)-expressing empty capsids (EC) in the hepatocellular cytoplasm. Herein, we extend our understanding of the functional consequences of EC accumulation in the presence of HBcAg-specific $CD8^+$ T cells and identify another 4th-generation class II CAM (ATI-1645) that may foster EC degradation.
Method: HBV Tg mice were treated with ATI-1428 or ATI-1112 (a class II CAM causing abnormal EC accumulation) at 50 mg/kg every day (QD) for 16 days. Antiviral potency, drug- or T cell-induced liver injury and HBcAg distribution in hepatocytes (HCs) that, divided or not, were assessed at autopsy (d7 after T cell transfer). ATI-1645 was profiled in HepAD38 cells, HBV-infected HepG2-NTCP cells, and HBV Tg mice.
Results: While inhibiting HBV replication, neither ATI-1428 nor ATI-1112 caused liver injury. T cell transfer in ATI-1112-treated mice induced higher serum alanine aminotransferase peak levels and failed to eliminate ECs, even from post-mitotic HCs becoming nuclear HBcAg-negative (see Figure and PMID: 8057429). By contrast, ECs disappeared from the liver of ATI-1428- and T cell-treated animals. ATI-1645 showed sub-nM EC_{50}/EC_{90} potency profiles with low nM activity against covalently closed circular DNA establishment.

Pharmacokinetic (PK)/pharmacodynamic analyses and safety/efficacy studies in HBV Tg mice indicated that 1645 possesses excellent PK and anti-HBV activity. 28-day ATI-1645 treatment (50 mg/kg QD) cleared ECs from the cytoplasm of most HCs in the absence of any drug- or immune-mediated liver injury.



Conclusion: ATI-1112-related abnormal accumulation of cytoplasmic ECs sensitized HCs to T cell-mediated killing and allowed these particles to survive in resting and post-mitotic HCs no longer replicating HBV. This suggests that CAMs fostering an EC-accumulating phenotype may generate targets of inadequate immunopathology. Conversely, the lack of cytoplasmic EC accumulation that typifies the in vivo behavior of ATI-1428 or ATI-1645 should not interfere with productive T cell-mediated viral clearance. The subsequent characterization of 1645 as an ultra-potent HBV inhibitor that may induce cytoplasmic EC degradation makes it a promising candidate for clinical development.

OS140

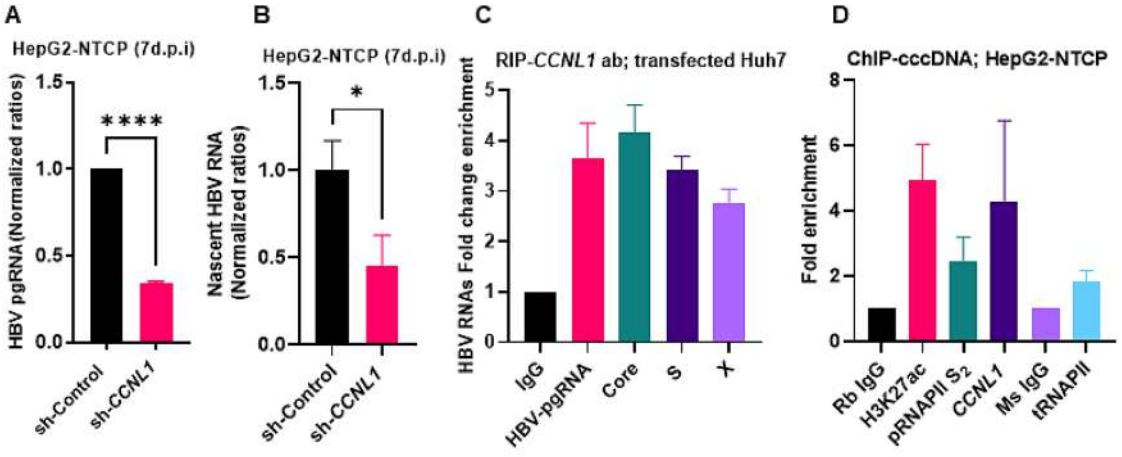
Identification of cyclin L1 as a hepatitis B virus host factor regulating viral transcription

Collins Oduor Owino[1], Yi Lin Gian[2], Pauline AW Poh Kim[1], Nivrithi Ganesh[1], Balakrishnan Chakrapani Narmada[2], Giridharan Periyasamy[2], Pablo Bifani[3], Ramanuj Dasgupta[1]. [1]*Genome Institute of Singapore (GIS), Singapore, Singapore;* [2]*Experimental Drug Development Centre, Singapore, Singapore;* [3]*Department of Microbiology and Immunology (MD4), Singapore, Singapore*
Email: dasguptar@gis.a-star.edu.sg

Background and aims: HBV remains a global public health threat, with over 250 million people chronically infected and about 800, 000 deaths reported annually. Even though much work has been done to understand HBV pathogenesis, how the virus manipulates the host cell machinery remains underexplored. In this study we aimed to identify novel host factors that affect HBV replication and gene expression. We describe the role of cyclin L1 (*CCNL1*), a non-canonical cyclin with transcriptional regulatory functions as a novel host cell factor in the control of HBV transcription.

Method: We employed whole transcriptome analysis of HBV infected primary human hepatocytes (PHH), as well as reverse genetics to identify and validate the role of *CCNL1* during HBV replication. Using RNAi and ectopic expression models, we studied the function of cyclin L1 on HBV replication in hepatoma cells and PHH. We also analyzed the effect of *CCNL1* knockdown on the production and stability of HBV RNAs. Using RNA immunoprecipitation (RIP), chromatin immunoprecipitation (ChIP), and immunoprecipitation (IP) techniques, we evaluated the interaction between cyclin L1 and HBV RNAs as well as HBx and HBc. Lastly, we explored the expression profiles of cyclin L1 in chronic HBV patient cohorts and publicly available microarray datasets GSE83148 and GSE52752.

Results: Knockdown of cyclin L1 resulted in a remarkable reduction of HBV gene expression in both hepatoma cells (HepAD38.7 and HepG2NTCP) and PHH. We observed a remarkable reduction in the levels of HBV surface and e antigens, pre-genomic RNA, and extracellular HBV DNA. Interestingly, overexpression of *CCNL1* resulted in enhanced HBV gene expression with a significant increase in the viral transcripts, thus, corroborating its pro-viral effect. Furthermore, loss of function of cyclin L1 resulted in reduced levels



Knockdown of *CCNL1* affects HBV pgRNA and nascent RNA production (A and B). Cyclin L1 interacts with HBV RNAs (C). Phosphorylated RNAPII s_2 ,total RNAPII and *CCNL1* bind to the cccDNA (D)

Figure: (abstract: OS140)

of HBV nascent RNA, highlighting its role during HBV transcription. RIP data showed that *CCNL1* might be modulating HBV RNA production through direct interaction with viral RNAs. Lastly, we observed enhanced expression of cyclin L1 in CHB from our patient cohort data and publicly available data sets underscoring its putative function in HBV replication and virus-induced liver disease.
Conclusion: Here, we report that cyclin L1 is a novel HBV host factor modulating the production and stability of viral RNAs. Our data contributes towards the understanding of HBV infection biology and provide a new perspective towards developing host-directed anti-HBV therapies.

OS141

Liver-resident T cell PD-1 correlates with intrahepatic HBV-DNA and is reduced following prolonged antiviral therapy

Mireia García-López[1], Laura J. Pallett[2], Sergio Rodriguez-Tajes[1], Ernest Belmonte[3], Thais Leonel[1], Ester García-Pras[1], Sabela Lens[1], Zoe Mariño[1], Concepció Bartres[1], Ariadna Rando-Segura[4], Francisco Rodríguez-Frías[4], Xavier Forns[1], Mala Maini[2], Sofía Pérez-del-Pulgar[1]. *[1]Liver Unit, Hospital Clínic, University of Barcelona, IDIBAPS, CIBEREHD, Barcelona, Spain; [2]Division of Infection and Immunity, Institute of Immunity and Transplantation, University College London, London, United Kingdom; [3]Radiology Department, Centro de Diagnóstico por la Imagen (CDI), Hospital Clínic, University of Barcelona, Barcelona, Spain; [4]Liver Pathology Unit, Department of Biochemistry and Microbiology, Hospital Universitari Vall d'Hebron, Universitat Autònoma de Barcelona, CIBERehd, Barcelona, Spain*
Email: sofiapp@clinic.cat

Background and aims: PD-1 is known to be upregulated on global and virus-specific T cells in the HBV-infected liver and is a major target of current immunotherapies in chronic hepatitis B (CHB). However, factors driving its expression in the liver compartment, and potential modulation by antivirals have not been well-defined. Here we therefore investigated the relationship between intrahepatic HBV load and liver-resident T cell PD-1 and whether this could be reduced by prolonged NUC suppression.
Method: This study included 22 CHB patients who underwent hepatic fine needle aspiration (FNA) and biopsy, 9 of whom were treated with NUCs for at least 4 years; a subset had a repeat FNA following treatment withdrawal. Multiparameter flow cytometry was used for immunophenotyping PBMCs and intrahepatic leukocytes extracted from FNAs. Liver biopsies were used to determine total intrahepatic HBV-DNA (iHBV-DNA) and cccDNA levels.
Results: T cells with a tissue-resident memory (T_{RM}) phenotype were excluded from PBMC but detectable in all FNAs whether treated with antivirals or not, confirming reliable sampling of the intrahepatic compartment ($CD103^+CD69^+$: 3%, IQR 2–7%, $CD103^-CD69^{hi}$: 17%, IQR 10–23%). PD-1 expression was strikingly higher on intrahepatic than circulating CD8 T cells, particularly the tissue-resident fraction ($CD103^-CD69^+$ and T_{RM}, $p < 0.0001$) as described previously (Fisicaro et al. 2010, Pallett et al. 2017). Measurement of liver viral parameters showed that CD8 T cell PD-1 expression correlated with both iHBV-DNA ($r = 0.6$, $p = 0.007$) and cccDNA ($r = 0.7$ $p = 0.002$) but not with ALT. Supporting a role for HBV in driving PD-1 expression, FNAs from the cohort with prolonged viral suppression on NUCs had significantly lower proportions of PD-1-expressing T cells and lower expression levels. By contrast, no significant changes in CD8 T cell PD-1 between NUC-treated and naïve patients were detectable in the periphery. Therefore, although CD8 T cell PD-1 in PBMC and intrahepatic lymphocytes showed an overall correlation, blood sampling cannot fully predict the impact of NUCs on this immune target in the liver compartment. In a small subset of patients re-sampled by FNA 6 months after NUC discontinuation, preliminary data suggested the withdrawal of viral suppression had the potential to drive re-expression of high levels of PD-1 on intrahepatic T cells.
Conclusion: Our results reveal a close association between intrahepatic HBV-DNA and global liver-resident T cell PD-1 expression within the liver, with a reduction on prolonged NUC therapy and the potential for re-expression following treatment withdrawal. The mechanism by which HBV load associates with global (rather than just HBV-specific) T cell PD-1 remains to be explored. These findings underscore the need for further consideration of NUC-induced changes in global liver T cell PD-1 when targeting this axis in HBV functional cure.

Phospho-proteomic analysis of HBV infection revealed novel mechanisms for the regulation of viral transcription and pro-fibrotic stellate cell activation

Alessia Virzi[1,2], Zakaria Boulahtouf[2,3], Sarah Durand[1,2,4], Emanuele Felli[2,3,4], Patrick Pessaux[2,3,4], Oliver Popp[5,6], Evelyn Ramberger[5,6], Philipp Mertins[5,6], Eloi Verrier[2,3], Catherine Schuster[1,2,4], Thomas Baumert[2,3,4,7], Joachim Lupberger[2,3]. *[1]Inserm U1110, Strasbourg, France; [2]Université de Strasbourg, Strasbourg, France; [3]Inserm U1110, Strasbourg, France; [4]Institut Hospitalo-Universitaire, Pôle Hépato-digestif, Nouvel Hôpital Civil, Strasbourg, France; [5]Max Delbrück Center for Molecular Medicine, Berlin, Germany; [6]Berlin Institute of Health, Berlin, Germany; [7]Institut universitaire de France (IUF), Paris, France*
Email: joachim.lupberger@unistra.fr

Background and aims: Chronic hepatitis B virus (HBV) pathological course are characterized by the dysregulation of fibrogenic and oncogenic signalling. Considering the lack of efficient anti-fibrotic therapies and treatment to eradicate cccDNA, the understanding of regulatory pathways is urgently needed. To identify the potential drivers of this dysregulation, we studied HBV-induced signalling in HBV infection models.
Method: Proteomic and phospho-proteomic analysis of HBV-infected HepG2-NTCP were performed using liquid chromatography-mass spectrometry. The deregulated signalling pathways were examined by gene set enrichment analysis and validated in primary human hepatocytes. Perturbation studies, trans-dominant phospho-dead/mimetic mutagenesis and *ex vivo* experiment were performed to validate the results.
Results: Our data revealed a strong HBV-induced dysregulation of signalling involved in extra-cellular matrix (ECM) and cell cycle. ECM-associated leading-edge genes comprised collagen VI, which was upregulated in HBV-infected hepatocytes. Interestingly, silencing of *COL6A1* impairs viral transcription suggesting a pro-viral role of collagen VI. Myofibroblasts account for the majority of collagen I deposed into the ECM. We found that treatment of hepatic stellate cells (HSCs) with collagen VI significantly induced an expression of HSCs activation markers, revealing a role of collagen VI in promotion of liver fibrosis. In addition, our phospho-proteomics provides new insight on viral life cycle regulation. Although HBV predominantly replicates in G1/G2 phase, we found linker histones H1.4 among the top hits of the HBV phospho-proteomic analysis. Linker histones are generally phosphorylated during S/M phase and associated to chromatin relaxation. We found that mimicking H1.4 detachment by RNAi augmented viral transcription, while a trans-dominant phospho-dead mutation S104A in H1.4 inhibited HBV RNA transcription. This suggests that HBV requires H1.4 phosphorylation to maintain cccDNA transcription. Chip experiments with the H1.4 mutants are under way.
Conclusion: We identified the phospho-proteomic landscape of HBV-host interaction which serves as a resource for the identification of novel drivers regulating viral life cycle and pathogenesis. We revealed a previously unrecognized role of collagen VI and linker histones in HBV replication with potential impact on liver fibrosis progression and cccDNA transcription, respectively.

CD4 T cell immunity to HEV-infection is characterized by sustained capsid-specific responses that correlate with neutralizing antibodies

Benedikt Csernalabics[1], Stefan Marinescu[1], Lars Maurer[2], Katharina Wild[1], Katharina Zoldan[1], Marcus Panning[3], Philipp Reuken[4], Tony Bruns[5], Christoph Neumann-Haefelin[1], Bertram Bengsch[1], Maike Hofmann[1], Robert Thimme[1], Viet Loan Dao Thi[2], Tobias Böttler[1]. [1]*University Hospital Freiburg, Department of Medicine II, Freiburg, Germany;* [2]*Heidelberg University Hospital, Department of Infectious Diseases and Virology, Heidelberg, Germany;* [3]*University Hospital Freiburg, Institute of Virology, Freiburg, Germany;* [4]*Jena University Hospital, Department of Medicine IV, Jena;* [5]*University Hospital RWTH Aachen, Department of Medicine III, Aachen, Germany*
Email: benedikt.csernalabics@uniklinik-freiburg.de

Background and aims: CD4 T cells are key protagonists in shaping an antiviral immune response. However, there are only limited insights into their specificity and distinction in the context of a hepatitis E Virus (HEV) infection. Therefore, we aim to characterize the specificity, phenotype and differentiation of CD4 T cells targeting different epitopes of the HEV polyprotein and their correlation with neutralizing antibodies targeting hepatitis E virions.
Method: HEV-specific CD4 T cells targeting different HEV-specific CD4 T cell epitopes from the viral polyprotein were identified by intracellular cytokine staining in 7 acutely infected and 33 resolved patients. Surface markers, relevant costimulatory receptors and transcription factors were analysed by using HEV-specific HLA-DRB1*01:01 and *04:01 tetramers. Additionally, neutralizing antibodies targeting naked (nHEV) and quasi-enveloped (eHEV) virions were determined (n = 72).
Results: Robust and multi-specific CD4 T cell responses were identified against the viral capsid and non-structural polyprotein (NSP). In contrast, only few phosphoprotein-specific responses were detectable. Overall, the virus-specific CD4+ T cell response was stronger and broader in acutely infected versus resolved patients. Moreover, a switch from a highly activated Th1 and Tfh cell phenotype towards a heterogeneous memory population was observed after viral elimination. Noteworthy, the presence of a capsid-specific IFN-γ- or IL-21-producing CD4 T cell response positively correlated with IgG- and neutralizing antibody titers against nHEV.
Conclusion: Collectively, our results reveal important novel insights into the HEV- specific CD4 T cell response by demonstrating a solid maintenance of capsid- and NSP-specific CD4 T cell responses with the formation of a robust HEV-specific memory compartment. They also reveal a clear immunodominance with phosphoprotein being less immunogenic.

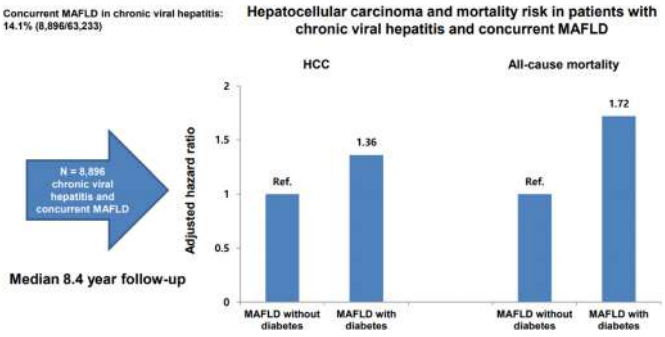
Email: ahnsh@yuhs.ac

Background and aims: Metabolic dysfunction-associated fatty liver disease (MAFLD) is a recently proposed concept for fatty liver disease. However, heterogeneous disease severity and prognosis might exist even among patients with the same disease category of MAFLD. We investigated the risk stratification of long-term outcomes according to MAFLD subgroups based on diagnostic criteria in patients with chronic viral hepatitis using a nationwide cohort.
Method: We included 63, 233 chronic hepatitis B and chronic hepatitis C patients who underwent health examinations in 2009. Hepatic steatosis was defined as a fatty liver index ≥60. MAFLD was defined as the presence of hepatic steatosis with any one of the following three conditions, overweight/obesity (body mass index ≥23 kg/m^2), diabetes, two or more metabolic dysregulation. The primary end points of this study were incident hepatocellular carcinoma (HCC) and all-cause mortality.
Results: The prevalence of MAFLD was 14.1% (n = 8, 896). During a median 8.4-year follow-up, we documented 3, 732 HCC cases and 4, 778 deaths. Compared to patients with no MAFLD (n = 54, 377), the risk of HCC and mortality was significantly higher in patients with MAFLD (adjusted hazard ratio [aHR] = 1.34, 95% confidence interval [CI] = 1.23–1.46) for HCC; aHR = 1.26, 95% CI = 1.17–1.36 for mortality). Among patients with MAFLD, 687 HCCs and 861 deaths were documented. The prevalence of diabetes among patients with MAFLD was 25.9% (n = 2, 303). The risk of HCC and mortality was significantly higher in patients with diabetes (aHR = 1.36, 95% CI = 1.16–1.59 for HCC; aHR = 1.72 95% CI = 1.50–1.97 for mortality) compared to patients with no diabetes, among patients with MAFLD. When we stratified patients with MAFLD according to the other criteria (overweight/obesity or metabolic dysregulations), risk of HCC and mortality was not different across the groups (all p > 0.05).
Conclusion: Concurrent MAFLD was associated with higher risk of HCC and mortality in patients with chronic viral hepatitis. Our results suggest that diabetes can stratify the risk of HCC and mortality in patients with chronic viral hepatitis and concurrent MAFLD.



OS145

Long term persistence of anti-HBs antibodies after vaccination with a 3-antigen HBV vaccine compared to a single-antigen HBV vaccine

Timo Vesikari[1], Aino Forstén[1], Vlad Popovic[2], Johanna Spaans[2], Francisco Diaz-Mitoma[2]. [1]*Nordic Research Network Oy, Tampere, Finland;* [2]*VBI Vaccines Inc., Canada*
Email: timo.vesikari@nrnetwork.fi

Background and aims: Hepatitis B virus (HBV) infection is a serious public health problem that can be effectively prevented with

hepatitis B vaccination. The magnitude of the immune response to HBV vaccination can be measured by serum levels of anti-HBs, persistence and durability, which is believed to be dependent upon the induced peak levels. PROTECT was a double-blind, randomized, Phase 3 study to evaluate immunogenicity and safety of a 3-antigen HBV vaccine (3A-HBV, manufactured by VBI Vaccines) and a single-antigen HBV vaccine (1A-HBV, Engerix-B®). Three doses of vaccine were administered IM at Days 1, 28, and 168. Seroprotection rate (SPR-% of subjects achieving anti-HBs ≥10 mIU/ml) and geometric mean concentration (GMC) of anti-HBs were evaluated for 12 months. Following the completion of PROTECT, this follow-up investigator-initiated study of PROTECT aimed to assess the long-term persistence of anti-HBs titers 2–3 years after the 3rd dose in participants enrolled in Finland.

Method: Subjects were eligible for the follow-up study if they had been enrolled in PROTECT study in Finland and had achieved seroprotection (anti-HBs ≥10 mIU/ml). Between February 2021 and June 2021, subjects were contacted to participate in the follow-up study. Serum samples were tested for Anti-HBs titers at the central laboratory (LabConnect, USA) using the same validated anti-HBs quantitative assay [VITROS, Ortho 3600 NJ, USA] as used in the PROTECT study.

Results: Of the 528 subjects contacted, 465 agreed to participate in the follow-up study, including 244 [52.5%] vaccinated with 3A-HBV and 221 [47.5%] vaccinated with 1A-HBV. Baseline characteristics were well balanced between the groups and consistent with the PROTECT study population, the mean age for both vaccine groups was 59 years. Data from the PROTECT study demonstrated a peak GMC of anti-HBs of 8021.9 mIU/ml for 3A-HBV and 3787.3 mIU/ml for 1A-HBV in study participants one month after the third dose (Day 196). Data from this follow-up study showed that approximately 2.5 years following Day 196 in the PROTECT study, the mean concentration of anti-HBs was 1382.9 mIU/ml for 3A-HBV participants and 251.4 mIU/ml for 1A-HBV participants. Additionally, more than 2x the number of subjects vaccinated with 3A-HBV retained anti-HBs ≥100 mIU/ml compared to 1A-HBV (72.9% vs. 32.6%). After approximately 2.5 years, 27.6% in the 1A-HBV group and 11.9% in the 3A-HBV group no longer had seroprotective levels of anti-HBs (titers <10 mIU/ml).

Conclusion: 2.5 years after achieving peak seroprotection in the PROTECT study, the mean anti-HBs titers were five times higher in the 3A-HBV group than in the 1A-HBV group. Additionally, the percentage of participants who no longer had seroprotective levels of anti-HBs (titers <10 mIU/ml) was more than double in the 1A-HBV group compared to the 3A-HBV group.

OS146

Fatty liver index as a risk factor for all-cause and liver related mortality in patients under therapy for chronic hepatitis B (ANRS CO22 Hepather cohort study)

Paul Hermabessiere[1], Mathieu Chalouni[2], Marc Bourliere[3], Pierre Nahon[4], François Teoule[5], Clovis Lusivka-Nzinga[5], Helene Fontaine[6], Stanislas Pol[6], Fabrice Carrat[5], Victor de Lédinghen[1], Linda Wittkop[2]. *[1]Hôpital Haut-Lévêque Magellan, Pessac, France; [2]ISPED, Bordeaux, France; [3]Hospital Paris Saint-Joseph, Paris, France; [4]Jean-Verdier Hospital Ap-Hp, Bondy, France; [5]Hospital Saint-Antoine Ap-Hp, Paris, France; [6]Cochin Hospital, Paris, France*
Email: hermabessierepaul@gmail.com

Background and aims: A quarter of patients with chronic hepatitis B (CHB) have associated fatty liver disease and the prognosis of these patients has been poorly investigated. In the general population, Fatty Liver Index (FLI) is a recommended alternative to ultrasonography for the diagnosis of steatosis (EASL 2016) and predict clinical outcomes related to non-alcoholic fatty liver disease (NAFLD). The aim was to evaluate the association between FLI and all-cause and liver-related mortality in treated CHB participants from the ANRS CO22 HEPATHER cohort.

Method: All patients under CHB therapy at entry in the ANRS CO22 HEPATHER cohort were selected. Patients with history of liver transplantation or hepatitis D virus co-infection were excluded. Multiple imputations of GGT, triglycerides, waist circumference and BMI were realized. Outcomes were first, the occurrence of death from any cause, then death from liver complication (primary liver cancer, decompensated cirrhosis, and liver transplantation). Proportional hazard adjusted on age, gender and diabetes status. Cox models were performed. Potential non-linear relationships were examined using fractional polynomial models.

Results: 2877 treated CHB patients were included. Median age was 48.9 years [Interquartile range (IQR): 38.1; 59.8] and 2044 (71.0%) were men. Almost all patients were treated by nucleos (t)idic analogues (98%) for a median time of 2.9 years (IQR [0.4; 5.2]) and 92.0% had an HBV DNA level <2, 000 UI/ml at entry. After a median follow-up of 7.0 years (IQR [6.2; 7.6]), incidence of all-cause mortality was 7.7/1000 person/years (95% Confidence Interval (CI) 6.6–9.1), and 4.0/1000 person/years (95% CI 3.2–5.0) for liver-related mortality. After adjustment, an increase of ten points of FLI was significantly associated with an increased risk of all-cause mortality (Hazard Ratio (HR): 1.09 [1.02–1.16]) and tended to be associated with liver-related mortality (HR: 1.08 [0.99–1.19]).

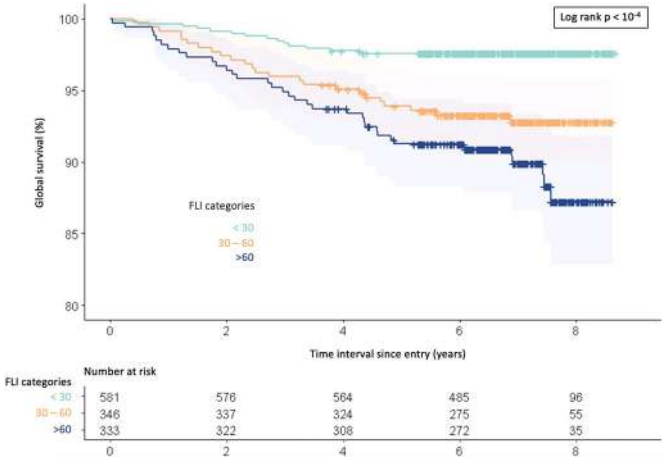


Figure: Kaplan-Meier survival estimates according FLI categories. ANRS CO22 HEPATHER cohort, treated CHB participants.

Conclusion: In this first large prospective cohort of French patients with treated chronic HBV infection, FLI was independently associated with all cause and liver-related mortality.

OS147

The discriminatory power of risk scores for hepatocellular carcinoma in treated chronic hepatitis B patients with and without diabetes: a territory-wide study of 48,706 subjects

Terry Cheuk-Fung Yip[1], Mandy Sze-Man Lai[1], Vincent Wai-Sun Wong[1], Yee-Kit Tse[1], Yan Liang[2], Vicki Wing-Ki Hui[2], Henry LY Chan[3,4], Grace Lai-Hung Wong[1]. *[1]The Chinese University of Hong Kong, Medical Data Analytics Centre (MDAC), Department of Medicine and Therapeutics, Institute of Digestive Disease, Faculty of Medicine, Hong Kong; [2]The Chinese University of Hong Kong, Medical Data Analytics Centre (MDAC), Department of Medicine and Therapeutics, Faculty of Medicine, Hong Kong; [3]Union Hospital, Department of Internal Medicine, Hong Kong; [4]The Chinese University of Hong Kong, Medical Data Analytics Centre (MDAC), Faculty of Medicine, Hong Kong*
Email: wonglaihung@cuhk.edu.hk

Background and aims: Patients with chronic hepatitis B (CHB) are aging with a rising prevalence of diabetes mellitus (DM) to over 20% in recent years. While DM is associated with a doubled risk of hepatocellular carcinoma (HCC) in CHB patients, few HCC risk scores

include DM as a factor. We aimed to compare the performance of HCC risk scores among DM and non-DM patients on nucleos (t)ide analogue (NA) treatment.

Method: Adult CHB patients on at least 6 months of entecavir or tenofovir treatment from January 2005 to March 2020 were identified using a territory-wide database in Hong Kong. DM was defined by any use of non-insulin antidiabetic agents, continuous use of insulin for ≥28 days, haemoglobin A_{1c} ≥6.5%, fasting glucose ≥7 mmol/L, and/or diagnosis codes. Two HCC risk scores with DM as a factor for treated CHB patients (*i.e.*, cirrhosis, age, male sex, and DM [CAMD] score and Real-world Effectiveness from the Asia Pacific Rim Liver Consortium for hepatitis B virus [REAL-B] score) were studied; 2 other HCC risk scores without DM as a factor (*i.e.*, PAGE-B and modified PAGE-B [mPAGE-B] scores) were also examined. The discriminatory power of the scores was assessed by area under the time-dependent receiver operating characteristic curves (AUROCs) with death as a competing event. Comparisons were done based on 1, 000 bootstrap samples.

Results: Of 48,706 patients included, the mean age was 54.3 ± 13.6 years; 62.1% were male and 12.7% had cirrhosis. The prevalence of DM rose steadily from 15.5% to 24.3% in those who started NA treatment in 2005–08 and 2017–20 respectively. At a median (25th percentile–75th percentile) follow-up of 4.4 (2.2–5.0) years, 2, 157 (4.4%) patients developed HCC. All the 4 HCC scores were less predictive in DM patients than non-DM patients (all p < 0.001; Figure). DM was an independent risk factor for HCC on top of the risk groups of PAGE-B score (adjusted hazard ratio [aHR] 3.85, 95% CI 2.06–7.18, p < 0.001), and had an interaction with PAGE-B risk groups (aHR [95% CI]: 0.40 [0.21–0.77] for intermediate-risk group and 0.27 [0.14–0.51] for high-risk group as compared to non-DM patients in low-risk group). DM was however found to be not associated with HCC after adjusting for mPAGE-B score (aHR 1.04, 95% CI 0.95–1.14, p = 0.423).

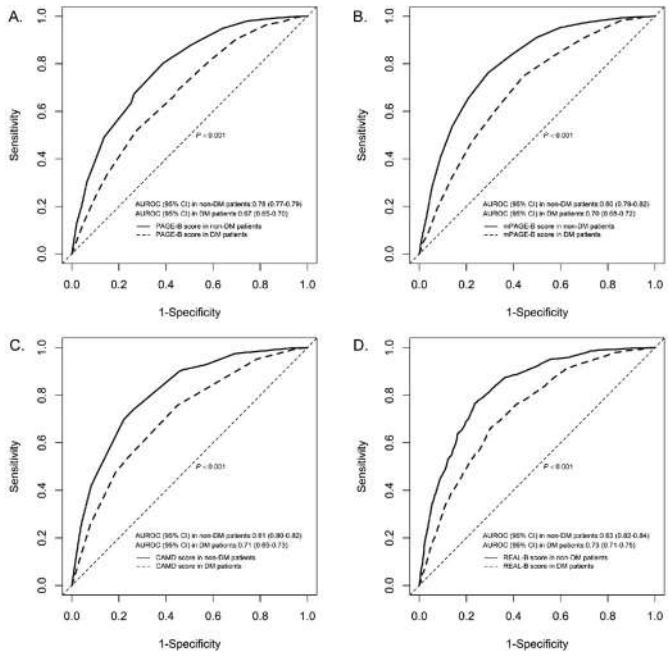

Figure: The area under the time-dependent receiver operating characteristic curves (AUROCs) of A. PAGE-B score; B. mPAGE-B score; C. CAMD score; and D. REAL-B score for predicting the development of hepatocellular carcinoma in nucleos (t)ide analogue-treated chronic hepatitis B patients with and without diabetes mellitus (DM).

Conclusion: HCC risk scores are less accurate in NA-treated diabetic CHB patients than their non-diabetic counterparts, with a drop of AUROCs from around 0.8 to 0.7 regardless of whether DM is a component in the risk scores or not.

OS148

Hepatocellular carcinoma incidence is reduced in cirrhotic chronic hepatitis B patients with HBsAg seroclearance comparing to those with viral suppression

Rachel Wen-Juei Jeng[1,2,3], Chien-Hung Chen[1,4], Hwai-I Yang[5], Yi-Cheng Chen[1,2,3], Yen-Chun Liu[1,2,3], Chia-Ying Wu[2,3], Rong-Nan Chien[1,2,3], Yun-Fan Liaw[1,2]. *[1]Chang Gung University, College of Medicine, Taiwan; [2]Linkou Chang Gung Memorial Hospital, Liver Research Unit, Taiwan; [3]Linkou Chang Gung Memorial Hospital, Department of Gastroenterology and Hepatology, Taiwan; [4]Kaohsiung Chang Gung Memorial Hospital, Division of Hepatogastroenterology, Department of Internal Medicine, Taiwan; [5]Academia Sinica, Genomic Research Center, Taiwan*
Email: rachel.jeng@gmail.com

Background and aims: Cirrhosis is a major risk factor for hepatocellular carcinoma (HCC) development in chronic hepatitis B patients. It remains unknown whether HBsAg seroclearance in cirrhotic patients reduces the risk of HCC compared to those under long-term Nuc treatment. This study aims to investigate the HCC incidence between these two groups.

Method: The study recruited chronic hepatitis B patients with cirrhosis undergoing Nuc therapy with viral suppression (Nuc arm, N = 805) and cirrhotic CHB patients with HBsAg seroclearance (S-loss arm, N = 165, 65 untreated, 90 off-therapy, 10 on-treatment HBsAg loss) from two medical centers and REVEAL-HBV cohort. The baseline in the Nuc arm was set since HBV DNA being undetectable (complete viral suppression) while in the S-loss arm was set since HBsAg loss. Those with HCC occurred prior to the baseline or within 6 months after the baseline were excluded from this analysis. Kaplan Meier analysis and log rank test were done for the cumulative HCC incidence comparison.

Results: Comparing the baseline features between Nuc arm and S-loss arm, the mean age (55.5 vs. 56.8, P = 0.14), gender (male: 74.5% vs. 81.2%, P = 0.07) and HBV genotype (p = 0.27) were comparable. The median ALT (29 vs. 20 U/L, P < 0.001) and AFP (4.16 vs. 3.0 mg/dL, P < 0.001) level were higher in the Nuc arm while follow-up duration was longer in the S-loss arm (median: 7.9 vs. 4.3 years, P < 0.001). In univariate analysis, older age [crude HR (cHR): 1.04, P < 0.0001], higher FIB-4 level [cHR: 1.1, P = 0.0004], higher AFP level [cHR: 1.02, P < 0.001] were positively associated with HCC occurrence while HBsAg loss is a protective factor for HCC [cHR: 0.502, P = 0.0314]. In multivariate analysis, older age [adjusted HR (aHR): 1.04 (1.02–1.06), P < 0.0001] and HBsAg loss [aHR: 0.19 (0.05–0.76), P = 0.0193] are the two independent predictor for HCC. The annual incidence and 8-year cumulative HCC incidence in cirrhotic patients in Nuc arm versus S-loss arm were 2.43% and 16% versus 1.16% and 8%, respectively (Log tank test, P = 0.0282). After propensity score matching with age, gender and FIB-4 at 1 to 1 ratio with 77 patients at each arm. HBsAg loss arm still had much lower HCC incidence than those under Nuc arm (annual incidence: 0.46% vs. 3.2%, log rank test, P = 0.0035).

Conclusion: This is the first study proved the HBsAg seroclearance, reflecting the inactive transcriptional activity of cccDNA, is a protective factor for HCC in cirrhotic chronic hepatitis B patients.

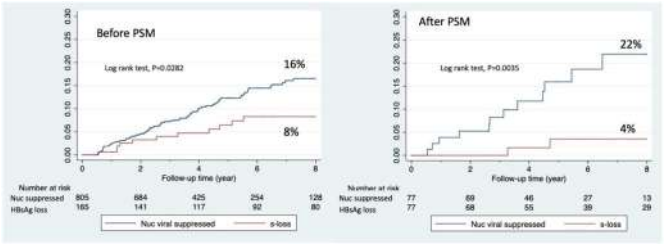

Figure: Cumulative HCC incidence between cirrhotic CHB patients with Nuc viral suppressed (blue line) and HBsAg loss (red line) before and after propensity score matching.

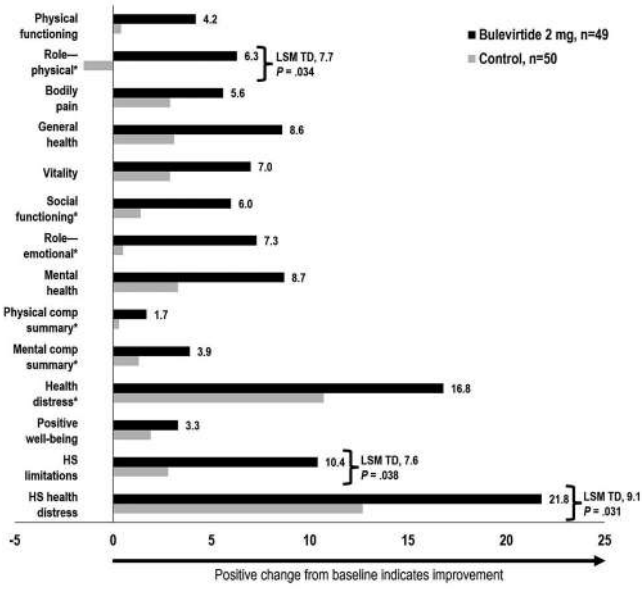
Migliavacca" Center for Liver Disease, University of Milan, Milan, Italy*
Email: mbuti@vhebron.net

Background and aims: Chronic hepatitis delta (CHD) infection is caused by a defective RNA virus that requires the presence of the hepatitis B virus (HBV) surface antigen for replication and transmission. Compared with HBV monoinfection, patients with CHD have a greater risk of cirrhosis, hepatocellular carcinoma, liver transplant, and liver-related mortality. In 2020, the European Medicines Agency granted conditional marketing authorisation to bulevirtide (BLV) 2 mg, a novel NTCP entry inhibitor, as the first treatment approved for CHD. We report an exploratory analysis of health-related quality-of-life outcomes in patients with CHD after 48 weeks of treatment with BLV 2 mg in an ongoing Phase 3 trial.

Method: MYR301 (NCT03852719; EudraCT 2019-001213-17) is a randomised, open-label, parallel-group, multicentre trial that assigned 150 CHD patients (1:1:1) to 3 exploratory arms (BLV 2 or 10 mg or control) for up to 3 years. (As BLV 10 mg is not an approved dosage, we do not report that treatment arm.) Control patients received no active anti-HDV treatment until Week (W)48. Patients completed the Hepatitis Quality of Life Questionnaire (HQLQ), including the SF-36 and 15 supplemental items, at study baseline (BL), W24, and W48. Higher scores on the HQLQ (range 0–100) indicate better health. Interim results collected at W24 were reported previously.[1]

Results: BL characteristics were well balanced between BLV 2 mg (n = 49) and controls (n = 51). For BLV 2 mg, mean age was 44 years, BMI was 24 kg/m^2, 61% were male, 83% were White, and 47% had compensated cirrhosis. Across groups, patients reported varying scores of HQLQ. From BL to W48, BLV 2 mg was associated with improvements in all HQLQ domains; notably, >5-point improvements in mean values were observed for 10 of the 14 items (Figure). Treatment differences vs controls in least-squares mean changes from BL to W48 were statistically significant ($p < 0.05$) for role-physical, hepatitis-specific (HS) limitations, and HS health distress. Improvements with BLV 2 mg seen at W24 were largely maintained or increased at W48.

Figure. LSM change from baseline to Week 48 in HQLQ domain scores, full analysis set



Patients in the control group received no active treatment until Week 48.
*n=49 for control group.
Comp, component; **HQLQ**, Hepatitis Quality of Life Questionnaire; **HS**, hepatitis-specific; **LSM**, least-squares mean; **TD**, treatment difference.

Conclusion: CHD patients treated with BLV 2 mg showed an improvement at W48 in all domains of the HQLQ, while patients in the control group remained largely unchanged, apart from substantial improvements in health distress and HS health distress. Patients receiving BLV 2 mg reported significant improvements in quality-of-life domains, including role-physical, HS limitations, and HS health distress, compared with controls.

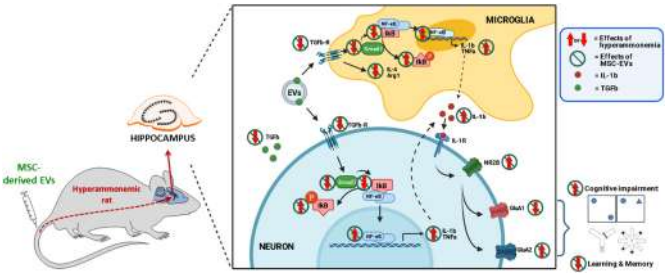
Extracellular vesicles from mesenchimal stem cells reduce neuroinflammation in hippocampus and restore cognitive function in hyperammonemic rats

Paula Izquierdo-Altarejos[1], Carlos Sanchez-Huertas[2], Victoria Moreno-Manzano[3], Vicente Felipo[1,4]. *[1]Centro de Investigacion Principe Felipe, Neurobiology, Valencia, Spain; [2]Instituto de Neurociencias CSIC-UMH, Laboratory of Bilateral Neural Circuits, Alicante, Spain; [3]Centro de Investigacion Principe Felipe, Neuronal and Tissue Regeneration Lab, València, Spain; [4]CIPF Centro de Investigación Príncipe Felipe, Valencia, Spain*
Email: vfelipo@cipf.es

Background and aims: Chronic hyperammonemia, a main contributor to hepatic encephalopathy, leads to neuroinflammation which alters neurotransmission leading to cognitive impairment. Currently there are no specific treatments for the neurological alterations in hepatic encephalopathy. Extracellular vesicles (EVs) from mesenchymal stem cells (MSCs) reduce neuroinflammation in some pathological conditions. The aim of this work was to assess if treatment of

hyperammonemic rats with EVs from MSCs reducesneuroinflammation, improves neurotransmission in hippocampus and restorescognitive function and to analyzethe mechanisms involved.
Method: Treatment with EVs from MSCs was performed in vivo by intravenous injection and ex vivo in hippocampal slices in hyperammonemic and control rats. Effects on neuroinflammation (microglia and astrocytes activation and content of inflammatory markers in hippocampus) were assessed by immunohistochemistry, immunofluorescence and western blot. Learning and memory were assessed using the following tests: object location, object recognition, Y maze and radial maze.
Results: The EVs injected reached the hippocampus. Hyperammonemia induced neuroinflammation in hippocampus and impaired learning and memory in the tests performed. Treatment with EVs reduced microglia and astrocytes activation, the content of IL-1beta and NF-kB activation and restored performance of hyperammonemic rats in all the behavioral tests. Studies adding EVs to hippocampal slices ex vivo showed that these beneficial effects were dependent on TGFbeta present in the EVs, which reduced NF-kB activation and the subsequent neuroinflammation.



Conclusion: Extracellular vesicles from mesenchymal stem cells reduce neuroinflammation in hippocampus and restore cognitive function in hyperammonemic rats. EVs from MSCs may be useful to improve cognitive function in patients with Minimal Hepatic Encephalopathy.

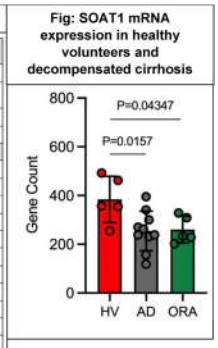
OS151
Lipidomics analyses of ATTIRE trial patients' plasma at day 1 demonstrates that reduced cholesterol esterification predicts development of hospital acquired infection

Harriett Fuller[1], Thais Tittanegro[2], Alex Maini[2], Louise China[2], James Thorne[3], J. Bernadette Moore[1], Alastair O'Brien[2]. *[1]University of Leeds School of Food Science and Nutrition, Leeds, United Kingdom; [2]UCL Institute for Liver and Digestive Health Upper 3rd Floor, University College London Division of Medicine, London, United Kingdom; [3]School of Food Science and Nutrition @ Parkinson (p2.32), Faculty of Environment University of Leeds, Leeds, United Kingdom*
Email: fshf@leeds.ac.uk

Background and aims: Hospital acquired infections (HAIs) are common in acute decompensation (AD) patients and studies support an anti-inflammatory role for statins. We investigated the role of lipid metabolism pathways in AD patients that developed HAIs.
Method: Plasma from 56 ATTIRE trial patients (31 male, 25 female) at day 1 (pre-albumin infusions or standard care) were analysed using Lipotype Shotgun Lipidomics platform. Patients were not diagnosed with infection nor taking antibiotics at sampling, with 26 subsequently developing HAI and 30 not. Lipidomic profiles predicting HAI status were analysed via multivariate statistical techniques (principal component analysis (PCA), partial least squares discriminatory analyses (PLSDA) and sparse PLSDA (sPLSDA)) on 245 lipids with <25% missing data prior to imputation. In non-ATTIRE patients without infection and not on antibiotics, we performed whole blood bulk RNA sequencing (RNA-seq) comparing healthy volunteers (HV, n = 5), outpatients with refractory ascites (ORA, n = 5) and hospitalised AD patients (n = 10). Finally, we examined HAI incidence in the 47 ATTIRE patients on statins at baseline.
Results: Median time to HAI was 6 days. PLSDA models including clinical covariates significantly predicted HAI development, with Bilirubin at baseline having a variable importance in projection (VIP) score of 2.5. Within each metabolite class, only PCAs of Cholesterol Esters (CEs) and Sphingomyelin (SM) class resulted in separation by HAI status, driven by CE 18.16.0, CE 18.2.1, CE 18.2.2 and SM 42.2.2. When included in PLSDA models, CE 18.1.0 and CE 18.2.0 were both important in predicting HAI (VIP >1) (table). RNA-seq showed reduced blood Sterol O-acyltransferase 1 (SOAT1) expression compared to HV (mean ± SD gene count: 384.0 ± 94.9) in ADs (254.9 ± 81.0; P = 0.02) and ORA patients (260.0 ± 55.1; P = 0.04, figure). There was no difference in HAI according to baseline statin use, which occurred in 9/47 statin (19.1%) and 141/730 non-statin (19.3%) patients.

Table: PLDSA Models to predict HAI in ATTIRE AD Patients

Model output	Model 1	Model 2	Model 3	Model 4
Outcome variance explained (R^2Y)	0.19	0.20	0.20	0.21
Outcome variance explained cross validation(Q^2Y)	0.13	0.13	0.14	0.14
p value - R^2Y	**0.05**	**0.05**	**0.05**	**0.05**
p value - Q^2Y	**0.05**	**0.05**	**0.05**	**0.05**
Included variables	**VIPs**			
Bilirubin D1	**2.51**	**2.75**	**2.19**	**2.27**
CE.18.2.0	-	-	**2.19**	**2.29**
CE.18.1.0	-	-	**1.11**	**1.15**
CE.16.0.0	-	-	0.71	0.73
Baseline creatinine	0.70	0.83	0.47	0.49
Age	-	0.68	0.57	0.59
MELD Score	0.42	0.46	0.35	0.36
SM.42.2.2	-	-	-	0.18
CRP D1	0.18	0.23	0.09	0.09
WCC D1	0.13	0.15	0.10	0.11
Baseline albumin	0.03	0.08	0.09	0.10
Sex	-	0.08	0.03	0.03
Statins use	0.03	0.04	0.02	0.02



Conclusion: Data are consistent with a downregulation of blood cholesterol esterification via SOAT1 in AD patients predicting development of HAI. Statins do not affect cholesterol esterification and were non-predictive of HAI status within PLSDA models and had no effect clinically, although small numbers were analysed. CE may be novel and functional biomarkers that predict HAI in AD, providing mechanistic insight.

OS152
Integrating single-cell RNA and spatial transcriptomic data defines altered cell state in human liver fibrosis

Nigel Hammond[1], Sokratia Georgaka[1], Syed Murtuza-Baker[1], Ali Al-Anbaki[1], Elliot Jokl[1], Harry Spiers[2,3], Ajith Siriwardena[1], Varinder Athwal[1], Neil Hanley[1], Magnus Rattray[1], Karen Piper Hanley[1]. *[1]The University of Manchester, United Kingdom; [2]University of Cambridge, Department of Surgery, Cambridge, United Kingdom; [3]Addenbrooke's Hospital, Department of Hepato-pancreato-biliary Surgery, Cambridge, United Kingdom*
Email: karen.piperhanley@manchester.ac.uk

Background and aims: Advances in single cell technology have revolutionised our understanding of the liver, enabling genome-wide RNA-profiling of thousands of transcriptomes at single cell resolution. Recent studies utilising single cell RNA sequencing (scRNA-seq) have characterised progenitor cell populations, uncovered gene expression zonation of multiple cell types, and revealed their contribution to disease pathogenesis. However, scRNA-seq does not capture the spatial distribution of transcripts in cells and dissociated tissue can cause transcriptomic changes. In contrast, the recent explosion of spatial transcriptomics (ST) technologies has enabled genome-wide characterisation of cellular heterogeneity at near single-cell resolution, while preserving spatial information.
Method: In this study, we have utilised ST to profile the fibrotic niche in human cirrhotic liver. Using 10X Genomics Visium, we

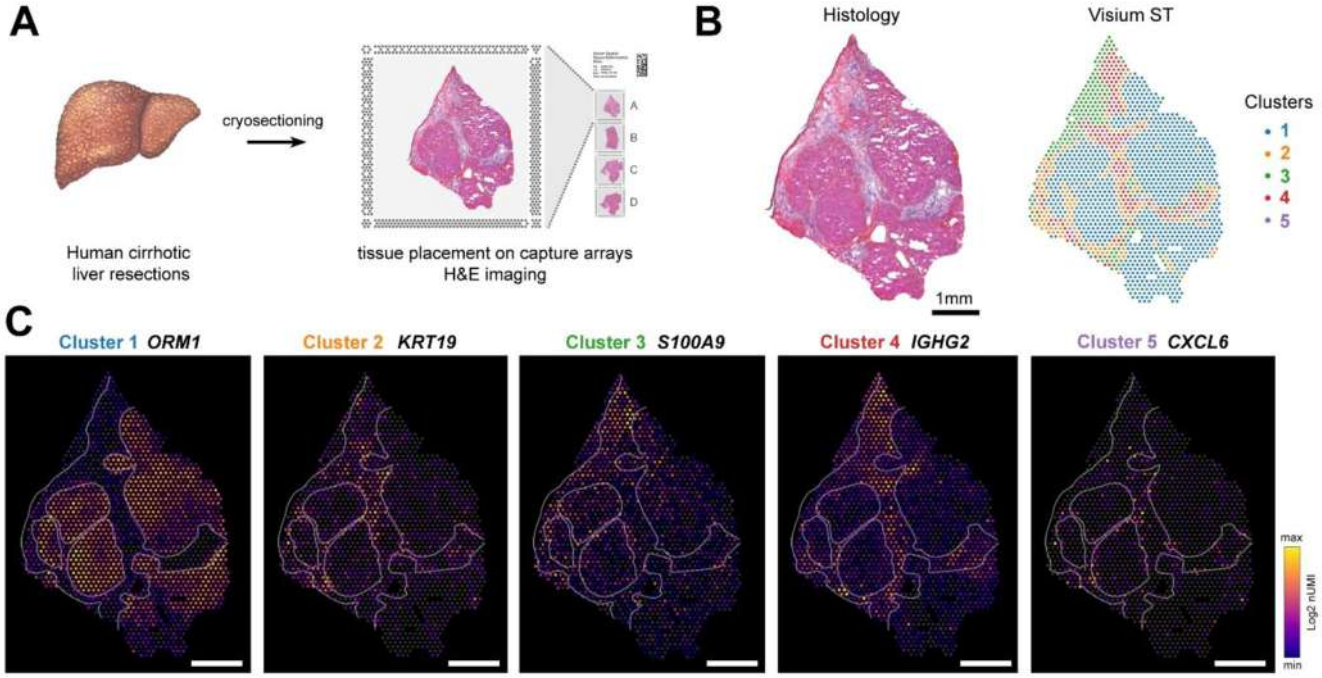


Figure 1: (abstract: OS152): Spatial trancriptomics of human cirrhotic liver. (A) Human cirrhotic liver resections are fresh frozen, cryo-sectioned and placed onto Visium ST capture slides. Tissue permeabilisation enables mRNA to be captured, ST libraries constructed, sequenced and mapped back to Visium spots. (B) Spatially-significant gene clusters were identified by performing dimensionality reduction followed by unsupervised clustering and projecting clusters back onto the tissue. (C) Gene expression of significant targets representing spatial clusters. Scalebars 1 mm.

demonstrate ST can resolve diseased liver tissue into discrete gene expression clusters which correlate with histological landmarks, revealing spatial expression profiles of the fibrotic scar and interface with regenerative nodules (Figure 1). To increase the resolution of ST data, we generated a complementary human cirrhotic liver scRNA-seq dataset. Through Cell2location computational approaches, we defined cell type clusters and deconvoluted multi-cell ST data to reveal spatial molecular signatures of several scar-associated cell sub-populations.

Results: Furthermore, our data spatially located impaired extracellular matrix (ECM) signalling associated with the pathogenesis of progressive liver disease and provided insight into mechanoadaptive mechanisms during myofibroblast activation.

Conclusion: This study demonstrates how comprehensive ST aligned to computational approaches can be used to delineate spatial gene expression patterns during liver disease. Our data highlights the future of ST in studies to understand mechanisms underlying progressive liver disease as well as its potential in clinical pathology.

Email: savykaur@gmail.com

Background and aims: Mesenteric lymphatic vessels (MLVs) are functionally impaired in cirrhosis. We explored therapeutic effects of a human recombinant pro-lymphangiogenic factor, vascular endothelial growth factor C (rhVEGF-C, Cys156Ser) on MLVs and the draining lymph nodes (LNs) in experimental cirrhosis.

Method: CCl4-induced rat models of cirrhosis were prepared. Molecular and histological studies of the MLVs were performed. rhVEGF-C (10 ug/kg), which binds to VEGF-receptor 3 (VEGFR3) on lymphatic endothelial cells (LyECs), was injected intraperitoneally in 5 doses on alternate days in cirrhotic models. CCl4 rats were given saline as vehicle. The sprouting and drainage of MLVs was analyzed using histology and whole-mount BODIPY of mesentery. To gain mechanistic insights, gene expression profiling of isolated and sorted mesenteric LyECs was performed by RT-PCRs. Dendritic Cell (DCs) and T cell subsets were quantified in LNs, portal and peripheral circulation by flow cytometry. Systemic inflammatory cytokines were examined. Gut bacterial translocation to mesenteric lymph nodes, liver, and systemic circulation was studied using orally administered GFP labelled *Salmonella typhimuriu*m.

Results: An increased gene and protein expression of VEGF-C was observed in the mesenteric tissues of treated rats in comparison to the vehicle. Histology displayed a significant increase in area per field of the MLVs in treated versus vehicle rats (1.8 vs 3.9, $p < 0.001$). Drainage of mesenteric lymph was increased in treated as compared to vehicle (30 a.u. vs 60 a.u., $p < 0.001$) with decreased lymph leakage (50 a.u. vs 20 a.u., $p < 0.001$) in comparison to vehicle. Sprouting of MLVs from pre-existing vessels was observed in treated rats with significantly reduced dilation wrt vehicle (200 µm vs 100 µm, $p < 0.001$). Sorted LyECs showed increased expression of LyVE1 (7.4 fc, $p < 0.01$) and Prox1 (7.7 fc, $p < 0.05$) in treated rats wrt vehicle. Enhanced expression of adhesion molecules such as VE-CAD (5 fc, $p < 0.05$) in LyECs correlated with decreased lymph leakage and permeability of MLVs in treated rats. Expression of CCL21 (2.04 fc $p < 0.05$), a chemoattractant for DCs and T cells, and CD86 (9.36 fc, $p < 0.05$), an antigen presentation molecule was increased in LyECs of treated wrt vehicle rats. Among all immune cells, LNs showed an increased percentage of activated CD8 T cells (24.07 vs 11.37, $p < 0.05$) and DCs (67.03 vs 55.52, $p < 0.05$) in treated versus vehicle. Treated rats also exhibited increased clearance in LNs as compared to vehicle ($p < 0.05$).

Conclusion: In cirrhosis, treatment with VEGF-C ameliorates mesenteric lymph drainage and permeability owing to the increased expression of adhesion molecule, VE-CAD in the LyECs. VEGF-C modulates gut immunity and bacterial clearance and thus may serve as an emerging therapy for combating gut infection and inflammation in cirrhosis.

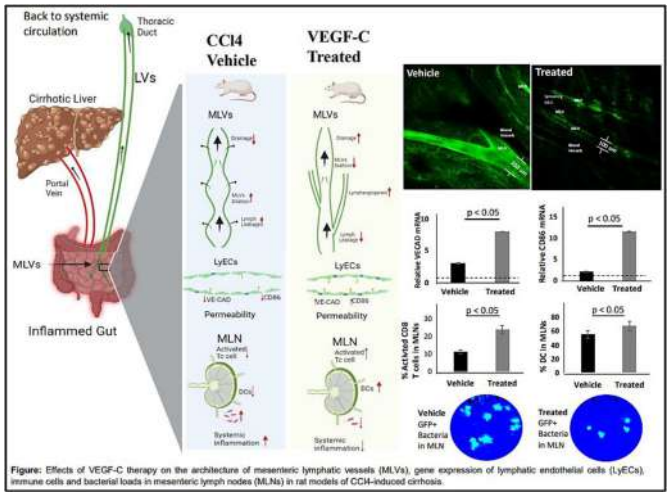

Figure: Effects of VEGF-C therapy on the architecture of mesenteric lymphatic vessels (MLVs), gene expression of lymphatic endothelial cells (LyECs), immune cells and bacterial loads in mesenteric lymph nodes (MLNs) in rat models of CCl4-induced cirrhosis.

Email: wjimenez@clinic.cat

Background and aims: Decompensated liver cirrhosis results from the worsening of the liver function and is characterized by the appearance of a clinical phenotype, frequently ascites and portal hypertension. The primary cause of portal hypertension is an increase in the resistance to portal blood flow. Architectural distortion, hepatic stellate cell contraction, and endothelial dysfunction with increased vasoconstrictor and deficient nitric oxide (NO) production are major factors governing this process. Here, we assessed the potential therapeutic effect of engineered poly (beta-amino esters) nanoparticles (PBAE NPs) containing an NO donor in experimental decompensated cirrhosis.
Method: NO donor pGFP PBAE NPs with retinol moiety were synthetized and characterized by dynamic light scattering. Next, liver cirrhosis was induced in male Wistar rats by repetitive carbon tetrachloride inhalation (1 g/l) twice a week until the appearance of ascites. Cirrhotic rat precision cut liver slices (PCLS) were treated with PBAE NPs and *ex vivo* transfection was evaluated by fluorescence microscopy. In order to assess organ biodistribution, the NPs were also administered intravenously. Finally, another group of cirrhotic rats received functionalized control or NO donor PBAE NPs (30 mg/kg body weight) and subsequently an hemodynamic study was performed.
Results: Engineered NO donor PBAE NPs had an average hydrodynamic size of 170 nm and were positively charged; remaining stable for at least 24 h. After 48 h treatment, the NPs were successfully internalized by cirrhotic PCLS. Besides, when administered *intravenously*, engineered PBAE NPs targeted the liver, spleen and kidney of already after 24 h, although the signal of the two latter was significantly of lower intensity. Notably, they did not reach the brain, heart or lung. Finally, the treatment with functionalized NO donor PBAE NPs resulted in a significant ($p < 0.05$) decrease of portal hypertension (9.6 ± 0.6 mmHg) in comparison to control NPs (13.2 ± 0.9 mmHg) in rats with decompensated cirrhosis. Remarkably, the treatment did not affect mean arterial pressure, being 96.7 ± 1.1 and 92.3 ± 4.2 mmHg, in cirrhotic rats treated with control or NO donor NPs, respectively. Likewise, the cardiac output was not affected (390.7 ± 80.8 L/min vs 301.3 ± 48.9 L/min).
Conclusion: Engineered NO donor PBAE NPs effectively target the liver, and could be therapeutically useful to mitigate portal hypertension.

Background and aims: Type C hepatic encephalopathy (HE) develops on the background of cirrhosis. Both hyperammonemia and inflammation contribute to disease development. Murine models of type C HE are either not available or poorly characterized, hampering translational research. This project aims to validate and characterize murine bile duct ligation (BDL) as a model for type C HE.
Method: Male C57BL/6j mice (n = 15/timepoint/group) were subjected to BDL or sham surgery. Animals were sacrificed on day 7, 14, 21 or 28. Standardized motor function tests were performed. Plasma samples were isolated for ammonia and cytokine measurement. Targeted metabolomics (LC-MS/MS) for amino acids, bile acids, energy metabolites and redox markers was performed on cerebrospinal fluid (CSF). Brain samples were taken for immunostainings and cytokine profiling. In a separate experiment, mice were injected with 4 kDa FITC-Dextran 15 min before sacrifice to assess blood-brain barrier (BBB) permeability changes.
Results: BDL induces motor dysfunction, demonstrated by increased beam traversal time (+60%, $p = 0.0056$ on day 7) and reduced travelling in the open field (−71%, $p < 0.0001$ on day 14). Concomitantly, plasma ammonia increases progressively in BDL mice ($p = 0.0012$ on day 21). CSF metabolomics reveal a significant glutamine increase from 14 days on ($p = 0.0029$). Additionally, a glutamate decrease is observed. Other osmolytes taurine and creatine transiently decrease. Interestingly, plasma ammonia correlates significantly with CSF glutamine ($r = 0.5076$, $p = 0.0113$).
AMP is depleted at 14 days ($p = 0.0021$), but other energy markers are not altered in BDL mice. Remarkably, tauro-conjugated bile acids ($p = 0.0016$), but also tryptophan ($p = 0.0084$) accumulate in CSF after 7 days.

Systemic inflammation is evident from 7 days onward with increased plasma IL-6 levels (p = 0.0002). From 14 days on, 3D reconstructed cortical microglial cells reveal activated morphology, indicating neuroinflammation (Figure 1). CCL2 levels are significantly increased in the cortex 28 days after BDL (p = 0.0418), coinciding with increased BBB permeability (p = 0.0031).

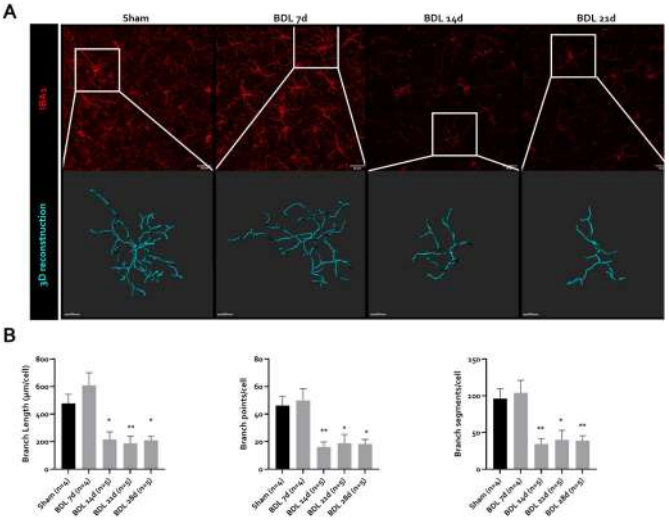

Figure 1. Microglial ramification at different timepoints after BDL. A. Representative confocal maximum intensity positive microglia and magnified 3D reconstructed microglia in prefrontal cortex at different timepoints after BDL. reconstructed microglia, showing branch length, number of branch points, branch segments and endpoints per cell. n = 4- statistical differences between sham and BDL at different time points using one-way ANOVA and Dunnett post-hoc test data are represented as mean + SEM. Scale bar IBA1 = 20 µm. Scale bar 3D reconstruction = 10 µm. BDL, bile duct ligation

Conclusion: Murine BDL reproduces clinical, metabolic and gliovascular features of type C HE. Early behavioural changes are obvious before plasma ammonia and brain glutamine accumulate, and potentially reflect the effect of systemic inflammation and cerebral bile acid/tryptophan accumulation on behaviour. Altogether, these data support the clinical relevance of this HE model, which can now be used for further neurobiological and intervention studies.

Yttrium-90 radioembolization versus drug-eluting beads chemoembolization for unresectable hepatocellular carcinoma: results from the TRACE phase 2 randomized controlled trial

Elisabeth Dhondt[1], Bieke Lambert[2,3], Laurens Hermie[1], Lynn Huyck[1], Peter Vanlangenhove[1], Anja Geerts[4], Xavier Verhelst[4], Maridi Aerts[5], Aude Vanlander[6], Frederik Berrevoet[6], Roberto Ivan Troisi[2,7], Hans Van Vlierberghe[4], Luc Defreyne[1]. *[1]Ghent University Hospital, Vascular and Interventional Radiology, Ghent, Belgium; [2]Ghent University, Faculty of Medicine and Health Sciences, Belgium; [3]AZ Jan Palfijn and AZ Maria Middelares, Nuclear Medicine, Belgium; [4]Ghent University Hospital, Gastroenterology and Hepatology, Gent, Belgium; [5]University Hospital Brussels, Gastroenterology, Belgium; [6]Ghent University Hospital, General and HPB Surgery and Liver Transplantation, Ghent, Belgium; [7]Frederico II University Hospital, Hepatobiliary and Minimally Invasive and Robotic Surgery, Naples, Italy*
Email: elisabeth.dhondt@uzgent.be

Background and aims: Transarterial chemoembolization (TACE) is the recommended treatment for intermediate hepatocellular carcinoma (HCC) in the Barcelona Clinic Liver Cancer guidelines. Prospective uncontrolled studies suggest that Yttrium-90 transarterial radioembolization (TARE) is a safe and effective alternative. The aim of the study was to compare the efficacy and safety of TARE to TACE for unresectable HCC.

Method: In this single-center prospective randomized controlled trial (TRACE), Yttrium-90 glass TARE was compared with doxorubicin-eluting beads TACE (DEB-TACE) in patients with intermediate stage HCC extended to Eastern Cooperative Oncology Group performance status 1 and early-stage HCC patients not eligible for surgery or thermoablation. Participants were recruited between September 2011 and March 2018. Primary end point was time to progression (TTP $_{overall}$; Kaplan-Meier analysis) in the intention-to-treat (ITT) and per protocol (PP) population.

Results: Ad interim analysis, 38 participants (median age, 67 years; IQR 63–72; 33 men) were randomized to the TARE arm and 34 (median age, 68 years; IQR 64–74; 30 men) to the DEB-TACE arm (ITT population). Median $TTP_{overall}$ was 17.1 months in the TARE arm versus 9.5 months in the DEB-TACE arm (ITT: HR 0.36; 95% CI: 0.18, 0.70; p = 0.002) (PP: 32 and 34 participants respectively: HR 0.29; 0.14, 0.60; p < 0.001). Median overall survival was 30.2 months after TARE and 15.6 months after DEB-TACE (ITT: HR 0.48; 0.28, 0.82; p = 0.006). Serious adverse events grade ≥3 (13 of 33 (39%) versus 19 of 36 (53%) after TARE and DEB-TACE respectively, p = 0.47) and 30-day mortality (0 of 33 (0%) versus 3 of 36 (8%), p = 0.24) were similar in the safety populations. Ad interim the HR for the primary end point $TTP_{overall}$ was <0.39, indicative to halt the study.

Conclusion: With similar safety profile, Yttrium-90 radioembolization conferred superior tumor control and survival compared to drug-eluting beads chemoembolization in selected participants with early and intermediate HCC.

Background and aims: Cholangiocarcinoma (CCA) is a rare and heterogeneous biliary cancer, with increasing incidence and related mortality. This study investigates the clinical course of CCA and subtypes (intrahepatic (iCCA), perihilar (pCCA), and distal (dCCA)) in a pan-European cohort.

Method: The ENSCCA Registry is a multicenter observational study. Patients with histologically-proven CCA diagnosis between 2010–2019 were included. Demographic, histomorphological, biochemical, and clinical studies were performed.

Results: Overall, 2, 234 patients were enrolled (male:female = 1.29). iCCA (n = 1, 243) was associated with overweight/obesity (58.5%) and chronic liver diseases involving cirrhosis (12.6%) and/or viral hepatitis (10.4%); pCCA (n = 592) with primary sclerosing cholangitis (8.8%); and dCCA (n = 399) with choledocholithiasis (10.3%). At diagnosis, 42.2% of patients had local disease, 29.4% locally-advanced disease (LAD), and 28.4% metastatic disease (MD). Serum CEA and CA19–9 showed low diagnostic sensitivity (69.1% and 40.9% below cutoff, respectively), but their concomitant elevation was associated with increased risk of presenting with LAD [OR = 2.16;95%CI:1.43–3.27] or MD [OR = 5.88;95%CI:3.69–9.25]. Patients undergoing resection (50.3%) showed the best outcome, particularly with negative-resection margin (R0) [median overall survival (mOS) = 45.1 months]; however, margin involvement (R1) [HR = 1.92;95%CI:1.53–2.41;mOS = 24.7 months] and lymph node invasion [HR = 2.13;95% CI:1.55–2.94;mOS = 23.3 months] compromised prognosis. Among patients with unresectable disease (49.6%), the mOS was 10.6 months for those receiving active palliative therapies, mostly chemotherapy (26.2%). Patients receiving best supportive care (20.6%) had mOS of 4.0 months, with iCCAs showing worst outcome compared to p/dCCAs. ECOG performance status [HR = 1.52;95%CI:1.01–2.31], MD [HR = 4.03;95%CI:1.82–8.92] and CA19–9 [HR = 2.79;95%CI:1.46–5.33] were independently prognostic for OS.

Conclusion: CCA is still diagnosed at advanced stage, a proportion of patients fail to receive cancer-specific therapies, and prognosis is dismal. Identification of preventable risk factors and implementation of surveillance in high-risk populations are required to decrease cancer-related mortality.

OS158

PRIME-HCC: phase Ib study of neoadjuvant ipilimumab and nivolumab prior to liver resection for hepatocellular carcinoma

Email: a.dalessio@imperial.ac.uk

Background and aims: Up to 70% of patients with early-stage hepatocellular carcinoma (HCC) treated with liver resection (LR) relapse within two years after surgery. Immune checkpoint inhibitors (ICPI) are an established treatment for unresectable HCC, but ICPI combinations have not been explored in the peri-operatory setting.

Method: PRIME-HCC is a phase Ib study investigating safety and bioactivity of the nivolumab (3 mg/kg, day 1 and day 22) plus ipilimumab (1 mg/kg, day 1 only) combination prior to LR in

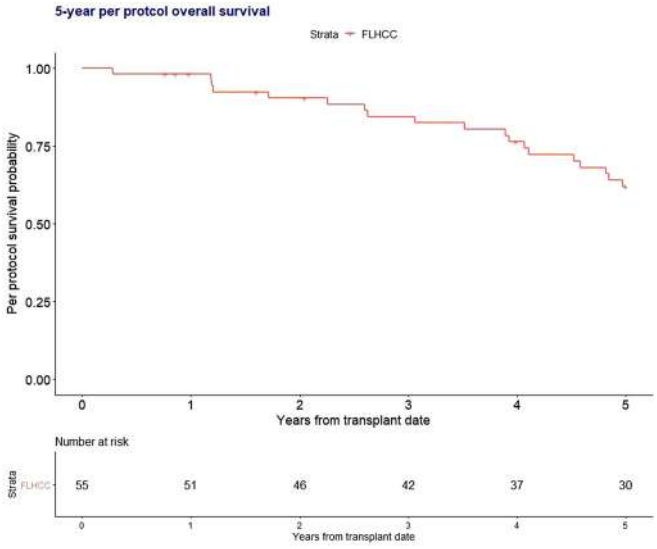
early-stage HCC. The primary safety analysis assessed treatment-related adverse events (trAE) and delays to surgery. Secondary end point included overall response rates (ORR) by RECIST v1.1 and pathologic responses on resection specimens.
Results: At data censoring on the 4th of November 2021, 12 patients were enrolled, of whom 83% (n = 10) were male, with a median age of 65 years (range 47–70). Liver cirrhosis was found in 75% (n = 9) of the patients, and the most frequent aetiology was viral hepatitis (50%, n = 4 with HCV and n = 2 with HBV infection). All patients were Child-Pugh A, with 58% classified as albumin-bilirubin (ALBI) grade 1. Median tumour diameter was 3.4 cm (interquartile range [IQR] 1.4, range 1.1–7.3), and the median number of liver nodules was 1 (IQR 1, range 1–3). Median baseline AFP was 6 mcg/L (IQR 115, range 2–11'777). Any-grade trAEs were reported by 75% of the patients (n = 9). Four patients (33%) reported grade 2 trAEs including hypothyroidism (n = 2), diarrhoea (n = 1), and fatigue (n = 1), and one (8%) grade 3 ALT/AST elevation. After a median follow-up of 9.1 months (IQR 19.1, range 2.5–24.9), no deaths had occurred, and one disease relapse was recorded 20.8 months after treatment commencement. Median time to LR from screening was 2.5 months (IQR 0.9, range 2.2–3.6). One patient had a surgery delay due to liver function worsening (ICPI-unrelated) and remained progression-free by RECIST 9.6 months post-screening. In another patient LR was switched to radiofrequency ablation by the treating surgeon due to surgical risk independent of ICPI exposure. One patient was found to have cholangiocarcinoma (CCA) on LR specimen and was excluded from efficacy analyses. ORR was 18%, with two partial responses. Disease control rate was 91%, and one patient with mixed HCC/CCA histology showed primary progression. Of the nine pathologically evaluable patients, seven (78%) achieved a pathological response, including two (22%) complete responses.
Conclusion: Neoadjuvant immunotherapy with nivolumab plus ipilimumab is tolerable and is characterised by evidence of anti-tumour efficacy in early-stage HCC.

OS159

Liver transplantation for patients with fibrolamellar hepatocellular carcinoma: a comprehensive multicenter analysis to support future decision making

Marco Claasen[1,2], Tommy Ivanics[1], Wojciech Polak[2], Jan Ijzermans[2], Gonzalo Sapisochin[1]. [1]*University Health Network, Multi-Organ Transplant Program, Toronto, Canada;* [2]*Erasmus MC Transplant Institute, University Medical Centre Rotterdam, Department of Surgery, Division of HPB and Transplant Surgery, Rotterdam, Netherlands*
Email: marco.claasen@uhnresearch.ca

Background and aims: Fibrolamellar hepatocellular carcinoma (FL-HCC) is a rare tumour accounting for ~1% of all primary liver cancers. Due to its rarity, there is a shortage of data on liver transplantation (LT) for patients with FL-HCC. Previously post-LT outcomes have been evaluated based on patients transplanted a decade ago, however contemporary and intention-to-treat (ITT) and recurrence outcomes are lacking. Therefore, to gain more insight on the management of these patients, we conducted a comprehensive multicenter analysis of FL-HCC patients looking at both post-listing and post-LT outcomes.
Method: All patients with a diagnosis of FL-HCC and listed for LT or transplanted between 1987–2019 were extracted from the UNOS registry. Re-LT and multi-organ transplants were excluded. Outcomes of interest were waitlist (WL) dropout and ITT overall survival (OS), derived from all patients with a FL-HCC diagnosis at listing, and post-transplant OS, recurrence-free survival (RFS), cumulative incidence of recurrence, and 30-/90-day post-transplant mortality, for all patients with a confirmed diagnosis of FL-HCC at explant pathology. WL dropout was defined as dropping out of the WL due to death, clinical deterioration, or medical unsuitability. Recurrence and death were the events for predicting RFS. For the cumulative incidence of recurrence, death was a competing event. For all other outcomes, death was the only event. Median follow-up times were 4.5 years (interquartile range [IQR] 1.2–8.2) from listing and 5.0 years (IQR 2.6–9.8) post-LT.
Results: A total of 96 unique patients with a diagnosis of FL-HCC at listing or post-LT were extracted. Of these, 53% were female and 76% adult, with a median age of 25.5 years (range 10–66). Cirrhosis was present in 10 patients (10%) and 8 patients had an underlying disease (8%): hepatitis C virus (5), non-alcoholic steatohepatitis (2), glycogen storage disease (1). Of all FL-HCC patients, 72 were diagnosed at listing (75%), 10 post-LT (10.5%), and of 14 the moment of diagnosis was unknown (14.6%). Sixty-nine patients received a LT, of which 55 were post-operatively confirmed of having FL-HCC. Eight patients received a living donor LT. WL dropout at 1- and 2-years post-listing was 15.3% and 19.4%. ITT OS at 1, 3, 5 years was 86.5%, 67.9%, 55.5%, where post-LT OS was 98.2%, 84.4%, 61.9% at 1, 3, 5 years. No patients died within 90 days post-LT. RFS was 85.3%, 69.9%, and 47.5% at 1, 3, and 5 years. The cumulative incidence of recurrence at 1, 3, 5 years was 12.8%, 24.4%, and 44.7%. There was no statistical difference in all outcomes between adult and pediatric patients.



Conclusion: LT for patients with FL-HCC offers acceptable long-term survival outcomes despite a substantial risk of tumour recurrence. Further research is needed to determine which patients with FL-HCC would benefit most from LT and potential adjuvant therapies to reduce the risk of recurrence.

OS160

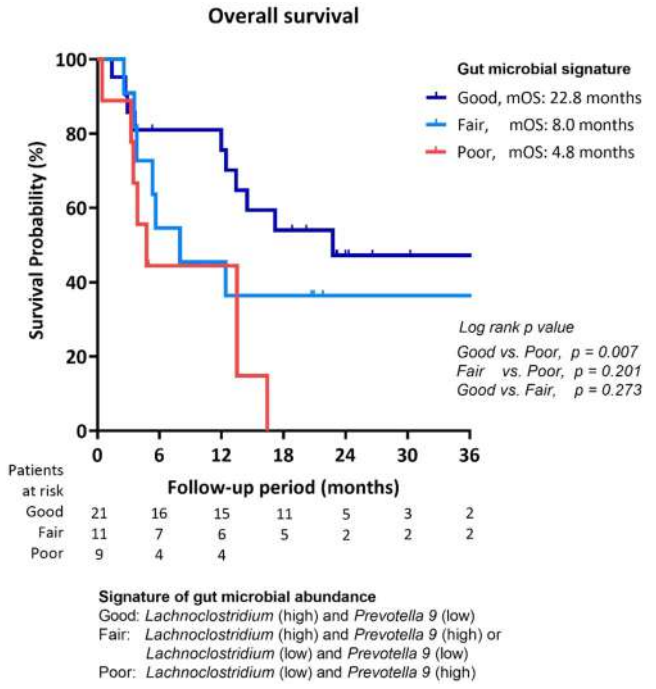
A preferable signature of gut microbiota and bile acids predicted better outcomes of unresectable hepatocellular carcinoma to immune checkpoint inhibitors

Pei-Chang Lee[1], Chijung Wu[1], Ya-Wen Hung[1], ChiehJu Lee[1], Chen-Ta Chi[1], I-Cheng Lee[1], Jiing-Chyuan Luo[1], Ming-Chih Hou[1], Yi-Hsiang Huang[1]. [1]*Taipei Veterans General Hospital, Division of Gastroenterology and Hepatology, Department of Medicine, Taipei, Taiwan*
Email: yhhuang@vghtpe.gov.tw

Background and aims: Immune checkpoint inhibitors (ICI) are newly emerged, promising therapeutic agents for unresectable hepatocellular carcinoma (uHCC). However, no effective biomarker has been found to predict treatment response. Gut microbiota could modulate outcomes of melanoma to immunotherapy. In this study, we aimed to investigate the effects of gut microbiota and metabolites on ICI-treated uHCC.
Method: From May 2018 to February 2020, patients who received ICI therapy for uHCC in Taipei Veterans General hospital were prospectively enrolled. Of them, fecal samples collected before treatment from

twenty objective responders and 21 non-responders (proved by radiology) were taken into analyses of microbiota and metabolites. Since March 2020, 33 consecutive Child-Pugh A, ICI-treated patients were investigated for validation. Besides, fecal samples from 17 healthy volunteers were also analyzed as control.

Results: A significant bacterial dissimilarity was observed between responders and non-responders before ICI treatment ($p = 0.016$ and 0.019 by Anoism and Adonis tests). *Lachnoclostridium, Lachnospiraceae*, and *Veillonella* were predominant faecal microbiota of responders; whereas, *Prevotella 9* was predominant in non-responders. Ursodeoxycholic acid and ursocholic acid were found significantly enriched in the feces of responders, and were strongly correlated with the abundance of *Lachnoclostridium*. A fecal signature of enriched *Lachnoclostridium* and depleted *Prevotella 9* could significantly predict better overall survival (OS) in these patients. In the validation cohort, the best objective response rate (52.6%) was noted in patients with a preferable microbial signature. Besides, the progression-free survival (PFS) and OS were better in patients with a preferable microbial signature as compared with the counter-group. (PFS: 8.8 vs. 1.8 months; OS: not reached vs. 6.5 months, both $p < 0.001$).



Conclusion: Pre-treatment fecal microbiota and bile acids are associated with treatment outcomes of ICIs for uHCC. These findings provided a potential strategy to enhance the efficacy of immunotherapy by modifying gut microbiota and metabolites in patients with uHCC.

OS161

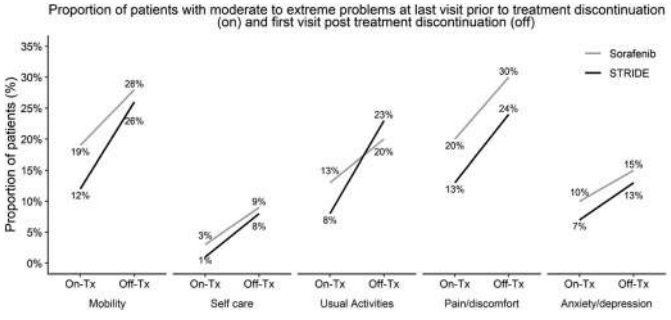
The impact of treatment and treatment status on health state utility in patients with unresectable hepatocellular carcinoma: an EQ-5D analysis from Himalaya

Lei Qin[1], Miguel Miranda[2], Cal Shephard[3], Abdul-Azeez Ganiyu[2], Vincent Tam[4]. [1]*AstraZeneca, Gaithersburg, United States;* [2]*AstraZeneca, Cambridge, United Kingdom;* [3]*Astrazeneca Canada, Mississauga, Canada;* [4]*Tom Baker Cancer Centre, Calgary, Canada*
Email: lei.qin@astrazeneca.com

Background and aims: The HIMALAYA trial (NCT03298451) showed that tremelimumab 300 mg added to durvalumab (STRIDE regimen) significantly improved survival compared to sorafenib for the treatment of patients with unresectable hepatocellular carcinoma (uHCC). This study also assessed predictors of health-related quality of life (HRQoL) using EuroQoL 5-Dimension, 5-Level health state utility (HSU) index (EQ-5D-5L) and visual analogue scale (VAS).

Method: EQ-5D-5L data were collected at baseline, every 8 weeks for 48 weeks, then every 12 weeks until treatment discontinuation, and additional assessments up to 12 weeks for patients with confirmed progression. Impact of treatment and treatment status on domain score and proportion of patients reporting any problem by domain at first off-treatment visit were assessed using last on-treatment visit as baseline. Impact on HSU was assessed by mixed models for repeated measures (MMRM). Univariate and multivariate analyses were conducted using treatment as base fixed effect and treatment status (on/off treatment), progression (progression-free/progressed) and baseline Child Pugh score as covariates. Interactions between covariates and treatment were considered. A random intercept model assuming independent within-subject errors was fitted to account for subject variability. Model performance was compared using AIC/BIC score. Analysis used algorithms reflecting societal preferences of UK, US and Canadian populations and validation analysis was conducted using VAS.

Results: Treatment and treatment status models were consistently the best fitting. Mean HSU for STRIDE was 0.815 (95% CI: 0.802, 0.827, $p < 0.0001$) and 0.785 (95% CI: 0.766, 0.804, $p < 0.0001$) for sorafenib, using a mapping algorithm reflecting Canadian preferences. Sorafenib treatment was associated with a utility decrement of −0.030 (95% CI: −0.046, −0.014, $p = 0.0002$) and a utility increment of 0.055 (95% CI: 0.046, 0.063, $p < 0.0001$) for those with a status of remaining on treatment. Results with UK and US algorithms, and when assessed by VAS, were consistent. Interaction of treatment and treatment status was non-significant in all models. The proportion of patients experiencing any problems on each domain of EQ-5D-5L increased between the last visit prior to- and first visit post-discontinuation for both regimens. The proportion of patients experiencing moderate to extreme problems was lower on all domains with STRIDE vs sorafenib for both on- and off-treatment, except usual activities (Figure 1).



Conclusion: The best predictors of HRQoL in patients with uHCC were treatment received and treatment status, where treatment with STRIDE and being on-treatment were associated with better HSUs compared to sorafenib treatment and being off-treatment. Results highlight there are notable HRQoL benefits for maintaining uHCC patients on treatment with STRIDE.

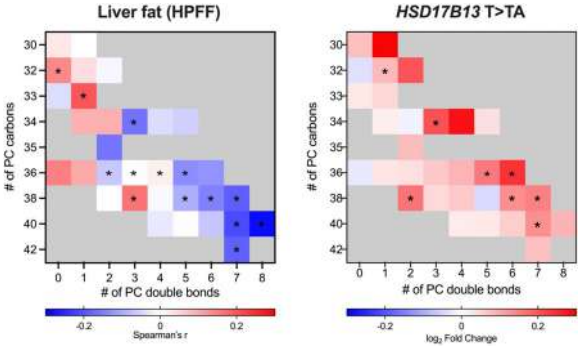
Heterogeneity of phosphatidylcholine metabolism in non-alcoholic fatty liver disease

Sami Qadri[1,2], Sami Blom[3], Kari Pitkänen[3], Noora Ahlholm[1,2], Kimmo Porthan[1,2], Panu K. Luukkonen[1,2,4], Anne Juuti[5], Henna Sammalkorpi[5], Anne Penttilä[5], Johanna Arola[6], Matej Orešič[7,8], Tuulia Hyötyläinen[9], Hannele Yki-Järvinen[1,2]. *[1]University of Helsinki and Helsinki University Hospital, Department of Medicine, Helsinki, Finland; [2]Minerva Foundation Institute for Medical Research, Helsinki, Finland; [3]Aiforia Technologies Oy, Helsinki, Finland; [4]Yale University, Department of Internal Medicine, New Haven, United States; [5]University of Helsinki and Helsinki University Hospital, Department of Gastrointestinal Surgery, Abdominal Center, Helsinki, Finland; [6]University of Helsinki and Helsinki University Hospital, Department of Pathology, Helsinki, Finland; [7]Örebro University, School of Medical Sciences, Örebro, Sweden; [8]University of Turku and Åbo Akademi University, Turku Bioscience Centre, Turku, Finland; [9]Örebro University, School of Science and Technology, Örebro, Sweden*
Email: hannele.yki-jarvinen@helsinki.fi

Background and aims: In murine models of non-alcoholic fatty liver disease (NAFLD), liver damage associates with a deficiency of phosphatidylcholines (PCs), particularly polyunsaturated PCs (PUFA-PCs). We studied whether human PC metabolism is altered by NAFLD or by the protective genetic variant in *HSD17B13* (rs72613567 T > TA).
Method: In 143 obese patients with a liver biopsy and genotyping for *HSD17B13* rs72613567, we analysed the hepatic lipidome (UPLC-MS). As the hepatic parenchymal fat fraction (HPFF) affects apparent concentrations of amphiphilic lipids, we normalised hepatic phospholipid concentrations to fat-free liver mass. To this end, we employed a state-of-the-art deep learning image analysis method (Aiforia Technologies) to accurately quantify HPFF in liver biopsies.
Results: Total unadjusted hepatic PCs correlated negatively with HPFF ($r_s = -0.26$, $P < 0.01$), but this association disappeared after normalising to fat-free liver mass ($r_s = 0.02$, $P = 0.81$). With increasing HPFF, concentrations of especially saturated and monounsaturated PCs significantly increased, whereas concentrations of PUFA-PCs decreased. Accordingly, the hepatic triacylglycerol composition significantly correlated with that of hepatic PCs. In carriers of the protective variant in *HSD17B13*, as compared to non-carriers, the hepatic lipidome was enriched in especially PUFA-PCs.
Conclusion: Patients with NAFLD have a deficiency of PUFA-PCs. The protective *HSD17B13* rs72613567 variant opposes these changes, increasing intrahepatic PC concentrations.

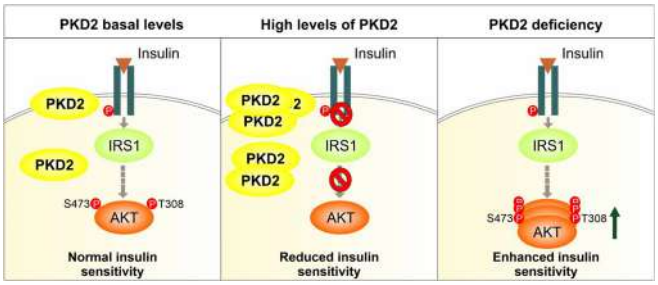


OS163

Unravelling the role of Protein Kinase D2 in the control of hepatic insulin sensitivity

Patricia Rada[1,2], Ana B. Hitos[1,2], Esther Rey[3,4], Elena Carceller-Lopez[1], Julia Pose-Utrilla[1,5], Carmelo Garcia-Monzon[4], Guadalupe Sabio[6], Teresa Iglesias[1,5], Águeda González[3,4], Angela Martinez Valverde[1,2]. *[1]Instituto de Investigaciones Biomédicas "Alberto Sols" (CSIC-UAM), Madrid, Spain; [2]Centro de Investigación Biomédica en Red de Diabetes y Enfermedades Metabólicas Asociadas (CIBERDEM), Madrid, Spain; [3]Centro de Investigación Biomédica en Red de Enfermedades Hepáticas y Digestivas (CIBEREHD), Spain; [4]Liver Research Unit, Instituto de Investigación Sanitaria Princesa, University Hospital Santa Cristina, Spain; [5]Centro de Investigación Biomédica en Red sobre Enfermedades Neurodegenerativas (CIBERNED), Spain; [6]Centro Nacional de Investigaciones Cardiovasculares Carlos III (CNIC), Spain*
Email: prada@iib.uam.es

Background and aims: Protein kinase D2 (PKD2) is a Ser/Thr kinase of the Ca^{2+}-Calmodulin kinase superfamily. Growing evidences support that PKD2 participates in the control of glucose homeostasis. Two previous studies, one conducted in global PKD2-deficient mice, and the other in mice lacking PKD2 in intestine, reported opposite results with metabolic dysfunction or protection against HFD-induced obesity, respectively. However, the role of PKD2 in the liver in the context of obesity-related insulin resistance has not been addressed and it is the aim of this study.
Method: PKD inhibition by pharmacological and genetic approaches was analyzed in primary hepatocytes and in Huh7 cells. To over-express PKD2, Huh7 cells were transfected with EGFP-PKD2-CA, a constitutively active PKD2 fused to EGFP. Insulin signaling cascade was examined by treating hepatocytes with insulin (10 nM, 5–15 min). As an *in vivo* model of hepatic insulin resistance, mice with a liver-specific PKD2 depletion ($PKD2^{\Delta Hep}$) were fed high fat diet (HFD, 20 weeks). Parameters assessing glucose homeostasis and hepatic insulin sensitivity were analyzed. PKD2 was overexpressed in liver by an injection of AAV bearing EGFP-PKD2-CA and insulin sensitivity was evaluated. PKD signature was analyzed in liver biopsies from NAFLD patients.
Results: PKD pharmacological inhibition resulted in an increased insulin sensitivity showed by a higher AKT phosphorylation after insulin stimulation in both primary mouse hepatocytes and Huh7 cells. Moreover, PKD2 knocking down by siRNA or shRNA-lentiviral particles enhanced the insulin response. Alternatively, EGFP-PKD2-CA overexpression in Huh7 cells reduced AKT phosphorylation upon insulin stimulation compared to EGFP-transfected cells. In this line, *in vivo* injection of AAV bearing EGFP-PKD2-CA resulted in a moderate impairment of glucose homeostasis and reduced IR and AKT phosphorylation in the liver. Importantly, HFD-fed $PKD2^{\Delta Hep}$ mice displayed a tendency to improve glucose tolerance and insulin sensitivity compared to control mice. These results were confirmed by analysis of AKT phosphorylation in liver extracts. Moreover, PKD immunostaining revealed that PKD2 was increased in NAFLD patients.



Conclusion: Our results strongly suggest that PKD2 is involved in the control of hepatic insulin signaling and point PKD2 as a new

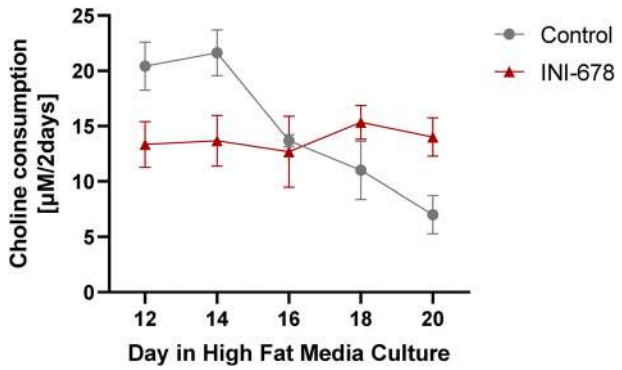
therapeutic target in the progression of hepatic insulin resistance-related pathologies.

OS164

Metabolomic changes in NASH phenotype liver-on-a-chip caused by INI-678, a small molecule HSD17B13 inhibitor, supports a role for HSD17B13 in inflammation and fibrosis

Heather Hsu[1], Michael Carleton[1]. [1]*Inipharm, Bellevue, United States*
Email: hhsu@inipharm.com

Background and aims: Polymorphisms producing catalytically inactive HSD17B13 protect against non-alcoholic steatohepatitis (NASH), cirrhosis, and liver cancer and are associated with reduced hepatic inflammation and fibrosis. Preliminary results demonstrated that INI-678, a novel selective inhibitor of HSD17B13, decreased fibrotic markers in response to high fat media in liver-on-chip (LOC) co-cultures The aim of this study was to determine the impact of inhibiting HSD17B13 with a well characterized inhibitor on metabolism in a NASH phenotype LOC.
Method: NASH LOC co-cultures containing primary human hepatocytes, homozygous for the active HSD17B13 allele; Kupffer cells, and stellate cells were cultured in a high fat containing media to induce a NASH phenotype. LOC were exposed to INI-678 or a DMSO vehicle control for Days 4–20. LOC co-cultures were analyzed for fibrotic markers by immunohistochemistry and media samples were analyzed for cell health markers, albumin and lactate dehydrogenase, by ELISA and activity, respectively. Metabolites were quantified in media samples using electrospray ionization by tandem mass spectrometry.
Results: Treatment of NASH LOC with INI-678 and related analog inhibitors of HSD17B13 decreased fibrotic marker proteins, alpha smooth muscle actin and collagen type 1, compared to vehicle control in LOC co-cultures. Choline consumption remained stable in INI-678-treated LOC throughout high fat media exposure. Choline consumption in the vehicle control was initially elevated and decreased throughout high fat media treatment ultimately lower than INI-678-treated LOC co-cultures. INI-678 treatment resulted in lower primary bile acids compared to vehicle control. INI-678 treatment significantly reduced hexose and increased lactate in the media.
Conclusion: The decrease in fibrotic markers in NASH LOC with INI-678 treatment was accompanied by changes in the metabolome. The metabolic changes include stabilization of choline, decreases in bile acids and decreased hexose. The inhibition of HSD17B13 significantly altered metabolism consistent with the hepatoprotective effect and anti-fibrotic effects observed in LOC. The direct effects of small molecule inhibitors of HSD17B13 are consistent with decreased fibrosis in NASH subjects carrying inactive HSD17B13 alleles. These results suggest a potential precision medicine approach to treating NASH.



OS165

The inhibition of the epigenetic efectors DNMT1 and G9a as a potential therapeutic strategy against the non-alcoholic fatty liver development

José María Herranz[1], Alex Claveria-Cabello[2], Leticia Colyn[2], Maria U. Latasa[2], Maite Perez-Araluce[2], Bruno Sangro[1,3,4], Julen Oyarzabal[5], Antonio A. Email: magarfer@unav.es

Background and aims: Non-alcoholic fatty liver disease (NAFLD) encompasses a spectrum of histological changes ranging from simple steatosis to inflammation and ballooning, which define non-alcoholic steatohepatitis (NASH). NASH can lead to cirrhosis and hepatocellular carcinoma. Currently, no drugs have proven efficacy for NAFLD treatment. Understanding the mechanisms leading to NAFLD progression is essential for the identification of effective therapies. Epigenetic mechanisms are fundamental for gene expression regulation and functional homeostasis, and their impairment is recognized to participate in disease. Here we have performed a systematic transcriptomic analysis of epigenetic genes in human liver tissues from patients with different stages of NAFLD. We identified marked alterations in a significant number of epigenetic effectors, including DNA methyltransferase 1 (DNMT1) and its epigenetic cofactor UHRF1. DNMT1 and UHRF1 work in concert with the histone methyltransferase G9a in DNA methylation and gene expression regulation. We evaluated the potential relevance of the DNMT1/G9a/UHRF1 complex in in vitro and in vivo models of NAFLD.
Method: We analyzed four publicly available liver transcriptome datasets integrating more than 520 patients. In vitro studies were performed in HepG2 cells challenged with a NASH cocktail. Cells were treated with the DNMT1/G9a/UHRF1 complex small molecule inhibitor CM272. In vivo studies were performed in C57BL6 mice fed with normal chow diet (ND) or high-fat diet (HFD, 45% fat) for 4 or 9 months and different regimes of CM272 treatment (one month and one week, respectively). Transcriptomic profiling, biochemistry and histologycal analyses were performed.
Results: Inhibition of DNMT1 and G9a with CM272 significantly reduced serum triglyceride and free fatty acids, and hepatic lipids accumulation in the two HFD models. Liver tissues transcriptomic analyses revealed that CM272 modulated metabolic pathways fundamentally involved in fatty acids and cholesterol metabolism and, intriguingly also the expression of genes involved in immune pathways, such as antigen presentation and processing. DNMT1 and G9a inhibition also caused significant changes in the expression of genes involved in energy expenditure and lipid metabolism in brown and white adipose tissue. In vitro studies confirmed most of the in vivo findings, including a robust induction by CM272 of carboxylesterase 1 (CES1), a key enzyme in the liver triglyceride metabolism.
Conclusion: A profound dysregulation in the expression of epigenetic effectors characterizes human NAFLD progression. We show that the pharmacological modulation of the epigenetic complex DNMT1/G9a/UHRF1 markedly affects the course of this disease in its early stages. Our findings suggest that characterization of epigenetic pathways in NAFLD may help to understand the disease and to expose new targets.

OS166

Molecular characterization of metabolic associated fatty liver disease as an immune-mediated inflammatory disease: IMID associated fatty liver disease

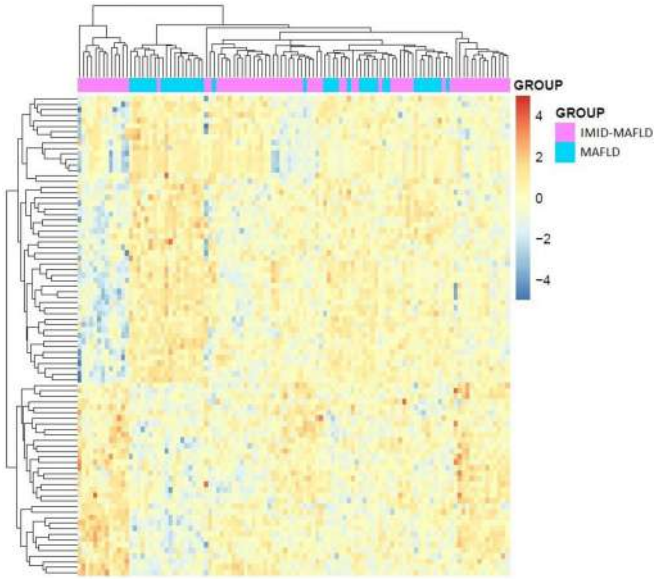
Email: javiercrespo1991@gmail.com

Background and aims: Growing evidence support an increased prevalence of metabolic associated fatty liver disease (MAFLD) in the context of immune-mediated inflammatory diseases (IMIDs) that can occur independently of classic metabolic risk factors. We aimed to characterize clinically and mechanistically a prospective cohort of IMID-MAFLD patients compared to regular MAFLD patients.
Method: Cross-sectional, case-control study including a subset of IMID patients (inflammatory bowel disease, psoriasis, hidradenitis, and spondyloarthritis). Controls from a random sample drawn from the general population were age, gender, type 2 diabetes, and BMI matched in a 1:2 ratio. MAFLD was established by the controlled attenuation parameter. Liver biopsies were collected when MAFLD with significant liver fibrosis was suspected. Total RNA was obtained from freshly frozen cases and analyzed by RNA-seq. Differential gene expression was performed with 'limma-voom' adjusting for BMI, sex and fibrosis severity. Gene set enrichment analysis (GSEA) was performed with fgsea R package with a pre-ranked "limma t-statistic" gene list. Serum protein concentrations were obtained using 'Quantikine ELISA Kit' in same patients analyzed by mRNA-seq.
Results: 1435 IMID patients and 2918 controls were included. MAFLD prevalence was significantly higher among IMID patients than controls, as well as the prevalence of advanced-MAFLD (LSM >9.7 kPa). In multivariate analysis, concomitant IMID was an independent and the strongest predictor of advanced-MAFLD. We compared transcriptomic data from 69 liver biopsies from IMID-MAFLD and 40 from MAFLD patients adjusted for BMI, sex, and fibrosis severity. We observed 87 highly significant genes differentially expressed between the two groups. Whereas genes like *IGFBP2* or *GPX2* showed an upregulated expression in IMID-MAFLD, others like *DGCR5* or the Metallotioneins *MT1M*, *MT1G* and *MT1F* were downregulated. Normalized expression values of significantly expressed genes and specific clustering of IMID-MAFLD and MAFLD cases are shown in Figure. A GSEA analysis detected the most relevant cellular activities in IMID-MAFLD vs. MAFLD. IMID-MAFLD cases displayed an enriched expression of genes implicated in pro-tumoral activities like signaling by Rho-GTPases or the control of the Cell Cycle concomitant with a negative expression of genes related to the metabolism. IGFBP-2 protein levels in serum samples from IMID-MAFLD and MAFLD validated the transcriptional data.



Conclusion: MAFLD has a disproportionately high tendency to occur in IMID populations, which may be explained by its distinctive chronic inflammatory burden. Supporting this, we provide a functional explanation to distinguish between MAFLD groups, and show that IMIDs can trigger a pro-tumoral liver condition that can lead to an aggressive form of MAFLD independently of classic metabolic pathways.

EphB2 is a novel signaling receptor in non-alcoholic steatohepatitis liver fibrosis

Patrice Mimche[1], Severin Donald Kamdem[1], Erika Egal[1], Quinian Johanson[1], Tuan Pham[2], Kimberley Evason[3], Sihem Boudina[4], Michael Ortiz[5], Francis Sprouse[5], Chinthaka Mahesh Udamulle Gedara[5], Karina Cortez[5], Mahmoud Ahmed[6], Hesham Sadek[6], Mark Henkemeyer[5]. *[1]University of Utah, Department of Pathology, Salt Lake City, United States; [2]University of Utah, Department of Internal Medicine, Division of Gastroenterology, Hepatology and Nutrition, Salt Lake City, United States; [3]University of Utah and Huntsman Cancer Institute, Department of Pathology, Salt Lake City, United States; [4]University of Utah, Department of Nutrition and Integrated Physiology, Salt Lake City, United States; [5]UT Southwestern Medical Center, Department of Neuroscience, Dallas, United States; [6]UT Southwestern Medical Center, Department of Internal Medicine and Molecular Biology, Dallas, United States*
Email: patrice.mimche@path.utah.edu

Background and aims: Emerging evidence suggests that the EphB2 receptor tyrosine kinase regulates tissue inflammation and fibrosis. However, its role in diet-induced non-alcoholic steatohepatitis (NASH) fibrosis has not been explored. We aimed to decipher the contribution of EphB2 to non-alcoholic steatohepatitis (NASH) development in mouse NASH models and in patients at various stages of non-alcoholic fatty liver disease progression.
Method: In NASH patients, hepatic EphB2 and serum sEphrinB2 ligand were evaluated. Disease phenotyping was performed in male and female wild type (WT), *EphB2*$^{-/-}$, EphB2-kinase-dead (*EphB2*^{K661R}), EphB2-kinase-overactive (*EphB2*^{F620D}) mice, and in hepatic stellate cell (HSC) specific *EphB2*$^{-/-}$ mice fed the obesogenic Gubra-Amylin NASH (GAN) diet for 22–28 weeks and the Choline Deficient Amino-acid improved (CDAA) high-fat diet for 10–12 weeks. The crosstalk between EphB2 and TGFβ signaling in primary human HSC was investigated *in vitro*. Pharmacological inhibition of EphB2 for the treatment of NASH was also evaluated *in vivo*.

Histology, flow cytometry, qPCR, biochemical assays, bulk RNA sequencing, and single cell RNA-sequencing were used to dissect the molecular mechanism underlying EphB2 function in NASH.
Results: Hepatic EphB2 was strongly upregulated in NASH patients and correlated with NASH fibrosis score. Serum sEphrinB2 was also elevated in NASH patients. In mouse models of NASH, *EphB2*$^{-/-}$ knockout mice showed a significant reduction in liver steatosis, inflammation, and fibrosis compared to WT mice. This is supported by a significant reduction of liver fat content, pro-inflammatory and fibrotic genes in *EphB2*$^{-/-}$ compared to WT mice. EphB2 forward signaling is likely the main driver of NASH progression as depicted by the significant increase in steatosis, inflammation, and fibrosis observed in *EphB2*^{F620D} kinase-overactive mice compared to WT and *EphB2*^{K661R} kinase-dead mice. Flow cytometry and single-cell RNA-sequencing reveal that macrophages and mesenchymal populations are reduced in *EphB2*$^{-/-}$ mice compared to WT mice. Consistent with the above results and upregulated expression in NASH, HSC-specific knockout of *EphB2*$^{-/-}$ also resulted in reduced NASH fibrosis. *In vitro*, rhTGFβ1, 2, and 3 upregulate EphB2 in human HSC and its silencing with *EphB2-siRNA* abrogates TGFβ-mediated HSC trans-differentiation into myofibroblasts-producing collagen. Finally, pharmacological inhibition of EphB2 reduced NASH fibrosis in mice.
Conclusion: We have identified EphB2 as a key player in the pathogenesis of diet-induced fatty liver disease in human and mouse and showed that therapeutic targeting of this receptor mitigates NASH fibrosis.

Liver transplantation and Acute liver failure: Clinical aspects

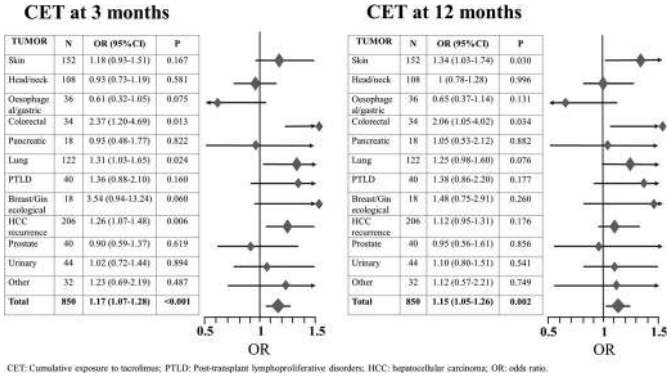
Email: ropeml@hotmail.com

Background and aims: Cancer, either de novo or recurred, is the leading cause of death after liver transplantation (LT). We aimed to evaluate the effect of maintenance immunosuppression on post-LT malignancy.
Method: Multicentre case-control nested study involving 16 LT institutions. The eligible cohort included adult patients undergoing LT (2010–2015) who received tacrolimus-based immunosuppression. Patients developing malignancy after LT, either de novo or recurred, formed the group of cases. Controls were selected among patients without cancer after an identical follow-up period. Cases and controls were matched by propensity score based on age, gender, smoking habit, aetiology of liver disease and hepatocellular carcinoma (HCC) before LT. The exposure to immunosuppressive drugs within the first year after LT was recorded. Cumulative exposure to tacrolimus (CET) was calculated by the area under curve of trough levels (PMID: 31107827). The relationship between the immunosuppression protocol and the risk of post-LT malignancy was evaluated using multivariate logistic and Cox's regression.
Results: The eligible cohort included 2, 495 patients. The study cohort comprised 425 patients who developed post-LT malignancy and 425 matched controls. The most frequent types of malignancy were: HCC recurrence (24%), non-melanoma skin cancer (16.1%), lung cancer (13.7%) and head and neck tumors (12.6%). Cases and controls were comparable in terms of age, gender, smoking habit, aetiology of liver disease and presence of HCC before LT. The immunosuppression protocol was similar in cases and controls (p = 0.51), and there were no differences in terms of individual drugs. Patients with post-LT malignancy had increased CET as compared with matched controls, both within the first 3 months (p = 0.002) and within the first 12 months (p = 0.009). An increased CET was the only independent predictor of post-LT malignancy after controlling for clinical features and concomitant immunosuppressive drugs: the hazard ratio (HR) of post-LT malignancy for a 20% increase of CET was 1.11 (95%CI 1.05–1.19; p = 0.001) at 3 months, and 1.10 (95%CI 1.03–1.17; p = 0.004) at 12 months. These results were consistent when considering exclusively de novo malignancy (CET at 3 months HR = 1.09; p = 0.020 and CET at 12 months HR = 1.10; p = 0.016).
Conclusion: CET is the most important immunosuppression-related risk factor of cancer after LT, thus highlighting the relevance of tacrolimus minimization.



CET: Cumulative exposure to tacrolimus; PTLD: Post-transplant lymphoproliferative disorders; HCC: hepatocellular carcinoma; OR: odds ratio.

Background and aims: Infections caused by bacteria resistant to 3 or more antibiotic families (multidrug-resistant bacterial infections or MDRBIs) are an increasing healthcare issue. Our aim was to analyze the prevalence, burden, and risk factors associated with MDRBIs after liver transplantation (LT).
Method: Retrospective multi-center cohort study including adult patients who underwent LT from January 2017 to December 2019. Risk factors related to pre-LT liver disease, surgical procedure, and post-operative stay were recorded. A multivariate logistic regression analysis was performed to identify independent predictors of MDRBIs within the first 90-days after LT.
Results: We included 1, 089 LT (1, 004 patients) performed in 9 tertiary Spanish hospitals. Mean age was 56.83 ± 9.31 years, 72.5% (784) were male, and alcoholic liver disease was the most prevalent underlying etiology (42.5% (452)). Bacterial infections occurred in 442 LT (40.6%), that presented a total of 706 infections (respiratory 19.6%, urinary 17.9%, bacteremia 12.7%, cholangitis 10.7% and surgical wound infections 9.3%, among others). MDR were isolated in 230 LT (21.1%) (358 infections, 50.7%). *E. faecium* 88 (24.6%), *E. Coli* 77 (21.5%) and *Klebsiella pneumoniae* 48 (13.4%) were the most frequent isolated bacteria. In the multivariate analysis, previous intensive care unit admission (0–3 months before the LT), previous MDRBIs (0–3 months before the LT), renal-replacement therapy after LT and the number of packed red blood cells units transfused during surgery were identified as independent predictors of MDRBIs (table 1). Mortality at 30, 90, 180 and 365 days was significantly higher in patients with MDRBIs.
Conclusion: MDRBIs are highly prevalent after LT and have a significant impact on prognosis. *E. faecium* is the most frequently isolated MDR microorganism. New pharmacologic or surveillance strategies aimed at preventing MDRBIs after LT should be considered for patients with high-risk factors.

Modeling ischemic cholangiopathy in human cholangiocyte organoid for screening of novel cholangio-protective agents

Shaojun Shi[1], Henk P. Roest[1], Marcel Bijvelds[2], Jeroen de Jonge[1], Hugo de Jonge[2], Jan Ijzermans[1], Monique M.A. Verstegen[1], Luc J.W. van der Laan[1]. [1]*Erasmus MC Transplant Institute, University Medical Center, Department of Surgery, Rotterdam, Netherlands;* [2]*Erasmus MC-University Medical Center, Department of Gastroenterology and Hepatology, Rotterdam, Netherlands*
Email: l.vanderlaan@erasmusmc.nl

Background and aims: Ischemic cholangiopathy refers to biliary damage caused by disruption of blood supply in the peribiliary plexus. Detailed knowledge of ischemic cholangiopathy pathogenesis remains scarce due to the lack of appropriate *in vitro* models. We aimed to recapitulate ischemia-evoked biliary damage using human intrahepatic cholangiocyte organoids (ICOs) *in vitro* for the study of ischemic cholangiopathy and preclinical drug discovery.
Method: Human ICOs (n = 5) were initiated from liver biopsies. Cultures were exposed to hypoxia (~1% O_2) for 72 hours and reoxygenated for 6 (H/R6 h) or 24 hours (H/R24 h). To enable immediate tracking of hypoxia, ICOs were transduced with a hypoxia-inducible factor 1alpha (HIF-1α) reporter. The effect of hypoxia on cell proliferation, apoptosis, and necroptosis was determined by immunostaining with Ki67, active caspase 3, and phosphorylated mixed lineage kinase domain-like protein, respectively, and ATP content.
Results: Extensive activation of the HIF-1α reporter was observed in ICOs at 72 h of hypoxia. This signal was partially reduced after H/R24 h. Hypoxia- and H/R6h-exposed ICOs were significantly smaller in size ($p < 0.001$) than untreated ICOs. Also, the disintegration of the cytoskeleton and disrupted epithelial integrity were observed. Cell viability of ICOs undergoing hypoxia or H/R6 h was drastically lower ($p < 0.05$) than under normoxia and was restored after H/R24 h ($p < 0.05$). Transcriptional and morphological analysis indicated a clear decrease of Ki67 expression after hypoxia or H/R6 h, which recovered after H/R24 h to normal levels. Immunostaining revealed that extensive apoptosis, but not necroptosis, was induced by hypoxia and H/R6 h. Exposure of the ICOs to Emricasan, a caspase inhibitor, failed to attenuate apoptosis but switched it into necroptosis. We further identified clinical-grade alpha-1 antitrypsin (AAT) as a potent inhibitor of hypoxia-induced apoptosis without necroptotic switch ($p < 0.05$). Treatment of ICOs with AAT in hypoxia exposed ICOs increased the cell viability ($p < 0.05$) and partially restored the Ki67 expression.
Conclusion: ICOs recapitulate ischemic cholangiopathy *in vitro,* featured by extensive apoptosis and reduced cell proliferation,

which could be partially restored by reoxygenation. AAT is identified as a novel cholangiocellular protective agent by restoring proliferation and preventing apoptosis.

OS171

The prognostic role of lysophosphatidylcholines and their immunomodulatory potential in acute liver failure

Francesca Maria Trovato[1], Salma Mujib[1], Florent Artru[1], Anna Cavazza[1], Ellen Jerome[1], Evangelos Triantafyllou[2], Mark J. W. McPhail[1]. [1]*Institute of Liver Studies, Inflammation Biology, London, United Kingdom;* [2]*St Mary's Hospital, Liver Unit, United Kingdom*
Email: trovatofrancesca@gmail.com

Background and aims: Acute liver failure (ALF) is a life-threatening disease in people without previous liver disease. It is characterised by inflammation and parallel immunoparesis with a high incidence of death from sepsis and multiorgan failure. In this context, immune cell function is often suppressed by multiple mechanisms, including inhibitory signalling via immune checkpoint pathways. The aim of this research was to modulate systemic immune responses through the immunometabolic Lysophosphatidylcholine (LPC)-Autotaxin (ATX)-Lysophosphatidylcholinic acid (LPA) pathway.
Method: 43 ALF, 21 cirrhotics, 24 HC, and 31 septic (as proinflammatory control) patients were included. The pathway of interest was identified on the basis of multivariate analysis of a 180 metabolite targeted metabolomics panel (Biocrates p180). Autotaxin and LPA levels were measured by ELISA. Plasma cytokines were analysed with an MSD V-PLEX kit. PBMCs were cultured with LPA 16:0, 18:0, 18:1, and their immune checkpoint surface expression (CLTA-4, TIGIT/CD155, PD-1/PDL-1, Tim-3) was assessed by flow cytometry.
Results: LPC 16.0 was identified as highly discriminant between ALF and HC (principal component analysis (PCA) and Orthogonal partial least squares discriminant analysis (OPLS-DA): R2X 0.592; R2Y 0.666, Q2 0.613, AUROC 0.969961). There was an increase in ATX (Kruskal-Wallis test, ALF vs HC $p < 0.001$) and its product LPA in ALF comparing to HC and Sepsis (Kruskal-Wallis test, ALF vs HC $p < 0.01$). LPC 16.6, 18.0 and 18.1 were reduced in ALF patient with poor prognosis (dead at 90 days or transplanted) (for LPC 16.0 and LPC 18.1 $p < 0.05$). Despite increased proinflammatory cytokines in plasma, PBMCs from ALF patients produced less IL-6 when stimulated with LPS ($p < 0.05$), and the addition of LPAs failed to reverse this. However, in monocytes LPA 16.0 increased and restored PDL-1 expression (% of positive cells, $p < 0.05$), usually reduced comparing to HC ($p < 0.05$), and reduced CD155 expression (% of positive cells and MFI, $p < 0.05$), without effect on the $CD4^+$ counterparts PD1 and TIGIT.
Conclusion: Reduced lysophosphatidylcholines (LPC16.0, LPC 18.0 and LPC 18.1) are biomarkers of poor prognosis in patients with ALF. The LPC-ATX-LPA axis appears to modulate innate immune response in ALF and requires further investigation to identify novel therapeutic agents.

OS172

Prescription event monitoring of checkpoint inhibitor-induced liver injury and outcomes of rechallenge: a 10-year experience

Edmond Atallah[1,2], Ana Oshaughnessy[3], Dolapo Igboin[3], Yvette Moore[3], Joyce Ntata[3], Ankit Rao[3], Hester Franks[4], Poulam Patel[4], Guruprasad Aithal[1,2]. [1]*University of Nottingham, Nottingham Digestive Diseases Centre, School of Medicine, Nottingham, United Kingdom;* [2]*Nottingham University Hospitals NHS Trust and the University of Nottingham, National Institute for Health Research (NIHR) Nottingham Biomedical Research Centre, Nottingham, United Kingdom;* [3]*Nottingham University Hospitals NHS Trust, Nottingham, United Kingdom;* [4]*BioDiscovery Institute, University of Nottingham, Centre for Cancer Sciences, Translational Medical Sciences, Nottingham, United Kingdom*
Email: edmond.atallah@nottingham.ac.uk

Background and aims: Among cancer patients on checkpoint inhibitors (CPI), 1-16% develop checkpoint inhibitor-induced liver injury (ChILI). However, there are limited accurate reports of the incidence rate of ChILI as assessed by time on treatment. Using a prospective database and review of patient records, we estimated the risk and incident rate of ChILI in all melanoma and renal cancer patients who received CPI at Nottingham University Hospitals (NUH) from 2011–2021.
Method: Using 'ChemoCare', a prospective oncology prescribing database, we identified all adult patients who received CPI for adjuvant or metastatic melanoma or metastatic renal cell carcinoma (RCC) since 2011. Prescription event monitoring was performed using patient-related records and digital records; ChILI, other immune-related adverse events (irAE) and response to rechallenge were recorded. International Expert Working Group (EWG) for drug-induced liver injury case definitions were used to define ChILI cases and grade severity. Causality was assessed using Roussel Uclaf Causality Assessment Method (RUCAM).
Results: Out of 432 patients, ChILI occurred in 38 (8.8%). RUCAM was 'possible' in 9, 'probable' in 22 and 'highly probable' in 7 cases. The incidence rate of ChILI was 10.93 (95% CI 5.66–18.75) per 1000 patient-months of CPI exposure, with most cases occurring in patients treated with dual checkpoint inhibition. ChILI severity was 'mild' in 11 and 'moderate' in 27 (based on EWG grading); 36 of 38 (94.7%) received corticosteroids. Mean time to resolution of ChILI was 77 days ±59 following steroid therapy compared to 49 days ±21 in those untreated. Of 38 ChILI cases, 15 (39.5%) were re-treated with a single CPI, and only one patient developed recurrent ChILI. However, three developed colitis, one each developed hypophysitis and severe neuropathy.

Table: Risk and incidence rate of ChILI per CPI regime.

Cancer	CPI Regime	Number of Patients	Mean number of cycles	Person-Time at risk (months)	ChILI cases	Risk	Incidence rate per 1000 patient-months
Melanoma	Ipilimumab	88	3	210.53	2	2.27%	9.50
	Ipilimumab + Nivolumab followed by Nivolumab maintenance	102	3 combination 8 Nivolumab	949.23	29	28.43%	30.55
	Nivolumab	22	12	281.20	0	0%	0.00
	Pembrolizumab	108	9	1035.37	3	2.78%	2.90
	Adjuvant Pembrolizumab	39	7	316.70	1	2.56%	3.16
RCC	Ipilimumab + Nivolumab followed by Nivolumab maintenance	19	3 combination 6 Nivolumab	160.10	2	10.53%	12.49
	Nivolumab	54	12	524.70	1	1.85%	1.91
Total		432		3477.83	38	8.8% (95% CI 6.2–11.8)	10.93 (95% CI 5.66–18.75)

Conclusion: Prescription event monitoring provides an accurate estimate of the risk of ChILI as well as its outcomes. Rechallenge with single-agent CPI is feasible, with most patients not having a recurrence of ChILI. However, there is a risk of developing other irAE, especially colitis. The benefits and risks of corticosteroid therapy should be evaluated in a larger cohort of ChILI patients.

OS173

Impact of increasing MELD 3.0 beyond 40 on liver transplant outcomes

W. Ray Kim[1], Ajitha Mannalithara[1], Branden Tarlow[1], Allison Kwong[1]. [1]*Stanford University School of Medicine, Stanford, United States*
Email: allison.kwong@gmail.com

Background and aims: MELD 3.0 improves upon MELD-Na by incorporating sex and albumin alongside bilirubin, creatinine, INR, and sodium, updating the existing coefficients, adding relevant

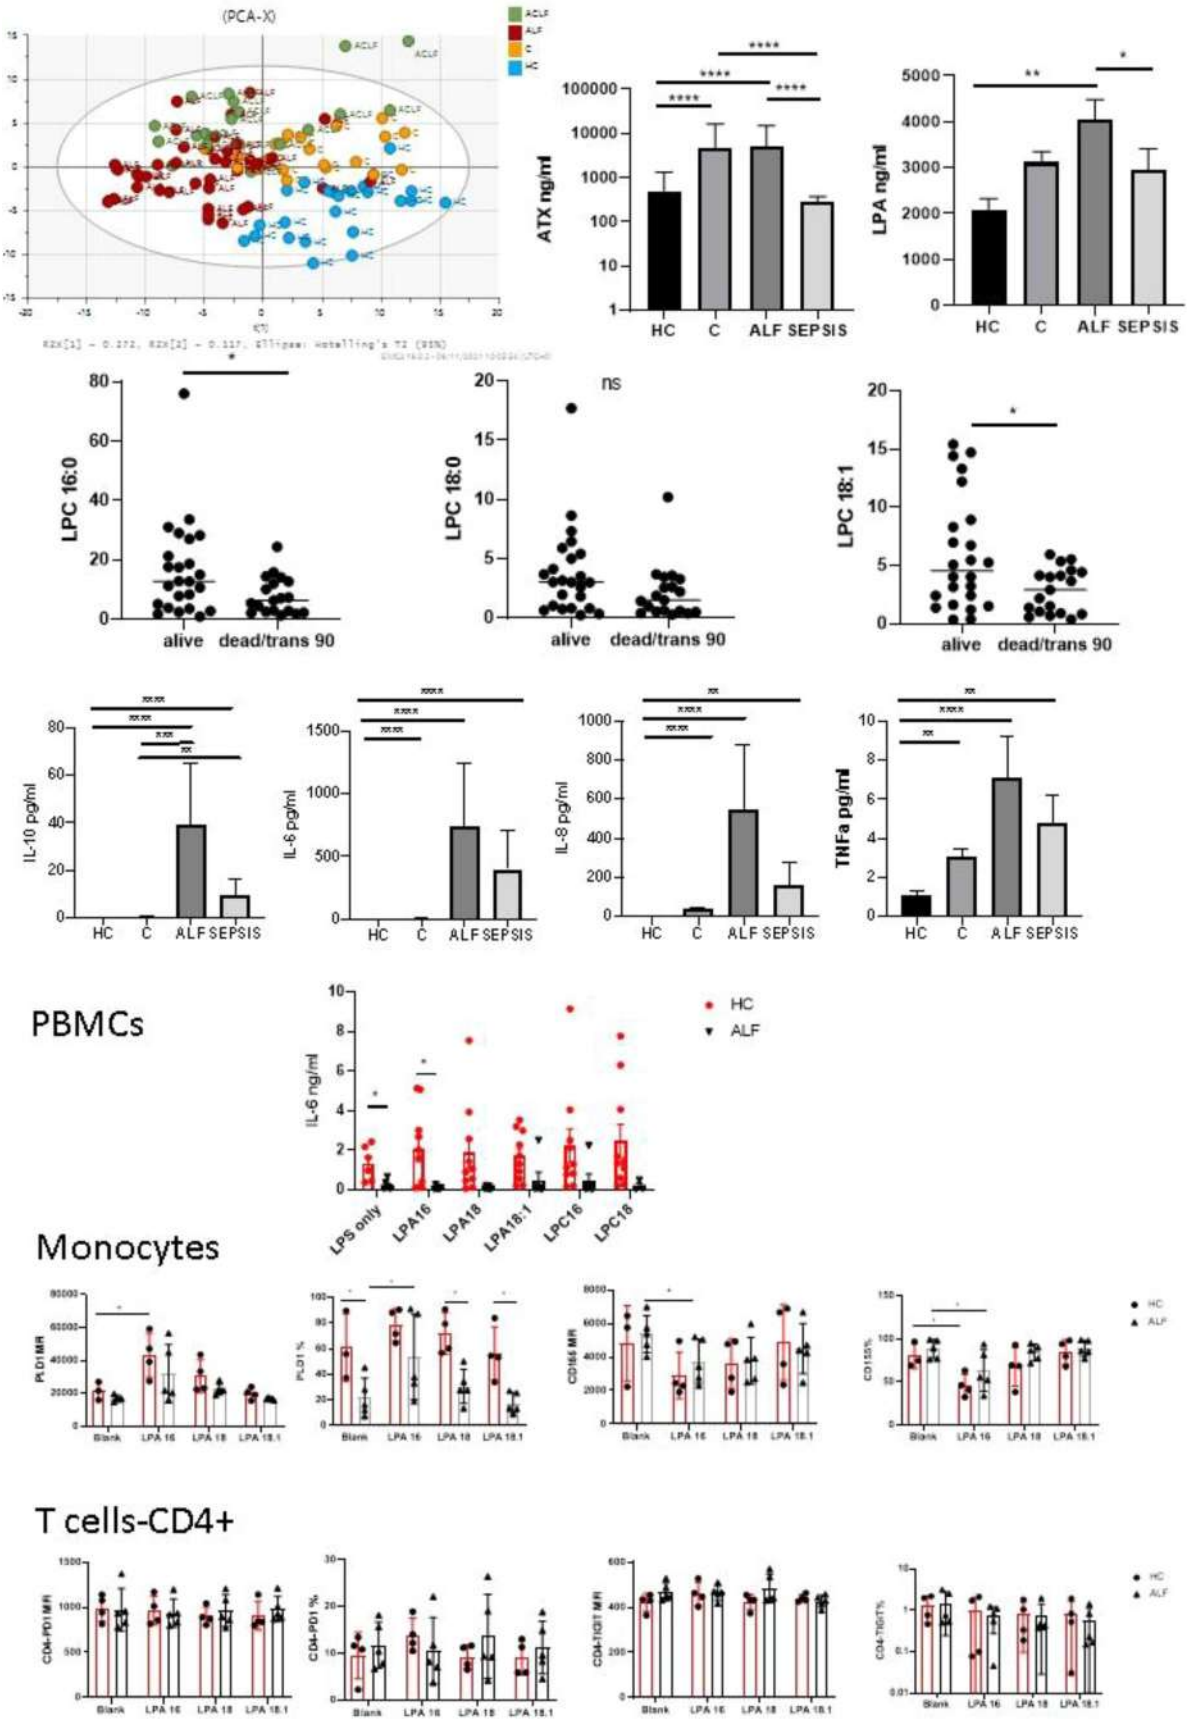

Figure: (abstract: OS171)

interactions, and resetting the upper bound of serum creatinine to 3.0 from 4.0 mg/dL. In the US liver allocation system, previous versions of MELD including MELD-Na have been capped at 40. We study the impact of increasing MELD score beyond this threshold on liver transplant outcomes.

Method: Adult waitlist registrations for liver transplantation from 15 Jan 2016 to 30 Jun 2021 were identified using OPTN data. MELD 3.0 = 1.33 (if female) + 4.56*$\log_e$ (bilirubin) + 0.82* (137-Na) – 0.24* (137-Na)*$\log_e$ (bilirubin) + 9.09*$\log_e$ (INR) + 11.14*$\log_e$ (creatinine) + 1.85* (3.5-albumin) – 1.83* (3.5-albumin)*$\log_e$ (creatinine) + 6. Survival analysis evaluated the effect of increasing MELD 3.0 beyond 40 on 30-day waitlist mortality. Individual follow-up time started from the first qualifying MELD score ≥40; patients were censored after 30 days of follow-up, at the time of an approved exception, death, or liver transplant, whichever occurred first. In a sensitivity analysis, the Cox regression model was performed to consider MELD 3.0 as a time-dependent covariate if MELD remained ≥40. 2-year posttransplant outcomes were also assessed.

Results: There were 54, 060 new waitlist registrations during the study period, 2476 (4.6%) with MELD-Na ≥40 and 2820 (5.2%) with MELD 3.0 ≥40 at listing. 23.9% of candidates with MELD ≥40 met clinical criteria for acute-on-chronic liver failure. An additional 3, 254 candidates recorded MELD 3.0 ≥40 during their waiting time. 30-day waitlist mortality was higher for each point increase in MELD 3.0 (HR 1.13, 95% CI 1.12–1.15), with a linear relationship from MELD 3.0 of 40 up to 55. 30-term waitlist mortality was higher for each increasing MELD stratum, from 65.6% to 88.7% for those with MELD 40–44 compared to MELD 50+ (Figure). Results were similar when MELD 3.0 considered as a time-dependent covariate. Posttransplant outcomes were comparable across MELD strata including MELD 35–39.

Conclusion: MELD 3.0 is anticipated to increase the proportion of patients reaching or surpassing the maximum allocation score of 40. Patients with MELD >40 may derive greater survival benefit from LT compared to MELD 40 without necessarily worse post-transplant outcome. Increasing the maximum score for MELD 3.0 may improve risk stratification of waitlist mortality and better represent liver transplant urgency for the sickest patients, including those with acute-on-chronic liver failure.

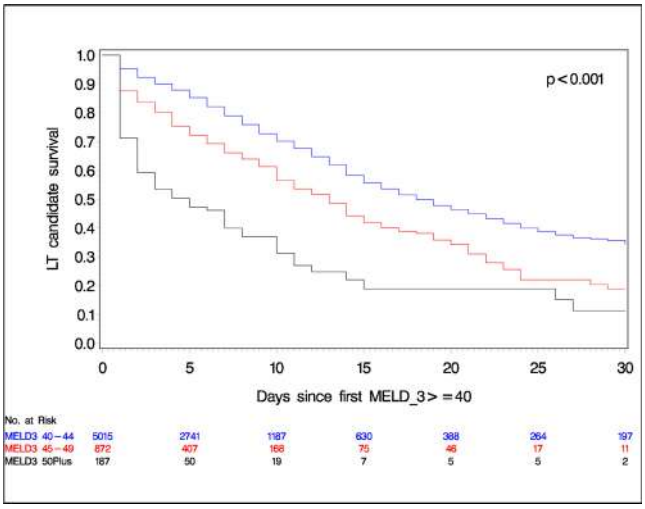

Figure: Kaplan-Meier curves: 30-day survival of patients with MELD 3.0 ≥40 at any time on waitlist.

MELD 3.0	n	Within 30 days since first MELD 3.0 ≥40 # Transplanted	# of deaths	30-day mortality	Median survival time in days (95% CI)
40–44	5015	3463	1304	65.6%	18 (17–20)
45–49	872	525	327	81.2%	13 (11–14)
50+	187	74	109	88.7%	5 (3–7)

OS174

Bile duct on a chip: engineering a microfluidic platform for studying biliary epithelium in a dish

Jorke Willemse[1], Mees N.S. de Graaf[2], Gilles van Tienderen[1], Luc J.W. van der Laan[1], Valeria Orlova[2], Jeroen de Jonge[1], Monique M.A. Verstegen[1]. [1]*Erasmus MC Transplant Institute University Medical Center, Department of surgery, Rotterdam, Netherlands;* [2]*Leiden University Medical Center, Department of Anatomy and Embryology, Netherlands*
Email: j.willemse@erasmusmc.nl

Background and aims: Biliary complications that may arise after liver transplantation, such as non-anastomotic strictures and diffuse bile leakage, are challenging and complex. Ischemia-related cell death and impaired regeneration of damaged biliary epithelium is known to be involved in causing these complications. Intrahepatic cholangiocyte organoids (ICO) allow for the expansion and study of cholangiocyte-like cells, but access to the lumen of the organoids is limited and can only be studied after disrupting the 3D structure. There are currently no *in vitro* models mimicking the circumstances as exposure of bile ducts to warm ischemia time or cold storage, and therefore we aimed to establish a microfluidic bile-duct-on-chip (BDOC) platform for studying the effect of these conditions on biliary epithelium *in vitro*.

Method: ICO were initiated from human liver biopsies (N = 5) obtained during liver transplant procedures. Three-channel BDOC (dimensions; length 1 cm, width and height 500 µm) were prepared by casting polydimethylsiloxane (PDMS) into a mold. Subsequently, plasma treated PDMS chips were bonded to glass slides. The BDOC channels were filled with collagen type I pre-gel and viscous finger patterning procedures were used to create channels inside these collagen hydrogels. ICO-derived cells ($25{\cdot}10^3$ cells/channel) were introduced into the channels and ICO expansion medium was added to the reservoirs. The BDOC were incubated for up to 21 days. Growth of epithelial cells was monitored using confocal microscopy and histology.

Results: ICO-derived cells populated the entire surface of the channels with a single layer of cells within 7 days after seeding. Whole mount confocal imaging revealed that cells were columnar in shape and morphologically looked like biliary epithelium. Zonula Occludens-1 (ZO-1) staining showed cholangiocyte-like polarization of cells in honey comb patterns. The cells express the cholangiocyte markers cytokeratin 7 and 19 on gene and protein level.

Conclusion: The results show that microfluidic approaches combined with cholangiocyte-like (KRT 7 and 19-positive) cells from ICO can be used to create healthy small diameter intrahepatic bile duct structures *in vitro*. This model allows for detailed analysis of epithelial damage and regeneration during warm and cold ischemic conditions that are known to cause post transplantation complications to the biliary system, and also to study onset and progression of biliary diseases.

Heavy alcohol intake along with ALDH2 polymorphism increases the risk of hepatocellular carcinoma and mortality in hepatitis B virus-related cirrhosis

Chih-Wen Lin[1], Ming Chao Tsai[2], Sien-Sing Yang[3], Chih-Che Lin[2], Wen-Lung Wang[2], Yao-Chun Hsu[2], Yaw-Sen Chen[2], Ming-Lung Yu[4], Jui-Ting Hu[3]. *[1]E-Da Hospital, Medicine, Kaohsiung, Taiwan; [2]Kaohsiung Chang Gung Memorial Hospital, Kaohsiung, Taiwan; [3]Cathay General Hospital, Taipei, Taiwan; [4]Kaohsiung Medical University Chung-Ho Memorial Hospital, Kaohsiung, Taiwan*
Email: lincw66@gmail.com

Background and aims: Hepatitis B virus (HBV) infection and alcoholism are risk factors for hepatocellular carcinoma (HCC) and mortality. We investigated the effect of heavy alcohol intake, ALDH2 polymorphism, and HBV infection on clinical outcomes and risk factors in cirrhotic patients.

Method: We enrolled 1515 cirrhotic patients (342 patients with HBV infection and alcoholism, 796 patients with HBV infection, and 373 patients with alcoholism) from three tertiary hospitals in Taiwan between 2005 and 2020.

Results: Of patients with concomitant HBV infection and alcoholism, HBV infection alone, and alcoholism alone, 81 (23.7%), 134 (16.8%), and 55 (14.6%) patients developed HCC and 151 (45.3%), 322 (40.5%), and 150 (39.8%) patients experienced mortality, respectively. The 15-year cumulative incidences of HCC (66.4% *vs.* 46.8% *vs.* 54.8%, $P < 0.001$) and mortality (88.9% *vs.* 81.9% *vs.* 90%, $P < 0.001$) were significantly higher in cirrhotic patients with HBV infection and alcoholism than in those with HBV infection alone or alcoholism alone before and after propensity score matching. The ALDH2 polymorphism (allele GA/AA) with heavy alcohol intake significantly increased the risk of HCC and mortality in HBV-related cirrhotic patients. Risk factors for HCC were baseline serum HBV DNA (HR = 4.08), antiviral therapy (HR = 0.13), alcohol intake (HR = 1.77 and 1.49), abstinence (HR = 0.41), and ALDH2 polymorphism (HR = 5.09). Risk factors for mortality were abstinence (HR = 0.22), ALDH2 polymorphism (HR = 1.49), Child-Pugh class (HR = 1.43 and 1.98), serum albumin (HR = 0.62), and HCC development (HR = 1.57) in cirrhotic patients with HBV infection and alcoholism.

Conclusion: Heavy alcohol intake along with the ALDH2 polymorphism significantly increased the risk of HCC and mortality in HBV-related cirrhotic patients.

THU002

Biomarkers for prediction of alcohol-related liver cirrhosis in the Swedish general population

Gustav Jakobsson[1,2], Mats Talbäck[3], Göran Walldius[3], Niklas Hammar[3], Ying Shang[4], Hannes Hagström[1,4,5]. *[1]Division of Hepatology, Department of Upper GI, Karolinska University Hospital, Stockholm, Stockholm, Sweden; [2]Department of Medicine Capio St Göran's hospital, Stockholm, Sweden; [3]Unit of Epidemiology, Institute of Environmental Medicine, Karolinska Institutet, Stockholm, Sweden; [4]Department of Medicine, Huddinge, Karolinska Institutet, Stockholm, Sweden; [5]Clinical Epidemiology Unit, Department of Medicine, Solna, Karolinska Institutet, Stockholm, Sweden*
Email: gustav.jakobsson@ki.se

Background and aims: Alcohol-related liver cirrhosis (ARLC) is a severe and well-known complication to chronic alcohol overconsumption. There are several known biomarkers associated with increased intake of alcohol and liver damage. There is limited knowledge on which biomarkers that have the best predictive capabilities for future ARLC, especially in a general population setting. Here, we investigated this in a large, population-based Swedish cohort.

Method: We used data from the AMORIS cohort, a general population cohort with blood samples from routine health care and outpatient visits in primary or occupational care collected from 1985 through 1996. The cohort consists of 812 073 individuals, approximately 35% of the total population in Stockholm county, Sweden, during this period. We included all persons above 18 years old, with a baseline blood sample of Alanine transaminase (ALT) and Aspartate transaminase (AST). We excluded subjects with known liver cirrhosis at baseline.

We ascertained incident cases of ARLC by linking the AMORIS cohort to Swedish national health registers. All subjects were followed until a first event of ARLC, death, emigration or end of the study period, December 31, 2011. Biomarkers were standardized to increase comparability. Associations between biomarkers and incident ARLC were analyzed with Cox regression models and discrimination was assessed using C-statistics.

Results: We identified 537 479 individuals with a mean follow-up time of 19.0 years. The biomarkers with the best predictive capabilities in both unadjusted and adjusted analyses were gamma-glutamyl transferase (GGT) and mean corpuscular volume (MCV), with an adjusted C-index of 0.81 and 0.85 respectively. The AST/ALT-ratio showed a lower predictive value, with a C-index of 0.70 (Table 1).

Table 1: Hazard ratios (HR) reflect an increase of one standard deviation for each parameter. *Unadjusted; **Adjusted for sex and age;[h] Harrell's C-index.

	Number	HR*	95 %	CI	C-Index [h]	HR**	95 %	CI	C-Index [h]
ALT	**537 479**	1.05	1.05	1.05	0.81	1.05	1.04	1.05	0.75

ELSEVIER

Conclusion: The best predictive biomarkers for ARLC in the general population were MCV and GGT, whereas the commonly used AST/ALT ratio had a lower predictive capability.

THU003

A history of bariatric surgery is independently associated with a younger age at onset of severe alcoholic hepatitis

Lukas Van Melkebeke[1,2], Annelotte Broekhoven[3], Tessa Ostyn[4], Minneke Coenraad[3], Hannelie Korf[1], Tania Roskams[4], Schalk van der Merwe[1,2], Frederik Nevens[1,2], Jef Verbeek[1,2]. [1]*KU Leuven, Laboratory of Hepatology, Belgium;* [2]*University Hospitals Leuven, Department of Gastroenterology and Hepatology, Belgium;* [3]*Leiden University Medical Center, Department of Gastroenterology and Hepatology, Netherlands;* [4]*KU Leuven, Department of Imaging and Pathology, Translational Cell and Tissue Research, Belgium*
Email: lukas.vanmelkebeke@kuleuven.be

Background and aims: Patients with prior bariatric surgery (BS) are at risk to develop an alcohol use disorder (AUD). We assessed the effect of prior BS on disease profile and outcome of patients with severe alcoholic hepatitis (sAH).
Method: From 01/2008 to 04/2021, consecutive patients admitted to our tertiary referral center with biopsy-proven sAH were included in a prospective database. Student's t-test, Wilcoxin rank sum test and Fisher's exact test were used. A p value <0.05 after multiple testing correction was considered significant.
Results: sAH patients (n = 158) were identified with a median follow-up of 366 (68–1656) days. Out of this cohort, 28 (18%) patients had a history of BS (BS-group): 27 (96%) underwent bypass surgery and 1 patient gastric banding. No patient underwent sleeve gastrectomy. The proportion of patients with BS increased significantly over time reaching a number of 4 (8%) within the first 5 years, 11 (19%) within the following 5 years and 13 (28%) during the last 4 years (p = 0.02) of the follow-up period. An important finding from our analysis was that patients in the BS-group were significantly younger at diagnosis of sAH, were more frequently female, featured an elevated body mass index (BMI) and advanced steatosis upon histological evaluation of the liver biopsy (Table 1). Furthermore, there were no differences in sAH disease severity (histological and Maddrey) or corticosteroid response (Lille score) (Table 1). Importantly, the correlation between BS and a younger age at diagnosis remained significant after correction for sex, steatosis and BMI in a multivariate regression analysis (p <0.001). Notably, survival determined after 28 or 90 days following the onset of sAH remained unchanged (Table 1).

		BS-group (n = 28)	Other (n = 130)	p value
Age*		44.3 ± 8.1	52.4 ± 10.3	0.0005
Sex (male)		8 (30%)	80 (62%)	0.02
BMI*		29.7 ± 4.9	26.6 ± 5.0	0.02
Steatosis	<33% 33-66% >66%	5 (18%) 4 (14%) 19 (68%)	48 (37%) 36 (28%) 45 (35%)	0.03
Polymorphonuclear infiltration	No or mild Severe	2 (7%) 26 (93%)	17 (13%) 113 (87%)	NS
Mallory bodies		28 (100%)	130 (100%)	NS
Ballooning	Occasional Marked	1 (4%) 27 (96%)	13 (10%) 116 (90%)	NS
Maddrey score$		56.3 (37.8-75.2)	53.6 (40.6-70.9)	NS
MELD score$		23.3 (20.7-29.9)	24.0 (21.1-27.6)	NS
Lille response		14 (74%)	56 (66%)	NS
Survival 28 days		27 (96%)	118 (91%)	NS
Survival 90 days		24 (86%)	91 (70%)	NS

* Mean + standard deviation; $ Median + interquartile range

Conclusion: The proportion of sAH patients with prior BS has increased 3-fold over the last 15 years. Bypass surgery is independently associated with younger age of sAH onset but not with corticosteroid response or short-term survival. These novel findings indicate the need for early and effective prevention of AUD and sAH in patients who underwent bypass surgery.

THU004

Cyclophilin inhibitor CRV431 as a potential therapy for alcohol-related liver disease

Elena Palma[1,2], Sara Campinoti[1,2], Una Rastovic[1,2], Nicola Harris[1,2], Tsin Shue Koay[1,2], Lola Ajayi[1,2], Bruna Almeida[1,2], Sandra Phillips[1,2], Daren Ure[3], Melissa Preziosi[4], Marjorie Yumol[4], Rosa Miquel[4], Yoh Zen[4], Andreas Prachalias[4], Krishna Menon[4], Nigel Heaton[4], Luca Urbani[1,2], Shilpa Chokshi[1,2]. [1]*The Roger Williams Institute of Hepatology, London, United Kingdom;* [2]*King's College London, Faculty of Life Sciences and Medicine, London, United Kingdom;* [3]*Hepion Pharmaceuticals, United States;* [4]*Institute of Liver Studies, King's College London, United Kingdom*
Email: e.palma@researchinliver.org.uk

Background and aims: Cyclophilins are peptidyl-prolyl isomerases that facilitate protein folding and regulate several biological processes with isoforms A, B, D being best characterised. Cyclophilin inactivation via therapeutic inhibition or genetic manipulation has been shown beneficial at various stages of liver disease, including steatosis, fibrosis, inflammation, cell injury and in hepatocellular carcinoma. CRV431 is a pan-cyclophilin inhibitor (non-immunosuppressant cyclosporin derivative) that is currently in clinical development for NASH (Phase 2A). Our study aims to evaluate the effects of CRV431 in human experimental models of Alcohol-related Liver Disease (ALD) and on fibrosis in primary hepatic stellate cell (HSC) cultures.
Method: Patient-matched Precision Cut Liver Slices (PCLS) and primary HSCs were prepared from human liver specimens (different fibrotic stages, n = 8). PCLS were exposed to hepatotoxic insults including ethanol 250 mM, fatty acids 0.1 mM, LPS 10 µg/ml individually and/or combined for up to 5days and HSCs activated with TGF-β1 for up to 10days, in the presence/absence of 5 µM CRV431. Tissue functionality was evaluated by histology, cytokeratin-18 release and mitochondrial assays. In PCLS and HSCs, fibrosis/HSC activation status was assessed by gene expression, immunofluorescence and secretion of fibrotic markers. Pro-inflammatory cytokines were quantified by Luminex.
Results: Features of alcoholic steatohepatitis were observed in human PCLS exposed to the insults, and CRV431 profoundly reduced the expression and secretion of pro-fibrogenic markers and restored a balanced cytokine profile. CRV431 alone was not hepatotoxic and did not induce cell death. In HSCs, CRV431 reduced αSMA and collagen deposition/expression when added simultaneously or after TGF-β1 activation. In addition, alignment of collagen fibers deposited by HSCs was significantly affected by the drug treatment.
Conclusion: Our results confirm the role of cyclophilins in liver fibrosis, including HSC activation, collagen deposition and orientation. These data reveal for the first time the potential for the cyclophilin inhibitor CRV431 to reduce ALD-induced fibrosis and suggest the possibility of using this drug as a therapy in ALD patients.

THU005

UK national service evaluation of transplant assessments for patients with alcohol related liver disease

Christopher Oldroyd[1], Varuna Aluvihare[2], Yun Chew[3], Andrew Holt[4], Steven Masson[5], Richard Parker[3], Neil Rajoriya[4], Jennifer Ryan[6], Liz Shepherd[6], Kenneth J. Simpson[7], Clare Wai[1], Ian Webzell[2], Michael Allison[1]. [1]*Cambridge Liver Unit, Addenbrooke's Hospital, Cambridge, United Kingdom;* [2]*Institute of Liver Studies, King's College Hospital NHS Foundation Trust, London, United Kingdom;* [3]*The Liver Unit, St James's University Hospital, Leeds, United Kingdom;* [4]*The Liver Unit, Queen Elizabeth Hospital, Birmingham, United Kingdom;* [5]*The Liver Unit, Freeman Hospital, Newcastle, United Kingdom;* [6]*The Sheila Sherlock Liver Unit, Royal Free Hospital, London, United Kingdom;* [7]*Scottish Liver Transplant Unit, Royal Infirmary of Edinburgh, Edinburgh, United Kingdom*
Email: christopher.oldroyd@nhs.net

Background and aims: Alcohol-related liver disease (ArLD) is responsible for 60% of all liver disease and 84% of liver related

death in the UK. Although we know how many patients with ArLD are registered for a liver transplant, it is not known how many people with ArLD are being assessed for liver transplantation.

Method: Prospective data was collected for all patients with a diagnosis of ArLD assessed at the seven UK liver transplant centres from 1st Aug 2020 to 31st July 2021. This included: gender, age category, indication for transplant, United Kingdom Model for End-Stage Liver Disease Score (UKELD), co-factors for liver disease, duration of abstinence from alcohol at assessment, listing decision and reasons for decline or deferral.

Results: 568 patients were included. Median UKELD was 54 (range 41–76). 144 patients (25%) were female. Median duration of abstinence was 12 months (range 0–240), with 18.4% of assessments having ≤6 months abstinence. 329 (58%) were listed for liver transplantation, with 204 (36%) not listed, and 35 (6%) deferred.

Indications for assessment were: UKELD ≥ 49 (90%), ascites (32%), hepatic encephalopathy (19%), hepatocellular carcinoma (16%) and other (11%) with most patients having multiple indications. The most common co-factor was non-alcoholic steatohepatitis (n = 57) with hepatitis C virus infection second most common (n = 24). Most common reasons for not listing were: medical co-morbidities (29%), potential recoverability (20%), too early to need transplant (19%), active or recent alcohol use (12%), concern about return to harmful drinking (11%) and surgical risk (5%).

Comparing patients listed for transplant with those not listed we noted higher UKELD (Mean 55.66 vs 53.77 p <0.001), longer duration of abstinence (Median 12 vs 11 months U = 35751, p = 0.018) and no significant differences between gender (Chi Sq p = 0.258) or age distribution (Chi Sq p = 0.53).

	Patients	Median UKELD (range)	Median months of abstinence (range)	Female
Listed	329	55 (41-74)	12 (3-204)	76 (23.1%)
Not Listed	204	53 (43-76)	11 (0-240)	56 (27.5%)
Deferred	35	54 (45-67)	10 (0-150)	11 (31.4%)
Totals	**568**	**54 (41-76)**	**12 (0-240)**	**143 (25.2%)**

Conclusion: This study provides a complete representation of all patients with ArLD assessed for liver transplantation over a 12-month period in the UK. Future work is planned to investigate outcomes of patients not listed for transplant and better understand reasons for patients being declined transplantation.

THU006

Fibroblast growth factor 21 is the main alcohol responsive peptide hormone in humans and individuals with alcohol use disorder exihibit increased plasma concentrations after alcohol intake

Amalie Lanng[1], Lærke Gasbjerg[1,2], Andrea Sucksdorff[1], Jens Svenningsen[3], Samuel Trammell[2], Tina Vilsbøll[1,4,5], Matthew Gillum[3], Filip Krag Knop[1,3,4,5]. [1]*Gentofte Hospital, Center for Clinical Metabolic Research, Hellerup, Denmark;* [2]*University of Copenhagen, Department of Biomedical Sciences, Faculty of Health and Medical Sciences, Copenhagen N, Denmark;* [3]*University of Copenhagen, Novo Nordisk Foundation Center for Basic Metabolic Research, Faculty of Health and Medical Sciences, Copenhagen N, Denmark;* [4]*Steno Diabetes Center Copenhagen, Herlev, Denmark;* [5]*University of Copenhagen, Department of Clinical Medicine, Faculty of Health and Medical Sciences, Copenhagen N, Denmark*

Email: amalie.rasmussen.lanng@regionh.dk

Background and aims: Alcohol use disorder (AUD) is responsible for 5.3% of worldwide deaths annually. The pathophysiology of AUD remains obscure. Fibroblast growth factor 21 (FGF21) is a liver-derived hormone secreted after alcohol intake. Several lines of evidence suggest that FGF21 inhibits preference for alcohol and reduces alcohol intake. Using plasma proteomics via proximity extension assay technology, we here establish FGF21 as the main alcohol responsive peptide hormone in healthy humans and, further, compare the plasma FGF21 response after an acute alcohol challenge in males diagnosed with AUD, healthy males with paternal AUD, and healthy males without any predisposition to AUD.

Method: Proteomics was evaluated in plasma sampled before and after alcohol intake (0.7 g per kg body weight) in 12 individuals. Subsequently, plasma FGF21 concentrations were evaluated before, during and for 10 hours after alcohol exposure (0.5 g per kg body weight ingested over 10 minutes) in 15 males diagnosed with AUD (Group A), 15 males with paternal AUD (Group B), and 15 males without any predisposition to AUD (Group C). The desire for alcohol was assessed by visual analogue scale.

Results: Out of 1, 472 proteins, only 11 changed after alcohol exposure in the 12 individuals, with FGF21 increasing the most (10-fold, p <0.0001) (Fig. 1A). The three groups were similar with regards to age and body mass index, and all participants had normal plasma concentrations of transaminases and bilirubin. Baseline plasma FGF21 concentrations did not differ between groups (p = 0.10). Peak plasma concentration of FGF21 was significantly higher in Group A (mean ± standard deviation: 4.0 ± 0.8 ng/ml) compared to Group C (1.8 ± 0.4 ng/ml) (p = 0.03) but not compared to Group B (2.2 ± 0.5 ng/ml) (p = 0.08) (Fig. 1B). Area under the curve for FGF21 was greatest in Group A (763 ± 150 ng/ml × min) followed by Group B (488 ± 120 ng/ml × min) and Group C (356 ± 77 ng/ml × min) with borderline statistical significant difference between Group A and C (p = 0.05) (Fig. 1B). Group A exhibited a greater desire to drink alcohol than seen in Group B (p = 0.02) and C (p = 0.01).

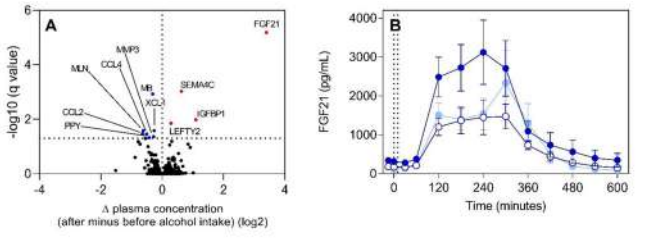

Figure 1. Volcano plot of differences in plasma proteomics before and after alcohol intake in healthy individuals (A). Horizontal dotted line indicates limit of statistical significance, red dots indicate peptides/proteins significantly upregulated by alcohol intake and blue dots indicate peptides/proteins significantly downregulated by alcohol intake. Plasma fibroblast growth factor 21 (FGF21) concentrations after alcohol intake (marked with dotted lines) (B) in individuals with alcohol use disorder (AUD) (Group A, dark blue), healthy individuals with paternal AUD (Group B, light blue) and healthy individuals without predisposition to AUD (Group C, white circles), respectively. CCL, C-C motif chemokine ligand; IGFBP1, insulin-like growth factor binding protein 1; LEFTY2, left-right determination factor 2; MB, myoglobin; MLN, motilin; MMP3, matrix metallopeptidase 3; PYY, pancreatic polypeptide; SEMA4C, semaphorin 4C; XCL1, X-C motif chemokine ligand 1. Data are mean ± standard error of the mean.

Conclusion: We show that FGF21 is the main alcohol responsive peptide hormone in healthy humans and we show greater plasma FGF21 concentrations after alcohol intake in individuals suffering from AUD compared to healthy individuals and individuals predisposed to AUD, respectively, implicating FGF21 in the pathophysiology of AUD.

THU007

Tight junction damage and increased gut permeability in alcohol-related liver disease may be mediated by gut proteases

Charlotte Skinner[1], Julian Marchesi[1], Benjamin H. Mullish[1], Hiromi Kudo[1], Lauren Roberts[1], Haoyu Sun[1], Roberta Forlano[1], Emma Lord[1], Mark Thursz[1], Nikhil Vergis[1]. [1]*Imperial College London, United Kingdom*

Email: cskinner@doctors.org.uk

Background and aims: Recent data have implicated gut-derived virulence factors in the pathogenesis of ArLD. However, it is not clear how virulence factors gain access to portal circulation. We investigated if gut-derived proteases enable bacterial translocation in

patients with ArLD including patients with severe alcohol-related hepatitis (sAH).

Method: Protease activity of faecal water (FW) was assayed using fluorescently-labelled casein. Madin Darby Canine Kidney (MDCK) cells grown to confluent monolayers on Transwell plate inserts were used to create a model of gut barrier function validated against CACO-2 cells. FW was applied to the apical surface of the insert and the transepithelial electrical resistance (TEER), a marker of monolayer integrity, was measured at 120 min. *Enterococcus faecalis* ($GelE^+$) supernatant served as a high-protease positive control while phosphate buffered solution (PBS) was a negative control. Zymography allowed differentiation of proteases in FW by substrate protein and molecular weight. Next, MDCK cells were grown to confluence on histology slides. FW was applied and the slides fixed and stained for the tight junction protein zonulin-1 (ZO-1). Finally, patient FW aliquots were plated on to protease-indicator agar and the bacterial isolates showing a protease phenotype were taxonomically characterised.

Results: FW samples were obtained from 38 subjects: sAH n = 14, decompensated ArLD n = 11 and control subjects n = 13. Protease activity in FW correlated with change in TEER (ΔTEER) for all subjects ($r = -0.5888$, $p < 0.001$) (Fig. 1). Interestingly, ΔTEER correlated with liver function ($r = -0.472$, $p = 0.0036$ for MELD) with the greatest change in TEER seen in sAH FW samples. Strikingly, a broad-spectrum protease inhibitor added to the FW abolished the correlation between ΔTEER and protease activity ($r = 0.0897$, $p = 0.644$) (Fig. 1) and MELD score ($r = -0.0645$, $p = 0.754$). ZO-1 staining was markedly decreased in slides treated with sAH FW samples vs controls (Fig. 1b+c). Zymography showed the altered pattern of proteases within the FW of sAH patients. Protease-differential agar culture identified *E. faecium*, *S. epidermidis* and *E. coli* as the putative source of proteases responsible for tight junction damage.

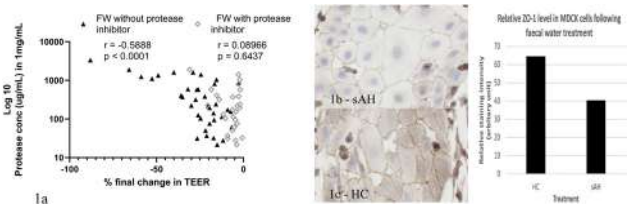

Figure: A:TEER change across MDCK monolayers vs protease activity of FW samples with and without a protease inhibitor. B: ZO-1 staining in AH FW samples. C: ZO-1 staining in control FW samples.

Conclusion: Protease activity in patient FW can cause tight junction damage and increased gut permeability *in vitro* and correlates strongly with liver function. This points to a potential mechanism for gut derived virulence factors to reach the liver in ArLD, and particularly in sAH.

THU008

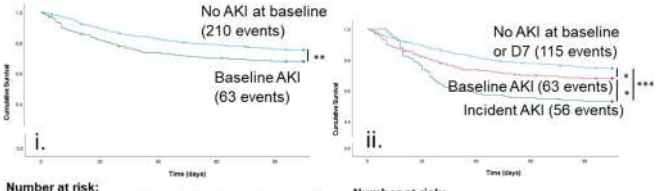
Incident acute kidney injury in severe alcohol-related hepatitis is strongly associated with mortality and can be predicted using micro-RNAs and markers of systemic inflammation

Luke D. Tyson[1,2], Stephen Atkinson[1,2], Michael Allison[3], Andrew Austin[4], Lily Cross[1], James Dear[5], Ewan Forrest[6], Tong Liu[1], Emma Lord[1], Steven Masson[7], Joao Nunes[8], Paul Richardson[9], Stephen Ryder[10], Mark Wright[11], Mark Thursz[1,2], Nikhil Vergis[1,2].
[1]*Imperial College London, Department of Metabolism, Digestion and Reproduction, London, United Kingdom;* [2]*St Mary's Hospital, The Liver Unit, London, United Kingdom;* [3]*Addenbrooke's Hospital, Cambridge, United Kingdom;* [4]*Royal Derby Hospital, United Kingdom;* [5]*University of Edinburgh, United Kingdom;* [6]*Glasgow Royal Infirmary, United Kingdom;* [7]*Newcastle Freeman Hospital, High Heaton, United Kingdom;* [8]*Meso Scale Diagnostics, Gaithersburg, United States;* [9]*The Royal Liverpool University Hospital, Liverpool, United Kingdom;* [10]*Queens Medical Centre, Nottingham, United Kingdom;* [11]*University Hospital Southampton NHS Foundation Trust, United Kingdom*
Email: luke.tyson@nhs.net

Background and aims: Acute kidney injury (AKI) can complicate severe alcohol-related hepatitis (sAH) and has been associated with increased mortality. However, the relative impact of AKI at baseline compared to AKI that develops on treatment has not been evaluated. Moreover, treatments that may modulate the risk of AKI are poorly defined. A range of biomarkers have shown promise to predict the development of AKI, but few have been independently validated in sAH.

Method: Data was available from 1051 sAH patients recruited to the STOPAH trial. AKI was defined by an adapted International Club of Ascites definition as either: an increase in creatinine >26.5 micromol/L above or 1.5x the lowest recorded; creatinine >133 micromol/L; or new renal replacement therapy. Incident AKI was defined as AKI at day 7 without baseline AKI. We compared baseline and incident AKI to 90-day mortality using Kaplan-Meier survival analysis and binary logistic regression. Further, we identified factors associated with baseline and incident AKI by multivariable models. Finally, we tested previously published and novel serum biomarkers and a micro-RNA panel measured by PCR array to predict incident AKI using AUROC analyses.

Results: Baseline AKI was present in 198/1051 (19%) patients and associated with increased D90 mortality (OR 1.42, 95% confidence interval 1.02–2.00, p = 0.038). Excluding 282 patients alive at D7 without D7 creatinine available, incident AKI developed in 119/769 (15%) patients and was associated with higher D90 mortality (OR 2.61, 1.72–3.96, p <0.001) and remained associated after adjustment for age and MELD. After adjustment for MELD score, prednisolone was associated with reduction in incident AKI (OR 0.57; 0.37–0.88, p = 0.011) but pentoxifylline was not (OR 1.10, 0.72–1.67, p = 0.656). Use of beta-blockers at baseline showed a trend to increased incident AKI after propensity-score matching for MELD and systolic blood pressure (p = 0.063). Baseline Cystatin C, NGAL, Beta-2 microglobulin and IL-18 were not predictive of incident AKI but TGF-beta2 and IL-8 were strongly associated (p <0.001) and a combination of bilirubin and IL-8 showed AUROC 0.72 (p <0.001) for incident AKI. Several micro-RNAs had AUROC >0.75, the highest of which was miR-4505 at AUROC 0.78 (p <0.006).



Number at risk:

Time (days)	0	20	40	60	80
Baseline AKI	198	161	143	136	131
No AKI at baseline	853	765	702	668	639

Number at risk:

Time (days)	0	20	40	60	80
Baseline AKI	198	161	143	136	131
Incident AKI	119	91	70	66	62
No AKI at baseline or D7	452	405	368	348	335

Kaplan-Meier survival curves for patients with severe alcohol-related hepatitis with a baseline acute kidney injury and without (i) and for baseline and incident acute kidney injury and without, excluding those alive at day 7 without creatinine available (ii)
**Beslow (Generalised Wilcoxon) P < 0.05; **P <0.01; ***P< 0.001*

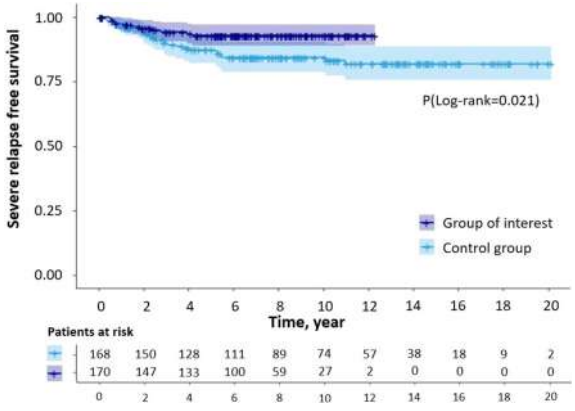
Conclusion: Incident AKI is associated with higher 90-day mortality compared to AKI present at baseline in patients with sAH. IL-8 and several micro RNAs, including 4505, show promise as biomarkers and should be validated in independent cohorts.

THU009

The impact of addiction team integration into the management of patients transplanted for alcohol-related liver disease: results from a multicenter comparative study

Jules Daniel[1], Jérôme Dumortier[2], Arnaud Del Bello[3], Lucie Gamon[4], Nicolas Molinari[4], José Ursic-Bedoya[1], Magdalena Meszaros[1], Georges-Philippe Pageaux[1], Hélène Donnadieu-Rigole[1].
[1]*University Hospital Center Saint Eloi Hospital, Montpellier, France;* [2]*University Hospital Center Édouard Herriot Hospital, Lyon, France;* [3]*University Hospital Center Rangueil Hospital, Toulouse, France;* [4]*University Hospital Center La Colombière Hospital, Montpellier, France*
Email: julesch.daniel@gmail.com

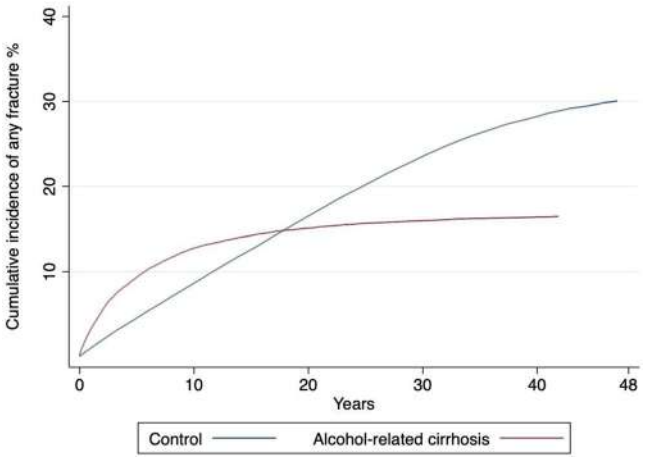
Background and aims: Alcohol-related liver disease (ALD) is the commonest indication for liver transplantation (LT) in Western Europe. Up to 40% of patients resume alcohol consumption after LT. Severe relapse is associated with a poor prognosis. Specific management of alcohol use disorder could reduce the rate of severe relapse after LT. The aim of this study was to evaluate the effect on prognosis of the integration of an addiction team into an LT center.
Method: This retrospective multicenter study included all adult patients transplanted for "pure" ALD, excluding mixed cirrhosis, between 2000 and 2015 at the three participating centers. Patients transplanted between 2008 and 2015 were managed by an addiction team embedded in the LT team at one of the centers (the interest group), unlike those at the other centers (control group). Propensity score matching (PSM) was performed to minimize differences between groups. The primary outcome was the rate of severe alcohol relapse defined as four or more standard drinks per day for at least 100 consecutive days.
Results: 616 patients were included, 195 of whom received specific addiction follow-up (entire cohort). 79.4% were men, with a mean age of 55.4 years. 58.3% had Child-Pugh C cirrhosis, their median MELD score was 19, and 32.7% had HCC. The median follow-up was 9 years, 6.6 years in the interest group and 11.1 years in the control group. The survival rate of the entire cohort was 97.4%, 83.8%, and 70.1% at 1, 5, and 10 years, respectively. After 1:1 PSM, 170 pairs were created (matched cohort) comparable for age, gender, smoking history, duration of pre-LT abstinence ± 6 months, cardiovascular risk factors, and MELD and Child-Pugh scores. Addiction follow-up was significantly associated with a reduced risk of severe alcohol relapse (6.5% vs. 15.5%; HR = 0.33, 95% CI 0.16–0.69; p = 0.0033) and the occurrence of severe cardiovascular events (10.0% vs. 20.0%; OR = 0.39, 95% CI 0.20–0.79; p <0.001). There were no significant differences in terms of mortality (HR = 1.00; p = 0.99), occurrence of *de novo* cancer (21.7% vs. 24.7%; OR = 0.86; p = 0.17), HCC recurrence (15.7% vs. 10.7%; OR = 1.67; p = 0.32), or alcohol-related graft cirrhosis (5.1% vs. 3.5%; OR = 1.60; p = 0.41) between the two groups.



Conclusion: In this multicenter study of a large cohort of patients transplanted for ALD, addiction follow-up was associated with a decrease in severe alcohol relapse.

THU010
Risk of fractures and subsequent mortality in alcohol-related cirrhosis: a nationwide population-based cohort study
Axel Wester[1], Nelson Ndegwa[2], Hannes Hagström[1]. [1]*Karolinska Institutet, Department of medicine Huddinge, Stockholm, Sweden;* [2]*Karolinska Institutet, Department of medical epidemiology and biostatistics*
Email: axel.wester@ki.se

Background and aims: Alcohol-related cirrhosis is linked to an increased risk of fractures. However, fracture risk assessments on a national level for this population are scarce. The aim was to evaluate the risk of fractures and post-fracture mortality in patients with alcohol-related cirrhosis compared to individuals from the general population.
Method: In this nationwide population-based cohort study, data were retrieved from the Swedish National Patient Registry on 23, 847 patients with alcohol-related cirrhosis from 1969 to 2016. Patients were matched for sex, age, and municipality with 229, 907 controls from the Swedish Total Population Registry. Cox regression models were fitted to investigate the risk of any fracture and post-fracture mortality in patients with a fracture during follow-up. The cumulative incidence of fractures was calculated while accounting for the competing risks of death or liver transplantation.
Results: A total of 47, 375 fractures occurred during 3, 410, 949 person-years of follow-up. Patients with alcohol-related cirrhosis had a higher incidence of fractures (35.9 per 1000 person-years) than matched controls (13.3 per 1000 person-years; adjusted hazard ratio [aHR] 3.6, 95% confidence interval [CI] 3.5–3.8). Results were consistent for osteoporotic fractures, fractures due to high-energy trauma, and all fracture sites. The cumulative incidence of fractures was higher for patients the first 18 years of follow-up, with a 5-year risk of 9.4% compared to 4.5% for controls. The post-fracture mortality rate was elevated in patients with alcohol-related cirrhosis compared to controls who also experienced a fracture at both 30 days (aHR 1.5, 95% CI 1.3–1.8) and 1 year (aHR 1.6, 95% CI 1.5–1.8).

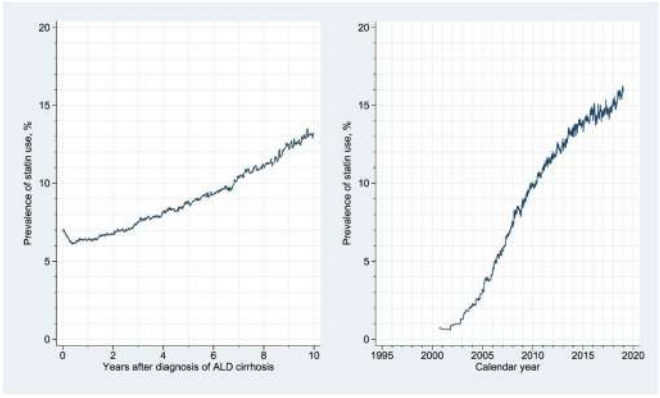


Conclusion: Alcohol-related cirrhosis is associated with a more than threefold increased fracture rate, resulting in a higher cumulative incidence of fractures the first two decades after initial diagnosis. In addition, alcohol-related cirrhosis is associated with a higher post-fracture mortality rate. Preventive interventions to reduce modifiable fracture risk factors in this population are justified.

THU011
Use of statins among patients with cirrhosis due to alcohol-related liver disease-a danish nationwide cohort study
Anna Marine Sølling Ramsing[1], Frederik Kraglund[1], Peter Jepsen[1]. [1]*Aarhus University Hospital, Department of Hepatology and Gastroenterology, Aarhus N, Denmark*
Email: marine.ramsing@me.com

Background and aims: Statins reportedly increase the survival of patients with cirrhosis due to alcohol-related liver disease (ALD cirrhosis) but may be underutilized due to fear of hepatotoxicity. It remains unclear how many patients with ALD cirrhosis use statins, and which factors predict statin initiation. We aimed to examine time-trends in prevalence of statin use and predictors of statin initiation among patients with ALD cirrhosis.

Method: Using data from the Danish healthcare registries, we conducted a nationwide cohort study, including all Danish citizens receiving their first diagnosis of ALD cirrhosis (ICD-10: K703 and K704) between 1995 and 2018. We examined how the prevalence of statin use has changed during this period and used Cox regression to identify predictors of statin initiation.
Results: During the 1995 to 2018 period, we identified 30723 patients, of whom 7% used statins at the time of cirrhosis diagnosis, and 4% became first-time statin users within 5 years after cirrhosis diagnosis. The prevalence of statin use rose sharply during the 1995–2018 period, reaching more than 15% in late 2018 (Figure). Factors predicting a higher probability of initiating statin use after diagnosis of ALD cirrhosis included diabetes (hazard ratio [HR] = 2.21, 95% CI: 1.85–2.65) and cardiovascular disease (HR = 2.97, 95% CI: 2.19–4.03), and compensated cirrhosis (HR = 1.40, 95% CI: 1.25–1.55). Socio-economic predictors included living with a partner (HR = 1.17, 95% CI: 1.06–1.30) as opposed to living alone, low educational attainment, i.e., primary school (HR = 1.22, 95% CI: 1.04–1.43) or secondary school (HR = 1.23, 95% CI: 1.05–1.44) as opposed to higher education, and older age (HR = 1.18 for every ten-year increase in age, 95% CI 1.11–1.24). Employment status and sex were not statistically significant predictors.



Conclusion: Use of statins has become common practice among patients with ALD cirrhosis in Denmark. Predictors of initiating statin use were diabetes, cardiovascular disease, compensated cirrhosis, living with a partner, low educational attainment, and older age.

THU012
Antibody response to gut microbiome bacteria in human alcoholic liver disease

Antonella Putignano[1,2], Shilpee Sharma[2], Anaïs Thiriard[2], Dalila Lakhloufi[3], Yiwei Jiang[2], Anne Botteaux[3], Eric Trépo[1], Delphine Degré[1], Christophe Moreno[1], Thierry Gustot[1], Arnaud Marchant[2]. [1]*CUB Erasme Hospital, Dept of Gastroenterology, Hepato-Pancreatology and Digestive Oncology, Bruxelles, Belgium;* [2]*Institute for Medical Immunology, ULB-Campus Erasme, Brussels, Belgium;* [3]*Molecular Bacteriology Laboratory, ULB-Campus Erasme, Brussels, Belgium*
Email: antonella.putignano@erasme.ulb.ac.be

Background and aims: Hypergammaglobulinemia (H-IgG) is a feature of chronic liver disease (CLD) but its origin remains poorly understood. Translocation of microbiome components could trigger B cells to produce microbiome-specific (M)-IgG and thereby stimulate the formation of immune complexes that could contribute to cirrhosis-associated immune dysfunction (CAID). Systems serology (SS) provides a global approach to profile antigen specific antibodies and their relationship with clinical outcomes. The aims of the study were to investigate the contribution of M-IgG to the H-IgG of CLD and to characterize their biophysical and functional features using a SS approach.
Method: A cohort of patients affected by alcoholic liver disease (ALD), including steato-fibrosis (n = 49), compensated cirrhosis (n = 54), decompensated cirrhosis (n = 64) and severe alcoholic hepatitis (n = 45) was studied. Fifty healthy adults were included as controls. Biophysical (titers, isotype, subclass, IgG Fc fragment glycosylation) and functional-antibody-dependent complement deposition (ADCD), macrophage phagocytosis (ADCP) and neutrophil phagocytosis (ADNP) and NK cell activation (ADCA)-features of M-IgG (*E.Coli, S.Aureus, St.Salivarius, E.Foecalis*) were investigated, and compared to vaccine (Diphtheria Toxoid, Tetanus Toxoid) antigen-specific (V)-IgG as control of passed antigen-exposure.
Results: Patients with ALD showed increased titers of M-IgG, M-IgG1 and M-IgG2 as compared to healthy controls. M-specific antibody titers correlated with H-IgG. Patients with ALD also had higher M-specific ADCD than healthy controls and levels of ADCD correlated with titers of M-IgG. The highest M-IgG titers and ADCD levels were observed in patients with decompensated cirrhosis or with severe alcoholic hepatitis. In contrast, similar levels of M-specific ADCP, ADNP and ADCA were detected amongst the ALD groups, suggesting an altered functional profile. The increased titers of M-specific antibodies in ALD patients were not associated with increased titers of V-specific antibodies and V-IgG did not correlate with H-IgG. Patients with ALD also had higher proportions of fucosylated and agalactosylated total IgG Fc as compared to healthy controls.
Conclusion: These results indicate that the H-IgG observed in ALD patients involves an increased production of antibodies directed against microbiome antigens. The biophysical features (subclass, Fc glycans) of M-IgG and their potent complement activation potential could promote inflammation and thereby contribute to the pathogenesis of ALD.

THU013
Socio-economic factors and healthcare setting are independently associated with medium and long-term outcomes from alcohol-related hepatitis

Joshua Lambert[1], Nikhil Vergis[2], Michael Allison[2], Andrew Austin[2], Ewan Forrest[2], Emma Lord[2], Steven Masson[2], Paul Richardson[2], Stephen Ryder[2], Mark Wright[2], Mark Thursz[2], Stephen Atkinson[2]. [1]*Imperial College School of Medicine, London, United Kingdom;* [2]*Imperial College London, London, United Kingdom*
Email: joshua.lambert17@imperial.ac.uk

Background and aims: Socio-economic factors are known to influence outcomes in liver disease but the impact in severe alcohol-related hepatitis (sAH) is unknown. Similarly, the healthcare setting where a patient is treated can modify outcomes in various diseases but its impact in sAH has not been studied. Here, we investigate the impact of these two factors on medium and long-term outcomes in sAH.
Method: Data was available from 1092 sAH patients enrolled in the STOPAH trial. Variables measured comprised education, housing, employment, relationship status, Index of Multiple Deprivation (IMD) and treating hospital setting. The latter was categorised as transplant, tertiary and secondary care centres using the British Society of Gastroenterology National Liver Disease Survey 2011. Multivariable logistic regression models were fitted for two distinct time periods: medium-term mortality between hospital admission to 90 days; and long-term mortality from 90 to 365 days (806 patients). Statistical adjustments were made for age, MELD and drinking status. Models were fitted using all available data plus data generated by multiple imputation for missing MELD scores and drinking status.
Results: In the medium-term, there was no association between IMD and 90-day mortality on univariate analysis; however adjustment for age and MELD revealed a significant independent association (OR, 1.16; 95% CI: 1.01–1.34). In the medium-term, treatment at a transplant centre was associated with a reduction in 90-day mortality

in univariate (OR, 0.61; 95% CI: 0.38–0.95) and adjusted models (OR, 0.47; 95% CI: 0.28–0.78). In the long-term, leaving education at 19 or older was the only factor associated with a reduced risk of death at 365 days compared to leaving education at 16 or younger in univariate (OR, 0.55; 95% CI: 0.30–0.94) and adjusted models (OR, 0.56; 95% CI: 0.30–0.97).

Logistic regression analysis for Index of Multiple Deprivation and healthcare settings for 90-day mortality.

Variable	Univariate Analysis OR 95% CI p			Adjusted Model OR 95% CI p		
Index of Multiple Deprivation*	1.0357	0·9132-1·1782	0·5886	1.1601	1.0064-1.3433	**0·0435**
Service						
Secondary centre	1·0000	(Reference)		1·0000	(Reference)	
Tertiary centre	0.7212	0.5318-0.9724	**0·0336**	0.7531	0·5378-1.0487	0·0958
Transplant centre	0.6075	0.3753-0.9534	**0·0355**	0.4731	0.2768-0.7829	**0·0047**

Associations are expressed as odds ratios (ORs) with 95% confidence intervals (CI) and p values (p) before (Univariate) and after adjustment for age and MELD (Adjusted).
*ORs are quoted per quintile change in Index of Multiple Deprivation, ranging from five (most deprived) to one (least deprived).

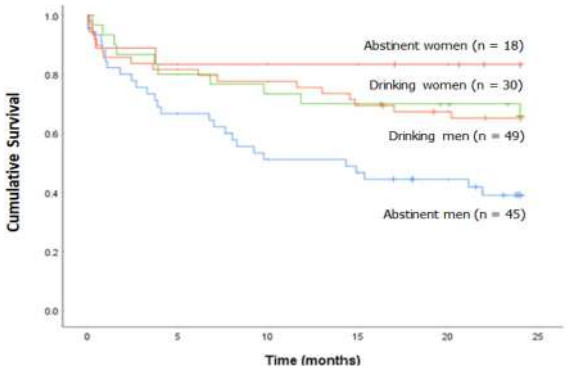
Conclusion: Socio-economic factors and type of healthcare facility in which an AH patient is treated are associated with medium and long-term survival outcomes. These findings reinforce the need to reduce health inequalities in alcohol-related liver disease.

THU014

Sex-related differences in outcomes in alcohol-related cirrhosis following an episode of hepatic decompensation do not explain subsequent management inequalities

Aaminah Mohammed[1], Nora Khattab[1], Clive Jackson[2], Jennifer Ryan[3], Marsha Morgan[1]. [1]*UCL Institute for Liver and Digestive Health, Division of Medicine, Royal Free Campus, University College London, London, United Kingdom;* [2]*Department of Clinical Neurophysiology, Royal Free Hospital, Royal Free NHS Foundation Trust, London, United Kingdom;* [3]*Department of Gastrointestinal and Liver Services, Royal Free Hospital, Royal Free NHS Foundation Trust, London, United Kingdom*
Email: marsha.morgan@ucl.ac.uk

Background and aims: There is evidence of sex-differences in the management of patients with alcohol-related cirrhosis to the detriment of the 30% who are female. Thus, women are less likely to be selected for liver transplantation; are 10% more likely to be delisted and have higher wait-list mortality rates (Cullaro *et al*, Am J Transplant 2018;18:1214). Erroneous assumptions about the natural history of alcohol-related cirrhosis in women may underlie these observed management inequalities. The aims of this study were to: (i) determine resolution and survival rates following an episode of hepatic decompensation, by sex; and, (ii) identify possible predictors of outcome.
Method: All patients with a primary diagnosis of alcohol-related cirrhosis admitted to the Royal Free Hospital in 2016 and 2018 with an episode of hepatic decompensation were reviewed. Patients who survived the index admission were followed for 24-months post discharge specifically in relation to their drinking behaviour, rates of hepatic recompensation and survival. Rates of recompensation were assessed using Box plots to map out the changes in MELD and Child Pugh scores by sex and drinking behaviour. Kaplan Meier curves were plotted to measure differences in survival by sex and drinking behaviour; data were censored at death, transplantation or end of follow-up; the Mantel-Cox test was used to determine significance. Cox regression analyses were used to identify variables which were significant predictors of survival.
Results: The study cohort comprised of 142 patients with cirrhosis (median [range] age: 54 [30–87] years; 66% men). During the follow-up period 79 (56%) people continued to drink excessively while 63 remained abstinent or else consumed alcohol at low risk levels. There was no significant difference in the proportions of men and women who continued to misuse alcohol (62.5% *vs*. 52.1%). There were no significance differences in the rates of recompensation, determined by changes in the MELD and Child Pugh scores, by sex or drinking behaviour. Fifty-one of the 142 (35.9%) patients died during a median follow-up of 23.5 (0–24) mo. The overall mean survival in women was significantly longer than in men (18.9 mo *vs*.15.7 mo; p = 0.034). There was no difference in survival between the men and women who continued to drink (18.1 mo *vs*. 18.0 mo) but women who drank little or nothing survived significantly longer than their male counterparts (20.2 mo *vs*. 13.4 mo; p = 0.002) (Figure). Age and the Child-Pugh score were the only independent predictors of survival.



Conclusion: Women with decompensated cirrhosis have similar recovery rates to their male counterparts but significantly better survival rates. Thus, the sex-related inequalities in disease management likely reflect undue bias and need to be urgently addressed.

THU015

Influence of comorbidities and lifestyle factors on health-related quality of life in alcohol-related liver disease: a population-based survey

Karen Dombestein Elde[1], Natasja Von Wowern[2], Matilde Winther-Jensen[3], Cathrine Lau[3], Lone Madsen[2], Peter Jepsen[4], Gro Askgaard[2,3,4]. [1]*Førde Central Hospital, Department of Internal Medicine, Førde, Norway;* [2]*Zealand University Hospital, Section of Gastroenterology and Hepatology, Medical Department, Køge, Denmark;* [3]*Bispebjerg and Frederiksberg Hospital, Center for Clinical Research and Prevention, Copenhagen, Denmark;* [4]*Aarhus University Hospital, Department of Hepatology and Gastroenterology, Aarhus, Denmark*
Email: karen_d_e@hotmail.com

Background and aims: Health-related quality of life (HRQoL) is impaired in alcohol-related liver disease (ALD). We examined the effects of extra-hepatic comorbidities, alcohol, and smoking on HRQoL in ALD and whether low HRQoL influenced survival.
Method: We used health registers to identify patients with ALD and comparators without ALD among the participants in the Danish National Health Surveys 2010–2017. Survey data on HRQoL (12-item Short Form), comorbidities, alcohol consumption, alcohol use disorder (CAGE score ≥ 2), and smoking was linked with vital statistics through 2020. Associations of comorbidities, alcohol, and smoking with poor HRQoL (Z-score <1.5) in ALD were studied with multivariable logistic regression adjusting for liver disease severity, age and sex. We calculated adjusted hazard ratios (HR) of mortality until 2020 according to stated HRQoL.
Results: Poor physical and mental HRQoL were found in 37% and 22% of 772 ALD patients compared to 10% and 9% of 4319 comparators. Asthma/COPD, cancer, disc herniation, and osteoarthritis were associated with poor physical QoL in ALD, whereas diabetes and cardiovascular diseases were not (Figure 1). Osteoarthritis, alcohol use disorder, and smoking >20 cigarettes/day were associated with poor mental HRQoL. Both poor physical and poor mental QoL were associated with higher mortality rates [HR 1.6 (95% CI: 1.3–2.0) and HR 1.4 (95% CI: 1.1–1.8)] in ALD.

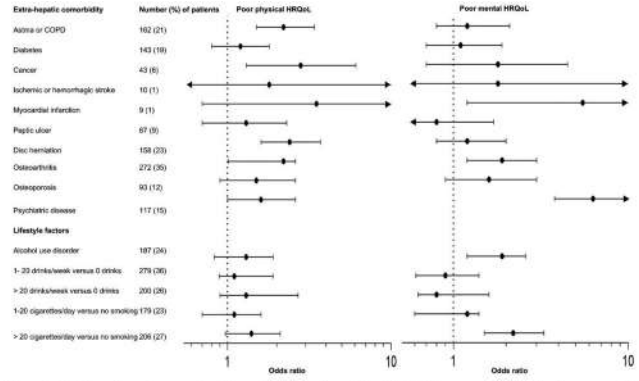


Figure 1. Odds ratios for poor health-related quality of life (HRQoL) scores according to comorbidities and lifestyle factors in patients with alcohol-related liver disease participating in the National Health Survey 2010, 2013, and 2017. Analyses are mutually adjusted and further adjusted for severity of liver disease, age and sex. N = 772

Conclusion: Respiratory and musculoskeletal diseases, cancer, alcohol use disorder, and smoking are associated with poor HRQoL in ALD. Poor HRQoL decrease survival in ALD. These findings should raise physicians' awareness on potentially modifiable factors affecting quality of life and survival in ALD patients.

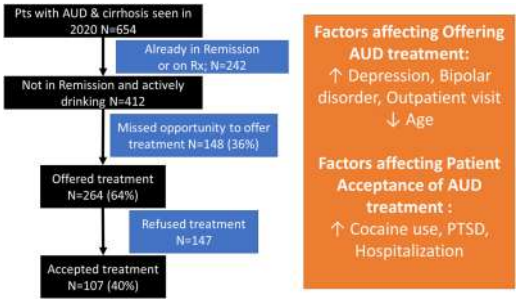
Patient and system-level factors underline offering and acceptance of alcohol use disorder therapy in veterans with cirrhosis

Rahul Chaudhari[1], Nikki Duong[1], Shreesh Shrestha[1], Neerav Dharia[1], Bryan Badal[1], James Wade[1], Linda Chia[2], Patrick Spoutz[2], Ernesto Robalino Gonzaga[2], Shari Rogal[2], Jasmohan S Bajaj[1]. [1]*Virginia Commonwealth University and Richmond VAMC;* [2]*Pittsburgh VA Medical Center*
Email: jasmohan.bajaj@vcuhealth.org

Background and aims: Cirrhosis with continued alcohol use disorder (AUD) is linked with poor outcomes. AUD Rx is efficacious, but a recent study showed only 12% of Veterans with AUD and cirrhosis received it. The reasons behind this are unclear.
Aim: Define patient, and system-level factors associated with AUD Rx.
Method: Veterans seen in 2020 with 2 ICD codes for cirrhosis/complications+AUD at 3 large VA centers were evaluated. Data regarding demographics, mental health comorbidities, and cirrhosis severity were collected, and an in-depth chart review performed to collect AUD Rx settings and details. Determinants of lack of uptake were examined using logistic regression.
Results: We included 654 pts with AUD and cirrhosis (95% men, 64.3 yrs, 56% white, 8% Hispanic). Common mental health conditions on chart review were depression 47%, PTSD 24%, anxiety 17%, cocaine use 25%, bipolar 5% and cannabis use disorder 19%. Cirrhosis decompensation was seen in 19%. AUD Rx history: 5% had received prior AUD medications, 24% got behavioral therapy, and 11% both. The remaining 60% were not on prior AUD Rx. At baseline, 24% (n = 174) were noted in the chart to be in AUD remission, while the remaining 76% had ongoing alcohol use (Figure). Course: Most pts were seen by primary care, hepatology, or both (48%, 5%, 35%); 28% were hospitalized in 2020. AUD Rx discussion: Of the 412 patients not on Rx or in remission at baseline, AUD Rx offered to 264 (64%). Most Rx offers were made in the outpatient setting (n = 207) then in inpatients (n = 30). This was most often offered by primary care (n = 162), hepatology (n = 45), or both (n = 41); fewer were offered Rx through mental health (n = 19). The factors significantly associated with AUD treatment offer in the regression model included depression (OR 1.58 95% CI 1.01–2.48, p = 0.05), bipolar disorder (3.0, 1.1–8.4, p = 0.03), seen as outpts (6.8, 3.3–14.3, p < 0.0001), and younger age (OR/yr 0.96, 0.94–0.99, p = 0.003). Decompensation, gender, race, ethnicity, hospitalizations, or decompensation were not significantly associated with Rx offer. Patient acceptance: Of the 264 pts offered AUD Rx, 40% agreed. Most Rx initiated was behavioral (n = 78), medication (N = 13) or both (n = 39). On regression, patients who were offered and accepted, were more likely to have PTSD (OR 2.1, 1.1–4.0, p = 0.03), cocaine disorder (2.3, 1.3–4.1, p = 0.004) and were offered Rx as inpatients (2.6, 1.5–4.7, p = 0.001).



Conclusion: Most Veterans with cirrhosis and AUD with opportunities to engage were offered AUD Rx but missed opportunities remain. Younger outpatients with co-occurring psychiatric disorders were more likely to be offered AUD Rx. When offered, Rx was accepted by only 40% of Veterans, especially inpatients and those with concomitant PTSD/cocaine abuse disorder. While system and patient-related factors are linked with Rx offers and initiation, in these three centers most eligible Veterans with cirrhosis were offered AUD Rx.

THU017

24-Norursodeoxycholic acid ameliorates experimental alcoholic liver disease in both preventive and therapeutic settings

Christoph Grander[1], Moritz Meyer[1], Daniel Steinacher[2], Thierry Claudel[2], Felix Grabherr[1], Julian Schwärzler[1], Timon Adolph[1], Michael Trauner[2], Herbert Tilg[1]. [1]*Medical University Innsbruck, Department Internal Medicine I;* [2]*Medical University of Vienna, Department of Medicine III*
Email: christoph.grander@i-med.ac.at

Background and aims: Alcoholic liver disease (ALD) is the hepatic manifestation of alcohol overconsumption. Ethanol toxicity, systemic pro-inflammatory cytokines as well as the intestinal microbiota contribute to the progression of ALD. 24-Norursodeoxycholic acid (norUDCA) is a side chain shortened UDCA with potent choleretic properties and therapeutic effects in non-alcoholic liver disease and primary sclerosing cholangitis. Therefore, we hypothesized that norUDCA could ameliorate experimental ALD.
Method: Female *wildtype* mice were fed an ethanol-containing diet (Lieber-DeCarli diet) or pair-diet for 15 days. Two different settings of experiments were performed: First, the diet was supplemented with 1 mg/ml norUDCA starting from day one. In a second experiment, mice received norUDCA (1 mg/ml) starting from day ten, mimicking a therapeutic approach.
Results: Ethanol-feeding resulted in hepatic injury, displayed by elevated ALT concentration, increased number of TUNEL$^+$ hepatic cells, indicating augmented apoptosis and hepatic steatosis. NorUDCA treatment diminished ALT levels ($p < 0.001$), reduced the number of TUNEL$^+$ cells ($p < 0.05$) and decreased hepatic steatosis compared to ethanol-fed controls. Moreover, the hepatic mRNA expression of pro-inflammatory cytokines like *Tnf-alpha* ($p < 0.001$), *Il-1beta* ($p < 0.01$), *Il-6* ($p < 0.001$) and *Il-10* ($p < 0.01$) was significantly reduced by norUDCA treatment in ethanol-fed mice. Important to note, systemic ethanol concentration was not altered by norUDCA administration. NorUDCA treatment enhanced bile acid metabolism in ethanol-fed mice, displayed by increased gall bladder weight ($p < 0.001$), circulating bile acids ($p < 0.001$) and the mRNA expression of hepatic *Sult2a1* ($p < 0.001$), *Mrp4* ($p < 0.001$) and *Cyp7a1* ($p < 0.001$), important regulators in bile acid metabolism. Interestingly,

norUDCA induced hepatic Ppar-gamma in ethanol-fed mice, which could mechanistically explain the observed protective effects.
In a second experiment we tested the efficacy of norUDCA in a therapeutic setting. In ethanol-fed mice the administration of norUDCA for 5 days resulted in a 45% reduction of ALT concentration. Furthermore, the hepatic mRNA expression of *Tnf-alpha* ($p < 0.05$) and *Il-6* ($p < 0.05$) was significantly decreased in ethanol-fed norUDCA treated mice compared to ethanol-fed mice.
Conclusion: NorUDCA ameliorates hepatic inflammation and steatosis in experimental ALD and could serve as a therapeutic agent for ALD in the future.

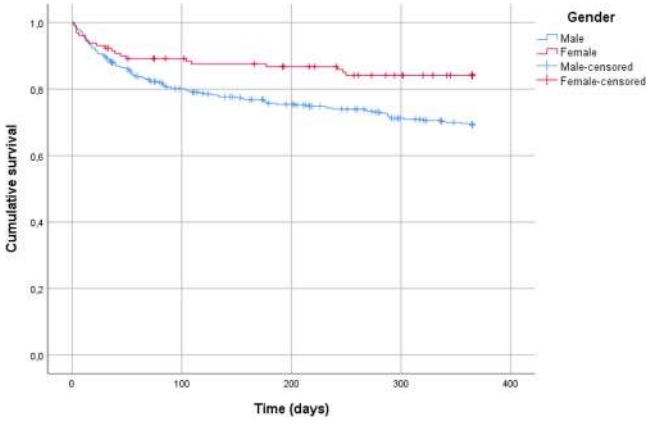
Email: EPOSE@clinic.cat

Background and aims: alcoholic hepatitis (AH) is a clinical syndrome characterized by recent onset of jaundice in the context of heavy alcohol use that bears a high mortality. Current studies on AH point female sex as associated with poorer prognosis. Also, information on prognosis and clinical features of recurrent AH is scarce. The aims of this registry were to gain knowledge on the epidemiology, clinical presentation and mortality of AH in Spain, with special focus on the influence of sex and recurrent AH.
Method: retrospective multicentric Spanish registry of hospitalized cases of AH from 2014 to 2020 including 20 centers. Criterion for inclusion was to meet the defined criteria for "probable HA" of the National Institute of Alcohol Abuse and Alcoholism (NIAAA). Clinical, alcohological, demographic and prognostic data of the cohort were recorded.
Results: Five hundred twenty-five patients were included. The majority were men (72%) with a median age of 51 and about half of them had no previous history of liver disease (51%). Most cases presented with hepatic decompensation of established cirrhosis (61%), mainly ascites and encephalopathy, and had important impairment in liver function (median MELD score 21). As for diagnosis of AH, liver biopsy was performed in 124 cases (21%); pathology was consistent with the clinical diagnosis in most of them (79%). There were 351 cases of severe AH (63%). Corticosteroids were prescribed in 229 patients (65%); enteral nutrition and pentoxifylline were also used (20% and 9%), while 23% of patients remained without specific treatment. Regarding mortality, 134 patients (26%) had died after one year, 51% of them during the index hospitalization. In the multivariate analysis, only male sex, older age, MELD score and failure to withdraw alcohol remained independently associated with mortality. Interestingly, women had significantly higher survival at one year (85% vs 71%, $p < 0.05$). These differences were more pronounced in the subset of severe AH (79% vs 62%, $p < 0.05$). No differences between men and women were found regarding liver function, alcohol withdrawal or corticosteroid treatment. Twenty-nine patients (5.5%) presented recurrent episodes of AH. Compared to patients with no recurrence, patients with recurrent AH were more frequently men (93% vs 72%, $p < 0.05$) and there was a trend to lower survival (83% vs 92%, $p = 0.091$).



Conclusion: AH in a large European cohort typically features young men, presenting with acute decompensation. Recurrent AH was not exceptional, especially in men, and was associated with a trend to higher mortality, which highlights the relevance of alcohol withdrawal and clinical follow-up in this population. In our series, women had higher survival rate; this finding questions the latest studies suggesting poorer prognosis in this group and deserves further investigation.

THU019

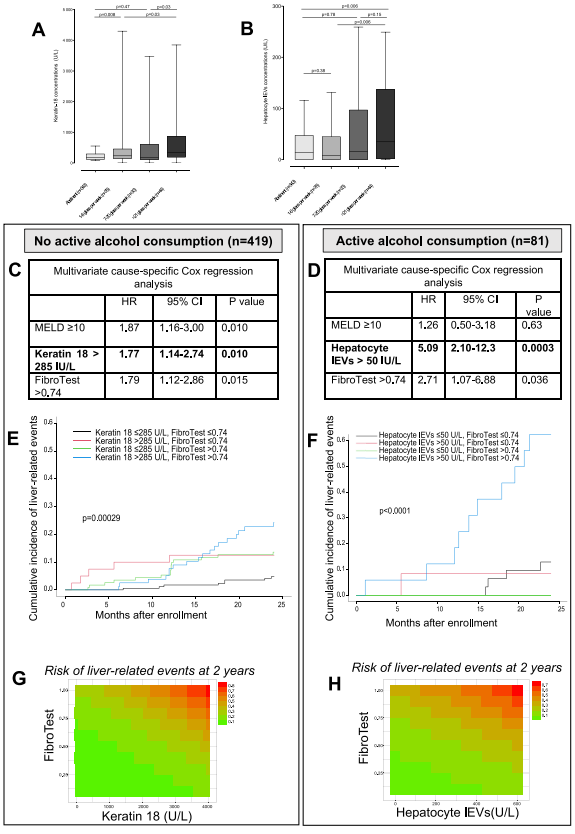
Hepatocyte-derived biomarkers concentrations predict liver-related events within 2 years in patients with Child-Pugh class A alcohol-related cirrhosis

Laure Elkrief[1], Nathalie Ganne-Carrié[2], Hana Manceau[3], Marion Tanguy[4], Nathalie Barget[5], Cendrine Chaffaut[6], Shantha Valainathan[7], Alix Riescher[7], Katell Peoch[3], Thierry Poynard[8], Sylvie Chevret[6], Pierre-Emmanuel Rautou[7]. *[1]Tours University Hospitals, Hepatogastroenterology, France; [2]Hôpital Avicenne, Liver Unit, France; [3]Hôpital Beaujon, Service de Biochimie, France; [4]Inserm, Centre de recherche sur l'inflammation, France; [5]Hôpital Avicenne, Centre de ressources biologiques, France; [6]APHP Hôpital saint Louis, Service de Biostatistique et Information médicale, France; [7]Hôpital Beaujon, Liver Unit, France; [8]Université Sorbonne Paris, France*
Email: laure_elkrief@yahoo.fr

Background and aims: Keratin-18 and hepatocyte derived large extracellular vesicles (lEVs) concentrations reflect disease activity in patients with liver disease, and are therefore attractive biomarkers. Their ability to predict liver-related events in patients with alcohol-related cirrhosis is unknown. The aim of the present study was to evaluate the usefulness of hepatocyte-derived biomarkers, alone or combined with MELD and FibroTest, to predict liver-related events in patients with Child-Pugh class A alcohol-related cirrhosis, taking into account the reported alcohol consumption status.
Method: We measured plasma keratin-18 and hepatocyte lEVs concentrations in 500 patients with Child-Pugh class A alcohol-related cirrhosis, from the prospective multicenter CIRRAL cohort

study. Primary end point was liver-related events at 2 years. Since the course of liver disease is largely influenced by alcohol consumption, patients were separated according to reported active alcohol consumption at enrollment (i.e. ≥7 glasses/week) or not. Cumulative incidence of liver-related events was estimated using the nonparametric cumulative incidence function, considering hepatocellular carcinoma and liver-unrelated deaths as competing events; in patients without active alcohol consumption at enrollment, alcohol relapse was considered as an additional competing event.

Results: Both keratin-18 and hepatocyte lEVs concentrations increased with alcohol consumption (Fig A and B). In patients without active alcohol consumption at enrollment (n = 419), keratin-18 concentration predicted liver-related events at 2 years, independently of FibroTest and MELD (Fig C). Patients with both keratin-18 concentration >285 U/L and FibroTest >0.74 had a 24% cumulative incidence of liver-related events at 2 years, versus 5% to 14% in patients with other combinations of these two markers (Fig E, G). Similar results were obtained when combining keratin-18 concentration >285 U/L with MELD ≥10 (not shown). In patients with active alcohol consumption at enrollment (n = 81), hepatocyte lEVs concentrations predicted liver-related events at 2 years, independently of FibroTest and MELD (Fig D). Patients with both hepatocyte lEVs concentration >50 U/L and FibroTest >0.74 had a 62% cumulative incidence of liver-related events at 2 years, versus 8% to 13% for patients with other combinations of these two markers (Fig F, H). Combining hepatocyte lEVs concentration >50 U/L with MELD >10 had a lower discrimination ability (not shown).



Conclusion: In patients with Child-Pugh class A alcohol-related cirrhosis, combining hepatocyte-derived biomarkers with FibroTest or MELD score identifies patients at high-risk of liver-related events, and could be used for risk stratification and patient selection in clinical trials.

Dynamic multiomics analysis characterizes circulating molecular determinants associated with poor outcome in patients with severe alcoholic hepatitis

Jaswinder Maras[1], Adil Bhat[1,2], Nupur Sharma[1], Manisha Yadav[1], Gaurav Tripathi[1], Babu Mathew[1], Vasundhra Bindal[1], Shvetank Sharma[1], Rakhi Maiwall[3], Shiv Kumar Sarin[3]. *[1]Institute of liver and biliary sciences, Molecular and Cellular Medicine, New Delhi, India; [2]University of California, Los Angeles, Pathology and Lab Medicine, Los Angeles, United States; [3]Institute of liver and biliary science, Hepatology, New Delhi, India*
Email: jassi2param@gmail.com

Background and aims: Severe alcoholic hepatitis (SAH) has high morbidity, with steroid therapy providing 65% 28-day survival. Steroid non-responders (NR) have higher incidence of infections and mortality. Faecal microbiota transplant (FMT) is another emerging therapy for SAH patients. We investigated whether multi-omic studies and machine learning (ML) approaches could identify non-responders to corticosteroid or FMT at baseline.

Method: Thirty SAH patients who were randomized in an on-going steroid vs. FMT protocol (Gov-no.NCT03091010) received either prednisolone (40 mg/day- 7 days, responders for 4weeks, n = 13) or FMT (daily through nasoduodenal tube for 7 days, n = 17). Multi-omic analysis was performed on blinded serial plasma samples collected at baseline, day-7 and day-28. Molecular determinants linked with non-response (NR) to steroid or FMT therapies were identified and validated for survival outcomes in a separate set of 70 SAH (NR = 21) patients using artificial neural networking (ANN) and ML.

Results: Baseline characteristics of derivative and validation cohorts were comparable. FMT treatment temporally increased amino-acid metabolism, primary bile-acid biosynthesis, energy metabolism and cori cycle metabolites ($p < 0.05$). Steroid therapy temporally induced vitamin and fat metabolism ($p < 0.05$). Circulating meta-proteome alpha/beta diversity was temporally increased by FMT with increase in bacterial species; orientia, geobacter and streptococci. Steroid therapy added ($p < 0.05$) desulfovibro, clostridales and other species at day 28. Compared with steroid therapy, FMT significantly reduced inflammatory metabolic pathways [arachidonic acid and tryptophan metabolism, TLR and immune-cell activation, complement cascade and prostaglandin synthesis ($p < 0.05$)] and increased antioxidant, vitamins, neurotransmitters signalling and energy metabolism ($p < 0.05$). Multi-omics profile of non-survivors was distinct, FMT non-survivors compared to survivors, showed highest alpha-diversity with increase in actinobacteria and firmicutes ($p < 0.05$). Using multi-omics integration along with ANN and ML, specific molecular clusters were identified in non-survivors. Cluster-1 specific to complement, coagulation and leukotriene biosynthesis, cluster-3 (P38-MAPK) in the FMT arm and cluster-7 (complement, TLR activation) in the steroid arm significantly predicted mortality (Norm Imp > 95%, AUC>0.90, log-rank<0.01). Of these clusters;>3Fold increase in molecules; CD44, 3-Oxosteroid and Proteobacteria; Ecoli for FMT and protoporphyrinogen-IX, MYCBP2, Proteobacteria; rhizobium for steroid arm were associated to higher mortality (AUC>0.95; log-rank<0.01).

Conclusion: Baseline levels of panel; CD44, 3-Oxosteroid, proteobacteria; E.coli, rhizobium protoporphyrinogen-IX and MYCBP2 can predict NR and non-survival in SAH patients.

THU021

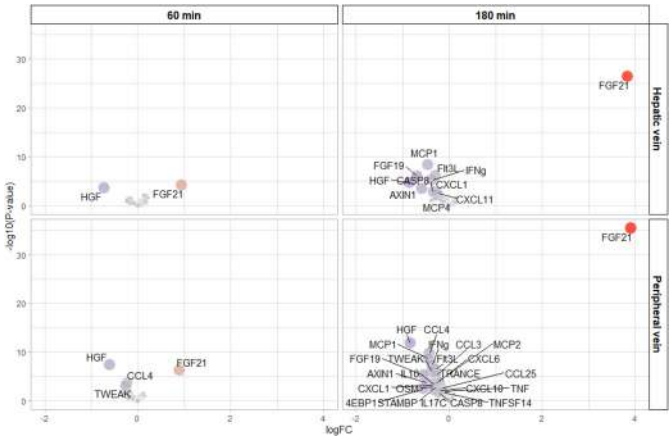
Alcohol-induced changes of inflammatory markers in hepatic and systemic venous blood in early alcohol-related and non-alcoholic fatty liver disease

Evelina Stankevic[1], Mads Israelsen[2,3], Helene Bæk Juel[1], Anne Lundager Madsen[1], Nikolaj Torp[2,3], Stine Johansen[2,3], Camilla Dalby Hansen[2,3], Katrine Prier Lindvig[2,3], Bjørn Stæhr Madsen[2,3], Maja Thiele[2,3], Aleksander Krag[2,3], Torben Hansen[1]. *[1]The Novo Nordisk Foundation Center for Basic Metabolic Research, København, Denmark; [2]Odense University Hospital, Department of Gastroenterology and Hepatology, Odense C, Denmark; [3]University of Southern Denmark, Department of Clinical Research, Faculty of Health Sciences, Odense C, Denmark*
Email: evelina@sund.ku.dk

Background and aims: Alcohol consumption is believed to increase intestinal permeability, leading to inflow of pathogens and other immune-activating compounds to the liver. Further, alcohol intake is known to suppress the immune system, and is related to an increased risk of systemic infections. Taken together, these factors could play a central role in the initiation of hepatic inflammation, an important step in the development and progression of alcohol-related liver disease (ALD). We aimed to investigate the effects of alcohol consumption on inflammatory markers in hepatic and systemic venous blood in people with ALD, non-alcoholic fatty liver disease (NAFLD) and healthy controls.

Method: We included 40 participants with three distinct hepatic phenotypes: 15 with ALD, 15 with NAFLD and 10 healthy controls. All participants received 2.5 ml of 40% ethanol per kg body weight, infused over 30 minutes via a nasogastric tube. Ninety-two circulating inflammatory cytokines were quantified using the Target-96 'Inflammation' panel from Olink Proteomics, in plasma samples obtained from two sites (hepatic and systemic vein), at three time points (0, 60 and 180 min). Linear (mixed) models were used and significant results ($p < 0.05$) reported after correcting for False Discovery Rate (FDR).

Results: At baseline, 31 cytokines were differentially expressed in the ALD group and 16 in the NAFLD group, when compared to the healthy group. Alcohol induced changes for 2 cytokines at 60 min and 11 cytokines at 180 min in hepatic venous blood, and for 4 cytokines at 60 min and 24 cytokines at 180 min in systemic venous blood, in all three groups combined. Fibroblast growth factor 21 (FGF-21) was the only cytokine that increased during the observation period. Hepatocyte growth factor (HGF) was the first cytokine (after 60 min) to decrease in hepatic venous blood, while the concentration of 8 additional cytokines dropped within three hours (Figure showing volcano plots (upregulated (red) and downregulated (blue) cytokines in hepatic and systemic circulation after 60 and 180 min. The X axis-log fold change and Y axis-log10 p value from a linear mixed model. Cytokines, significantly different after alcohol intoxication at FDR 5% are labeled)). Moreover, the concentration of 19 cytokines was different in hepatic vein, when compared to systemic vein.



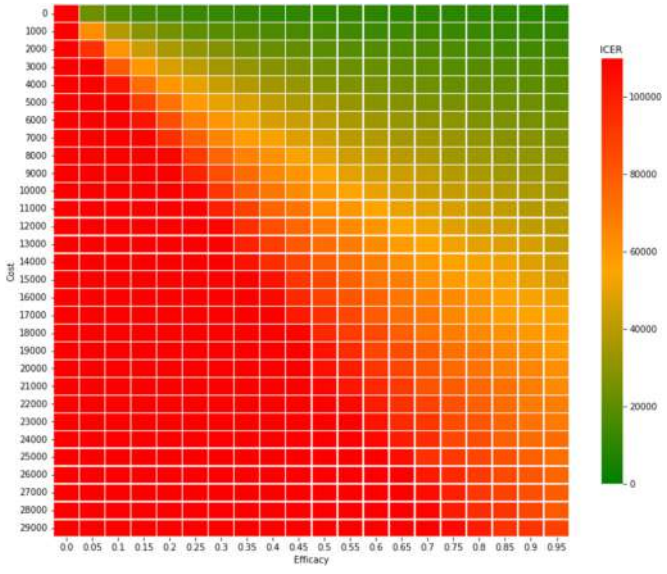
Conclusion: Our findings indicate that while ALD and NAFLD are associated with an increased concentration of inflammatory cytokines at baseline, acute alcohol consumption dampens the hepatic and systemic inflammatory response, which might affect the ability of the liver to deal with pathogens arriving from the portal vein. Differences in cytokine concentrations between hepatic and systemic vein suggests direct hepatic production or sequestration of these cytokines, respectively, further highlighting the central role of the liver in systemic inflammation.

THU022

New treatment for alcohol-related liver disease: combinations of efficacy and treatment cost required for cost-effectiveness

Maja Thiele[1], Davit Khlghatyan[2], Lars Asphaug[3], Stine Johansen[4], Hans Olav Melberg[2]. *[1]Odense University Hospital, University of Southern Denmark; [2]University of Oslo, Department of Health Management and Health Economics; [3]University of Oslo, Department of Health Management and Health Economics, Oslo, Norway; [4]Odense University Hospital, University of Southern Denmark, Department of Gastroenterology and Hepatology*
Email: maja.thiele@rsyd.dk

Background and aims: Alcohol-related liver disease (ALD) has a poor prognosis, with a 5-year survival rate below 50%, and substantial costs for the healthcare system with no effective treatment currently available. Recently, accurate diagnostic tools have allowed for early detection of ALD, further enabling the development of targeted interventions. Without an idea of future value, and by extension the likelihood of eventual reimbursement, producers and research funders may have less incentive to focus on this opportunity. We, therefore, aimed to identify the relationship between required efficacy and the cost of a potential new treatment for early ALD needed to achieve uptake into clinical practice.
Method: We simulated excessive drinkers with advanced fibrosis over their lifetime using a mathematical computer model. Two scenarios were applied: 1) no treatment (current standard) and 2) a progression-halting treatment modelled on a possible novel treatment in an ongoing trial. Model input data was in the no-treatment scenario sourced from the literature and a prospective Danish natural history study and the currently unknown treatment efficacy (reduced risk of progression)-and cost (USD) was simulated over a vast range of possible values. The simulation allowed the identification of pairs of treatment efficacies and costs resulting different ratios of incremental costs to incremental effectiveness (ICERs) compared to current management (Figure).



Results: In countries with a willingness-to-pay threshold of $ 50, 000, treatments halting progression in ALD at the fibrosis stage is cost-effective upon reaching 30% efficacy contingent on annual treatment costs not exceeding $ 5, 000, or 60% efficacy if costs are less than $ 10, 000 per annum. In the UK, where willingness to pay per quality-adjusted life-year is between 20 and 30 000 £, progression-halting treatments should reach an efficacy of 60% at an annual cost between £ 3000 and £ 5000 to be considered cost-effective.
Conclusion: Our results are useful for research funders and producers of new treatments for ALD in determining to reimburse or develop a new treatment for advanced liver fibrosis in patients with alcohol-related liver disease. The calculated ICERs can be interpreted across different healthcare systems with varying levels of cost-effectiveness thresholds.

THU023

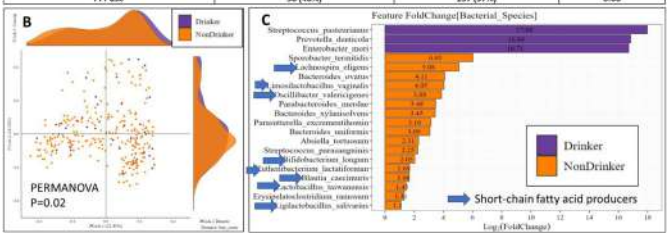
Active alcohol misuse is linked with lower short-chain fatty acid producing microbiota in a matched study of 450 patients with cirrhosis

Jasmohan S Bajaj[1], Amirhossein Shamsaddini[2], Masoumeh Sikaroodi[2], Brian Davis[1], Puneet Puri[1], Michael Fuchs[1], Andrew Fagan[1], Sara McGeorge[1], Patrick Gillevet[2]. *[1]Virginia Commonwealth University and Richmond VAMC; [2]George Mason University*
Email: jasmohan.bajaj@vcuhealth.org

Background and aims: Alcohol use disorder (AUD) alters gut microbiota and can lead to cirrhosis development. However, cirrhosis, regardless of etiology is also linked with microbial change. Several AUD pts continue to drink despite the development of cirrhosis but the interaction between active alcohol misuse and cirrhosis is unclear. Bacterial products such as short-chain fatty acids (SCFAs) can strengthen the intestinal barrier and promote abstinence in a small FMT trial. Aim: Determine the impact of active alcohol misuse on gut microbial structure and function in the background of cirrhosis.
Method: Outpts with cirrhosis diagnosed on biopsy, fibroscan or prior decompensation underwent stool collection while drinking habits (AUDIT-10), demographics, cirrhosis severity and medication use were collected. Active drinkers were matched with non-drinkers with respect to cirrhosis details and demographics. Non-drinkers had to be abstinent for ≥6 mths before stool collection. Microbiota structure was analyzed using 16SrRNA sequencing and predicted function using PiCRUST between actively drinking and non-drinking pts.

Results: We enrolled 451 patients with cirrhosis (MELD 10.3 ± 4.5, Age 58.8 ± 6.8, 80 actively drinking pts). They were matched 1:4 with at least 320 non-drinkers (Fig A). Groups were similar on demographics, cirrhosis details and medications apart from AUDIT-10 and alcohol-related etiology, which were higher in actively drinking patients. Alcohol use: Actively drinking subjects had constant drinking habits without binges. Abstinent pts had been abstinent for 15 ± 8 years before enrollment. Microbiota composition: β-diversity was different between groups (Fig B) but Shannon diversity was statistically similar. Prevotella, Enterobacter and Streptococcus spp were higher while potentially beneficial taxa belonging to Eubacterium, Bifidobacterium, Blautia, Roseburia, Alistipes, and Lactobacillus were lower in active drinkers. Short-chain fatty acid producing taxa specifically propionate and butyrate were lower in active drinkers (Fig C). Microbiota predicted function: Propanoate metabolism-related enzymes, which are also associated with branched amino acid degradation were higher in patients who were drinking (3-hydroxyisobutyrylCoA hydrolase and methylmalonylCoA carboxytransferase).

Figure A	Actively drinking pts (N=80)	Abstinent pts (N=371)	P value
Age	60.12±7.44	58.6±6.74	0.10
Male gender	70 (88%)	298 (80%)	0.14
Diabetes	18 (23%)	124 (33%)	0.06
AUDIT-10	18±9	3±4	<0.0001
Alcohol-related etiology	62 (78%)	80 (22%)	<0.0001
MELD score	10.51±4.38	10.32±4.56	0.74
Prior HE	13 (16%)	83 (22%)	0.27
Lactulose	13 (16%)	56 (15%)	0.79
Rifaximin	5 (6%)	31 (8%)	0.21
SBP prophylaxis	4 (5%)	21 (6%)	0.47
PPI use	38 (48%)	137 (37%)	0.08



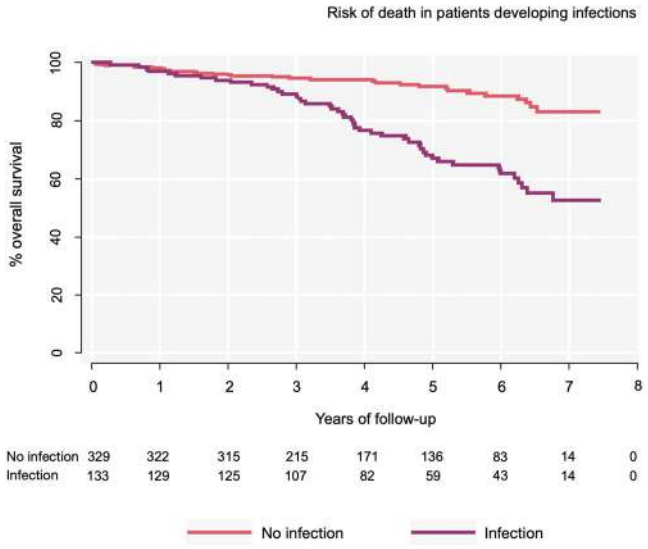
Conclusion: SCFA producing microbiota, especially butyrate and propionate metabolism, were significantly lower in actively drinking patients with cirrhosis compared to abstinent patients despite matching for demographics, cirrhosis severity and medication use. SCFAs could have a link with continued alcohol intake in this advanced population.

THU024

Infections are common in patients with early alcohol-related liver disease and increases the risk of death

Stine Johansen[1,2], Simon Langkjær Sørensen[1,2], Ditlev Nytoft Rasmussen[1,2], Mads Israelsen[1,2], Katrine Prier Lindvig[1,2], Maria Kjærgaard[1,2], Johanne Kragh Hansen[1,2], Camilla Dalby Hansen[1,2], Katrine Thorhauge[1,2], Nikolaj Torp[1,2], Peter Andersen[1,2], Sönke Detlefsen[2,3], Helene Bæk Juel[4], Torben Hansen[4], Aleksander Krag[1,2], Maja Thiele[1,2]. *[1]Odense University Hospital, Department of Gastroenterology and Hepatology, Denmark; [2]University of Southern Denmark, Department of Clinical Research, Denmark; [3]Odense University Hospital, Department of Pathology, Denmark; [4]University of Copenhagen, Novo Nordisk Foundation Center for Basic Metabolic Research, Denmark*
Email: stine.johansen@rsyd.dk

Background and aims: Infections are frequent in patients with alcohol-related liver cirrhosis and worsen prognosis. We hypothesized that this also applies in earlier stages of alcohol-related liver disease (ALD). We therefore aimed to examine 1) the incidence of infections in patients with early ALD, 2) risk factors associated with developing infections, and 3) the impact of infections on the risk of liver-related events and all-cause mortality.
Method: We performed a prospective cohort study of patients from primary and secondary care with a history of excess alcohol intake, excluding patients with decompensation or competing aetiologies for liver disease. At baseline, we performed liver biopsies along with clinical investigations. During follow-up, we reviewed patients' electronic healthcare records for infections, liver-related events, all-cause mortality, and alcohol intake.
Results: We included 462 patients with a mean age of 57 ± 10 years, 76% males, with fibrosis stage F0-1/F2/F3-4 = 259/107/96. During a median follow-up of 54 months (IQR 35–76), 133 patients (29%) developed a total of 307 infections with a median of two infections each (range 1–3). Seventy-six % of infections were treated during hospitalization, most frequently pneumonia (103/307, 34%) and urinary tract infections (56/307, 18%). In approximately half of all infections cultures were obtained, and the most common isolated bacterium was *Escherichia coli*. Liver stiffness measured by transient elastography was a stronger predictor of infections than fibrosis stage, consequently excessive drinking during follow-up and transient elastography were the only independent predictors of infections in multivariable regression (hazard ratio (HR) 2.08; 95%CI 1.33–3.27, and HR 1.87; 1.54–2.28). Eighty-seven patients (19%) developed a liver-related event during follow-up and 60 of these patients had 147 infections in total. Patients who developed at least one infection had a significantly increased risk of death (HR 3.36; 95%CI 2.12–5.33, p <0.001), but not of developing a liver-related event (HR 1.35; 95% CI 0.84–2.15, p = 0.22). Infections increased the risk of death independent of baseline fibrosis stage and liver stiffness.



Conclusion: In patients with early alcohol-related liver disease, infections are frequent and worsen prognosis. Risk of infections increases with liver disease severity and ongoing harmful use of alcohol.

THU025

Abstinence is associated with better outcome in patients with hepatocellular carcinoma

Adeline Donati[1], Jean Henrion[2], Maxime Regnier[3], Pierre Deltenre[1,4,5], Astrid Marot[1]. *[1]CHU UCL Namur, Department of Gastroenterology and Hepatology, Yvoir, Belgium; [2]Hôpital de Jolimont, Department of Gastroenterology and Hepatology, Haine St Paul, Belgium; [3]CHU UCL Namur, Department of biostatistics, Yvoir, Belgium; [4]Clinique St Luc Bouge, Department of Gastroenterology and Hepatology, Namur, Belgium; [5]CUB Hopital Erasme Université Libre de Bruxelles, Department of Gastroenterology, Hepatopancreatology and Digestive Oncology, Bruxelles, Belgium*
Email: astridmarot@gmail.com

Background and aims: Data suggest that patients with alcohol-related hepatocellular carcinoma (HCC) have a reduced survival as

compared to those with nonalcohol-related HCC. The role of abstinence in this setting in unknown. We aimed to compare access to treatment and prognosis of patients with alcohol-related HCC and nonalcohol-related HCC and to evaluate the impact of abstinence.
Method: All patients with HCC were retrospectively included in a single center during a 23-year period. Abstinence was defined as discontinuation of alcohol consumption at least 3 months before HCC diagnosis in patients with alcohol-related cirrhosis. Treatment by resection, ablation, and transplantation were considered curative. Multivariate Fine and Gray proportional hazards models were used to identify factors associated with 5-year overall mortality after adjustment for the lead-time bias. A logistic regression model was used to identify factors associated with access to curative treatment.
Results: 200 patients were included, 114 (57%) with nonalcohol-related HCC and 86 (43%) with alcohol-related HCC of whom 35 were abstainers and 51 were consumers. All of them had a cirrhosis. During a median follow-up of 14 months (95%CI: 11–16), 12 patients were transplanted and 156 died. At HCC diagnosis, consumers were younger as compared to abstainers and non-alcoholic patients (59 vs. 63 vs. 68 years, p = 0.001), had a worse liver function (MELD score: 11 vs. 10 vs. 8, p = 0.01, Child-Pugh score: 6 vs. 5 vs. 5, p = 0.02), were less likely to be screened for HCC (33% vs. 74% vs. 51%, p < 0.001) and had more frequently a metastatic disease (16% vs. 0% vs 6%, p = 0.02). After adjustment for the lead-time bias, the 5-year cumulative incidence rates of overall death were significantly lower in abstainers than in consumers and in non-alcoholic patients (51.5% vs. 78.4% vs. 80.5%, respectively, p = 0.04). In multivariate analyses, while abstainers were significantly associated with lower overall mortality as compared to consumers (HR: 0.47, 95% CI 0.28–0.80, p = 0.005), patients with nonalcohol-related cirrhosis and consumers had similar overall mortality (HR: 0.86, 95% CI 0.60–1.24, p = 0.4). The proportion of patients who received a curative treatment was 65% in abstainers, 44% in consumers and 57% in non-alcoholic patients (p = 0.1). In multivariate analyses, preserved liver function (Child A vs. B/C, OR: 3.10 95% CI 1.58–6.26, p = 0.001) and adherence to a screening program (OR: 4.96, 95% CI 2.50–10.15, p < 0.001) were the only two factors associated with a better accessibility to curative treatment.
Conclusion: Abstinence improves the outcome of patients with alcohol-related HCC because of better liver function, less advanced tumour disease and better adherence to screening.

THU026

In severe alcohol-related hepatitis, hepatocyte ballooning correlates with expression of p16 and components of a secretory phenotype that has been associated with cellular senescence

Nikhil Vergis[1], Isabelle Hall[1], Callum Arthurs[1], Hiromi Kudo[1], Stephen Atkinson[1], David Shapiro[2], Michael Lutz[2], Birgit Jung[2], Markus Weissbach[2], Wolfgang Albrecht[2], Luke D. Tyson[1], Tong Liu[1], Emma Lord[1], Lars Zender[3], Mark Thursz[1], Robert D. Goldin[1]. [1]*Imperial College, United Kingdom;* [2]*HepaRegeniX GmbH, Tuebingen, Germany;* [3]*University Hospital Tübingen, Klinik für Medizinische Onkologie and Pneumologie, Germany*
Email: nvergis@imperial.ac.uk

Background and aims: Poor outcome in severe alcohol-related hepatitis (sAH) is frequently attributed to failure of hepatic regeneration. This may be due to lack of trophic factors, inability of hepatocytes to proliferate and/or the induction of stable cell cycle arrest known as senescence. Senescent cells undergo morphological changes that may be consistent with the hepatocyte ballooning found in steatohepatitis. Here, we investigate the potential causes of regenerative failure in sAH and seek evidence for markers of senescence in ballooned hepatocytes.
Method: Data was available from 731 AH patients with sAH recruited to the STOPAH trial, 37 compensated cirrhotic patients (CLD) and 64 healthy controls (HC). We evaluated serum levels of the senescence associated secretory phenotype (SASP) for a range of trophic factors (HGF, EGF, IGF, VEGF, TWEAK) plus inflammatory and/or pro-regenerative cytokines (IL1b, IL6, IL8, IL10, IL22, and TNFa). Immunohistochemistry was used to identify cell proliferation (Ki67) and senescence (p16) in liver biopsy sections (n = 29). HandE stains were used to differentiate *occasional* from *marked* ballooning of hepatocytes. Digital image analysis was used to quantify staining and a nuclear morphology algorithm attributed stains to individual cell types.
Results: $p16^+$ hepatocytes were more frequent in sAH compared to control tissue without steatohepatitis (p <0.05). Moreover, in sAH tissue expression of p16 on hepatocytes strongly associated and co-localized with ballooned hepatocytes (p = 0.005, Figure 1). In contrast, no correlations were seen in cholangiocyte p16 expression nor with Ki67 expression in any cell type. Components of a secretory phenotype consistent with the SASP (serum IL1, IL6, IL8, TNFa, HGF, EGF, TWEAK) were associated with hepatocyte ballooning (p <0.05 for all). Serum bilirubin was higher in patients with marked ballooning (p = 0.0003) but prothrombin time was not (p = 0.24). Strikingly, HGF levels were >7-fold higher in sAH vs HC and CLD (p <0.001) and correlated with both baseline MELD (r = 0.21, p <0.001) and Lille score (r = 0.16, p <0.001). Conversely, EGF was lower in sAH vs HC vs CLD (p <0.001) and in sAH patients who died within 28 (p = 0.01) and 90 days (p = 0.003) compared to sAH patients who survived.

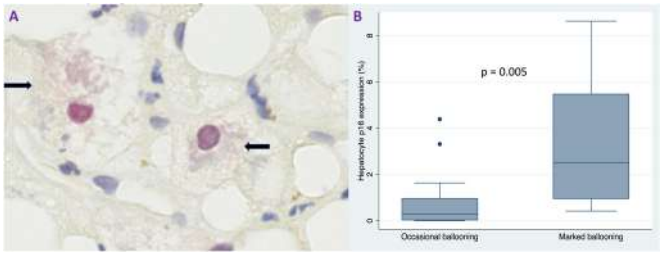


Figure: **A.** representative immunohistochemistry of two ballooned (black arrows) $p16^+$ (red) hepatocytes. **B**: Comparison of hepatocyte p16 expression in sAH liver biopsy samples with *marked* vs *occasional* hepatocyte ballooning

Conclusion: Serum proteins implicated in hepatocyte regeneration and senescence are associated with clinical outcome in sAH. $p16^+$ hepatocytes are prevalent and are strongly associated with hepatocyte ballooning in sAH liver biopsies. Further characterization of the senescent properties of $p16^+$ cells may stimulate senolytic or SASP-modulating therapies in sAH.

THU027

Targeting cyclin M4 as a new therapeutical approach to treat alcoholic liver disease

Irene González-Recio[1], Naroa Goikoetxea[1], Rubén Rodríguez Agudo[1], Jorge Simón Espinosa[1], Marina Serrano-Macia[1], Mikel Azkargorta[2], Felix Elortza[2], Irene Diaz-Moreno[3], Antonio Diaz-Quintana[3], Ute Schaeper[4], Ramon Bataller[5], Matías A Avila[6], Luis Alfonso Martinez-Cruz[1], María Luz Martínez-Chantar[1]. [1]*CIC bioGUNE, Liver Disease Lab, Derio, Spain;* [2]*CIC bioGUNE, Proteomics platform, Derio, Spain;* [3]*Instituto de Investigaciones Químicas (IIQ), Sevilla, Spain;* [4]*Silence Therapeutics GmbH, Berlin, Germany;* [5]*University of Pittsburgh, Department of medicine, Pittsburgh, United States;* [6]*CIMA, Hepatology program*
Email: mlmartinez@cicbiogune.es

Background and aims: An excessive alcohol consumption is a main reason of chronic liver disease and liver-related deaths in Western countries and causes alcoholic liver disease (ALD), featured by fatty liver, alcoholic hepatitis (AH), cirrhosis and liver cancer.
Approximately 50% of liver cirrhosis cases caused by alcohol abuse, result in 3.3 million deaths. Today, there are no effective treatments other than abstinence or liver transplantation for end-stage ALD.
Acute and chronic alcohol consumption are associated with a decrease in liver Mg^{2+} content. The underlying mechanisms remain

unknown. The alteration of Mg^{2+} levels in ALD and the key role of Mg^{2+} transporters in enabling the flux of Mg^{2+} across cell membranes, have prompted us to investigate the role of cyclin M4 in ALD. In this context, the inhibition of CNNM4 by RNA interference emerge as a new therapeutic approach for ALD.

Method: The expression of CNNM4 was studied in ALD patients, in primary hepatocytes under ethanol exposure and in mice under chronic and binge ethanol feeding (the NIAAA model). Primary hepatocytes were treated with a GalNAc siRNA targeting *Cnnm4* to evaluate the effect of silencing *Cnnm4* in hepatocytes exposed to 50 mM EtOH for 12 h, 24 h and 36 h. NIAAA model mice were divided into 2 groups after day 5 of the diet and treated with a control molecule or GalNAc siRNA that specifically silences *Cnnm4* in hepatocytes.

Results: The expression of *Cnnm4* was upregulated in the liver of patients with ALD and correlated with the stages of the disease: early AH, non-severe AH, severe AH, compensated HCV-related cirrhosis, AH explants and cirrhosis hepatitis C virus. Hepatic CNNM4 levels were overexpressed in the NIAAA model. Silencing *Cnnm4* exhibited a reduction in transaminases. Importantly, the absence of *cnnm4* resulted in a significant decrease in mitochondrial ROS and ER stress in hepatocytes. High-throughput proteomic analysis performed in liver tissue from NIAAA models revealed a significant representation of the following processes in the absence of CNNM4; oxidation-reduction, lipid metabolism, cellular response to oxidative stress, endoplasmic reticulum stress or protein folding families. The machinery for repairing damaged proteins, represented by the enzyme protein-L-isoaspartate (D-aspartate) O-methyltransferase (PIMT), was significantly overexpressed in the absence of CNNM4. Further experiments will investigate whether Mg^{2+} homeostasis mediated by silencing of CNNM4 modulates PIMT activity, which has been shown to be impaired during excessive ethanol consumption.

Conclusion: CNNM4 magnesium transport appears to be dysregulated in patients with AH and in NIAAA model. Targeting *Cnnm4* with GalNAc siRNA has emerged as a novel therapeutic approach for ALD that ameliorates AH in the NIAAA model. Further experiments will address the role of CNNM4 in the protein repair machinery mediated by PIMT activity.

THU028

Hepatic transcriptional signature of alcohol on genes involved in canonical retinoid metabolism

Marta Melis[1], Xia-Han Tang[1], Nabeel Attarwala[1], Qiuying Chen[1], Carlos Prishker[1], Lihui Qin[2], Steve Gross[1], Lorraine Gudas[1], Steven Trasino[1,3]. *[1]Weill Cornell Medical College, Pharmacology, New York, United States; [2]Weill Cornell Medical College, Pathology and Laboratory Medicine; [3]Hunter College, CUNY, Urban Public Health and Nutrition, New York, United States*
Email: st1647@hunter.cuny.edu

Background and aims: A large body of data show that alcohol abuse leads to reductions to hepatic vitamin A (retinoids) levels beginning in early stages of chronic alcohol abuse (<2–3 weeks), which is associated with progression of liver damage, and early stages of alcohol liver disease (ALD). However, to date, there remains little understanding of the genes involved in alcohol-driven hepatic retinoids depletions during early stages of ALD.

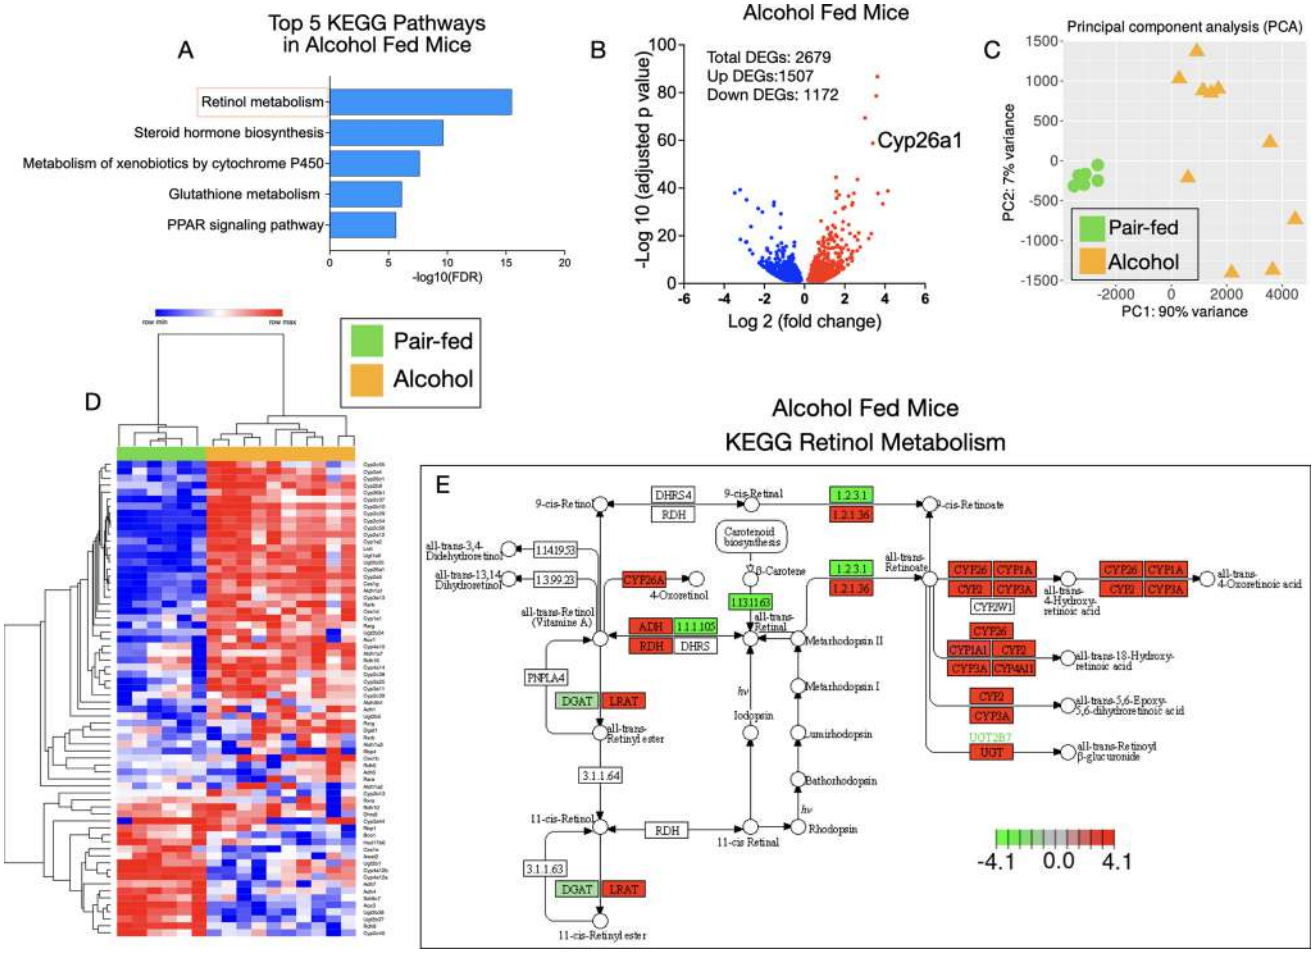

Figure 1: (abstract: THU028)

Method: Using a 3-week murine model of chronic alcohol intake and RNA sequencing technology, we determined the hepatic transcriptional signature of alcohol on genes involved in canonical retinoid metabolism.
Results: Our results show that 3 weeks of alcohol intake led to increases in serum retinol levels, but reductions to hepatic retinoids (retinol, and retinyl-esters), and concomitant increases in plasma AST, ALT, and macro and microvesicular steatosis. By RNA sequencing technology, we found that 3 weeks of chronic alcohol intake led to modulation of 68 transcripts involved in canonical retinoid metabolism. These transcripts include the genes *Ces1d*, *Ces1g, Rbp1*, *LRAT, Rdh10*, *Aldh1a1, Cyp26a1.* Interestingly, among the 2679 significant differentially expressed genes (DEGs) in livers of alcohol-fed mice, *Cyp26a1*, the major retinoic acid catabolizing enzyme was the 6th top significantly upregulated DEG. We also detected broad hepatic increases in transcripts of families of *Cyp1a, Cyp2a-c, Cyp3a-c* xenobiotic enzymes, capable of retinoid catabolism. Using western blotting we confirmed that compared to untreated mice, hepatic protein expression of the retinyl-ester hydrolases CES1D, CES1G, and a rate-limiting enzyme in retinoic acid synthesis, ALDH1A1, were significantly increased in livers of alcohol-fed mice. However, protein levels of RBP1, which is critical to hepatic retinol transport and homeostasis, was markedly decreased in livers of alcohol-fed mice. Moreoever, we detected specific reductions to RBP1 in hepatic stellate cells (HSC) and portal hepatocytes.
Conclusion: These data show for the first time that reductions to hepatic retinoid in early stages of ALD may be due to pleiotropic effects, involving impaired retinoid transport and metabolism in portal hepatocyte and HSCs, but also concurrent increases in hepatic retinyl-ester hydrolysis, and oxidative metabolism of retinol to retinoic acid, and CYP-mediated retinoid catabolism. Given that *Cyp26a1* was the 6th top DEG in alcohol-fed mice, our data also strongly suggest that retinoid metabolism is among the key micronutrient pathways negatively impacted in early stages of ALD. These data may help develop future therapies aimed at mitigateting hepatic retinoid losses in individuals that struggle with alcohol cessation.

THU029
COVID-19 pandemic impact on alcoholic hepatitis healthcare utilisation

Leya Nedumannil[1], Sukhdeep Steven Cheema[1], Karl Vaz[1], Ronald Ma[2], Daryl Jones[3], Stephen Warrillow[3], Josephine Grace[1,4], Darren Wong[1], Matthew Choy[1,4]. Email: leya.nedumannil2@austin.org.au

Background and aims: Alcoholic hepatitis (AH) is associated with significant morbidity, mortality and healthcare expenditure. The global SARS-CoV-2 (COVID-19) pandemic and related lockdown measures have potentially contributed to an increase in alcohol misuse. This study examines frequency and patient outcomes of AH admissions to an Australian quaternary liver transplant referral centre. We aimed to ascertain the change in AH severity, ICU admission rates and healthcare utilisation costs over the last 5 years to identify temporal associations with the COVID-19 pandemic.
Method: A retrospective analysis of patients aged 18 years and older fulfilling National Institute on Alcohol Abuse and Alcoholism diagnostic criteria for AH between January 2016 and March 2021 was conducted. Data were collected from electronic medical records and analysed. Primary end points were the frequency of AH admissions, ICU admission rates and healthcare costs, which were evaluated with a divergence at the beginning of lockdown restrictions (March 2020-March 2021 "COVID cohort") versus the "historical cohort" (January 2016-February 2020).
Results: In total, 105 eligible AH admissions were identified. Overall, 90 day mortality was 18% (19/105). AH admission rate for the COVID cohort was significantly higher at 3.38 cases/month (n = 44) compared to the historical cohort at 1.22 cases/month (n = 61), p <0.001. The COVID cohort had greater disease severity with a higher Glasgow Alcoholic Hepatitis Score during admission [8.5 (IQR 7–10) vs 7 (IQR 6–9), p = 0.04]. The AH COVID cohort trended towards a greater proportion requiring ICU admission, inotropic support and longer ICU length of stay. Whilst per-episode adjusted healthcare costs were similar across the study, monthly costs of the COVID cohort were higher compared to the historical cohort due to increased admission frequencies [mean (SD) $137, 549 (54, 058) vs $38, 000 (27, 448), p = 0.02 (Figure 1)]. No patients in this study were diagnosed with COVID-19.

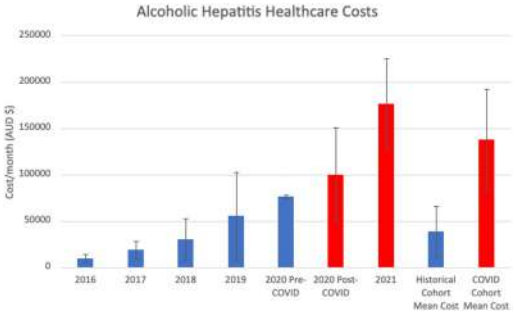

Figure 1: Alcoholic Hepatitis Healthcare Costs

Conclusion: In this study, alcoholic hepatitis admission frequency and healthcare costs were found to have increased since the COVID-19 pandemic. These observations provide the impetus for future studies to understand how the COVID-19 pandemic has led to increased AH presentations and develop preventative strategies that reduce alcohol related admissions and associated costs.

THU030
The role of integrated alcohol liver care in the management of patients with alcohol related liver disease in an acute hospital setting

Khin Han[1], Phyo Wah Wah[1], Ian Webzell[1], Joshua Stapleton[2], Huyen Adams[1], Abid Suddle[1], Michael Heneghan[1], Nicola Kalk[2], Naina Shah[1]. [1]*Kings College Hospital, Hepatology, London, United Kingdom;* [2]*South London and Maudsley, Psychological Medicine, London, United Kingdom*
Email: nkshah26@yahoo.com

Background and aims: Acute on Chronic Liver failure (ACLF)/Acute decompensation (AD) following Alcohol use disorder (AUD) is a common presentation to the Hospital. The office of national statistics in the UK reported 7, 423 deaths in 2020. 80% of these were attributed to Alcohol related Liver Disease. Alcohol related admissions and deaths costs the National health service (NHS) over 3.5 billion/year. As a part of the NHS long term plan, Alcohol care team comprising of Consultants: Hepatologist, Addiction Psychiatrist and clinical nurse specialists was established at Kings College Hospital in 2018, to manage AUD and prevent recurrent Hospital presentation. Integrated outpatient treatment providing medical treatment and alcohol interventions has been previously shown to improve abstinence in medically ill patients. Explore the utility of an integrated Alcohol Liver clinic led by Consultants: Hepatologist and Addiction Psychiatrist in facilitating abstinence in patients with ArLD.
Method: 159 patients with Alcohol related cirrhosis were reviewed in the clinic, male: n = 95 with a median age of 58 (36 ± 83), female, n = 64 with a median age of 54 (32 ± 77). 29/159 presented with ACLF.
Results: Abstinence led to a Liver recovery in patients with ACLF (table 1). 61/159 (38%) presented to the Hospital with decompensation. 51/61 (83%) recompensated following abstinence. Unfortunately 18/159 patients who died had AUD prior to presentation. The overall

abstinence rate was 104/159 (65%) (table 1). Number of patients achieving abstinence has increased following the implementation of integrated care service as shown in figure 1.

Table 1: Alcohol use disorder in patients with Alcohol related Liver disease

	Abstinent	Drinking	Harm reduction
ACLF grade 1 (n = 7)	5	2	0
ACLF grade 2 (n = 15)	6	5	4
ACLF grade 3 (n-7)	6	1	0
Decompensated ArLD (n = 61) recompensated (n = 51) 83%	51	6	4
Cirrhosis compensated (n = 69)	36	18	15
mortality (n = 22)	4	18	0

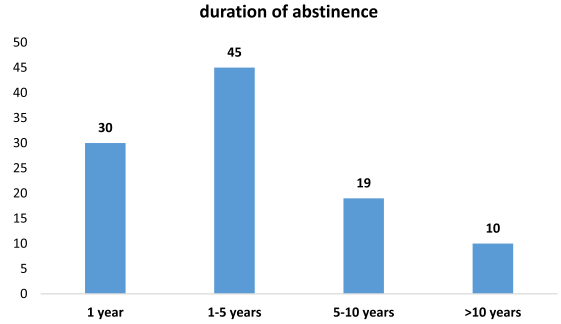

Figure 1: Number of patients achieving abstinence

Regular Liver health education, motivational intervention including engagement with the community and Hospital Addictions team has helped patients maintain abstinence. Sustained sobriety led to Liver recovery and prevention of Hospital presentation with complications related to portal hypertension/ACLF. This has led to a reduction in monthly readmission rate to 6–8%. In addition to being cost-effective, it has improved the long term prognosis of patients with ArLD.

Conclusion: Sustained abstinence leads to Liver recovery, reduced Hospital presentation and readmission. Facilitating abstinence is vital in improving the long term prognosis in patients presenting with ArLD. Integrated care approach should be considered as a standard of care in managing AUD.

There is an unmet clinical need in exploring pharmacological and psycho-social intervention tailored towards treating AUD in patients with ArLD thus preventing the development of ACLF/AD.

THU031

Untargeted lipidomics unveils a specific plasma signature of severe alcoholic hepatitis

Florent Artru[1,2], Stephen Atkinson[2], Francesca Trovato[1], Nikhil Vergis[2], Vishal C Patel[3,4,5], Salma Mujib[1], Anna Cavazza[1], Alexandros Pechlivanis[2], Ellen Jerome[1], Marc Zentar[1], Evangelos Triantafyllou[2], Elaine Holmes[2], Mark J W McPhail[1,2], Mark Thursz[2]. *[1]Institute of Liver Studies, King's College London, London, United Kingdom; [2]Imperial College London, London, United Kingdom; [3]The Roger Williams Foundation for Liver Research, Institute of Hepatology, London, United Kingdom; [4]King's College Hospital, Institute of Liver Studies, London, United Kingdom; [5]King's College London, School of Immunology and Microbial Sciences, London, United Kingdom*
Email: m.thursz@imperial.ac.uk

Background and aims: Severe alcoholic hepatitis (SAH) is associated with systemic inflammation and immune dysfunction. Lipids are involved in inflammatory and immune responses; however, lipidomics is understudied in the setting of SAH. We evaluated whether specific changes in the blood lipidome are observed in patients with SAH.

Method: Untargeted serum lipidomics was performed using reversed phase ultra-performance liquid chromatography coupled to mass spectrometry in patients with SAH participating in the STOPAH trial (n = 159), with cirrhosis (n = 81-including compensated and decompensated cirrhosis) and healthy controls (HC, n = 35). Serum lipidome changes between SAH and cirrhosis were evaluated in a derivation set (n = 160) and a validation set (n = 80) by principal component analysis (PCA) and orthogonal partial least squares discriminant analysis (OPLS-DA).

Results: Patients with SAH and cirrhosis had a similar age (51 vs. 51-year-old, p = 0.9) but different MELD scores (21.8 vs. 15.3, p < 0.0001). According to Lille score, 44.8% of SAH patients were responders to medical treatment with a 29.1% 90-day survival. The derivation and validation sets were well matched for clinical and biological variables. In the derivation cohort, PCA accurately discriminated between patients with SAH, cirrhosis and HC. In OPLS-DA both ionisation modes accurately discriminated SAH vs. cirrhosis (in positive mode: $R^2Y = 0.55$ $Q^2 = 0.49$ CV-ANOVA $p < 0.0001$ AUROC = 0.92; in negative mode: $R^2Y = 0.54$ $Q^2 = 0.36$ $p < 0.0001$ AUROC = 0.96). The 20 metabolites showing the greatest variable importance projection in positive and negative mode were included in multivariate analysis adjusting for age, sex and MELD score. Three lipids in positive mode (PC 34:2, PC 36:3 and PE 39:2) and five in negative mode (PC-0-19:0, PS 41:4, PG 41:0, LPC 16:0, ST 21:4;O2) disclosed independent associations with SAH. Using these lipids, we derived 2 scores relating to positive and negative ionisation modes; both accurately discriminated SAH from cirrhosis with an AUROC of 0.90 and 0.86 in the derivation set and 0.89 and 0.92 in the validation sets, respectively.

Conclusion: Untargeted lipidomic profiling by MS indicates a lipidomic signature-mainly composed by glycerophospholipids species-in patients with SAH distinct from cirrhosis. Since these lipids are involved liver repair, some immune-modulatory functions and are associated with organ failure in sepsis they urgently require further exploration in the SAH setting.

THU032

Toll-like receptor 2 activation in monocytes of alcohol use disorder patients contributes to systemic inflammation and alcohol-associated liver disease

Luca Maccioni[1], Joyce Kasavuli[1], Sophie Leclercq[2,3], Boris Pirlot[1], Géraldine Laloux[4], Yves Horsmans[5], Isabelle Leclercq[1], Bernd Schnabl[6,7], Peter Stärkel[1,5]. *[1]UCLouvain, Université Catholique de Louvain, Institute of Experimental and Clinical Research, Laboratory of Hepato-gastroenterology, Brussels, Belgium; [2]UCLouvain, Université Catholique de Louvain, Louvain Drug Research Institute, Metabolism and Nutrition Research Group, Brussels, Belgium; [3]UCLouvain, Université Catholique de Louvain, Institute of Neuroscience, Brussels, Belgium; [4]UCLouvain, Université Catholique de Louvain, de Duve Institute, Brussels, Belgium; [5]Cliniques Universitaires Saint-Luc, Department of Hepato-gastroenterology, Brussels, Belgium; [6]University of California San Diego, Department of Medicine, La Jolla, United States; [7]University of California San Diego, Department of Medicine, VA San Diego Healthcare System, San Diego, United States*
Email: luca.maccioni@uclouvain.be

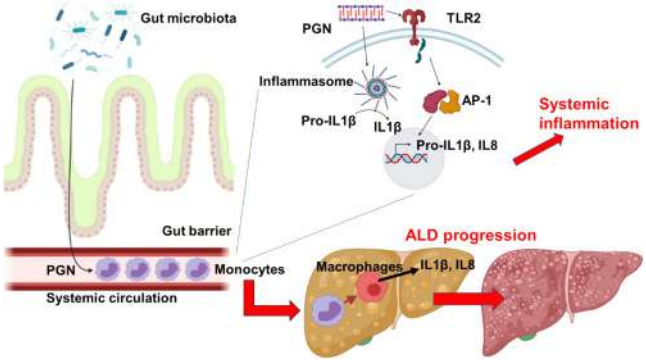
Background and aims: A minority of alcohol use disorder (AUD) patients develops progressive alcohol-associated liver disease (ALD) potentially linked to gut barrier dysfunction, microbial translocation and activation of systemic immune responses. Activation of circulating monocytes by microbial products might contribute to systemic and liver inflammation leading to ALD progression. Human data linking monocytes to early stages of ALD are lacking. We explored the links between changes in monocytes, microbial translocation, systemic inflammation and monocyte-derived macrophages in early human ALD.

Method: We included n = 123 AUD patients following a highly-standardized rehabilitation program and n = 26 healthy controls. We determined the total number of monocytes and proportion of monocytes subsets by FACS. Serum microbial translocation markers and cytokines were measured by ELISA and multiplex assay,

respectively. Cytokines reflecting activation of monocytes were assessed by qPCR. Toll-like receptor (TLR) expression in monocytes and activation as well as phagocytosis were assessed *in vitro*. ALD severity and liver inflammatory responses were analyzed in liver biopsies by histology, qPCR, immunohistochemistry and ELISA.

Results: In AUD patients, the number of blood monocytes increased ($p < 0.0001$). Among the 3 monocyte subpopulations, intermediate and non-classical increased while classical monocytes decreased compared to controls. Monocytes from AUD patients up-regulated IL1β and IL8 together with TLR2, down-stream AP-1 and inflammasome NLRP3. IL1β and IL8 were actively secreted by those monocytes upon stimulation *in vitro* with the TLR2 ligand Peptidoglycan. Stimulation with *E. coli* confirmed preserved bacterial phagocytic activity. Systemic levels of cytokines and alterations in monocytes correlated with microbial translocation markers.

In parallel, IL1β and IL8 were increased in ALD livers together with activation of intrahepatic macrophages (CD163+, iNOS+, TREM1+). Liver chemokines (MCP1, CX3CL1) involved in monocytes attraction were induced in liver tissue. IL1β and IL8 correlated with liver chemokines, iNOS+ up-regulation in macrophages and ALD severity markers (e.g. fibrosis, AST/ALT, CK18-M65 and M30).



Conclusion: Our results point to a contribution of activated monocytes to systemic and liver inflammation. Monocytes likely infiltrate the liver, transform into monocyte-derived macrophages and release IL1β and IL8 in response to Peptidoglycan and TLR2 activation, ultimately leading to ALD progression.

THU033

Improving NIAAA criteria for the diagnosis of alcoholic hepatitis, role of systemic inflammation

Elisa Pose[1,2,3], Emma Avitabile[4], Alba Díaz[5], Carla Montironi[6], Martina Perez[1,7], Jordi Gratacós-Gines[1,7], Helena Hernandéz Evole[1,7], Tejasav Sehrawat[8], Harmeet Malhi[8], Pol Olivas[7,9], Virginia Hernandez-Gea[1,3,7], Vijay Shah[8], Patrick S. Kamath[8], Pere Ginès[1,3,7,10]. *[1]Hospital Clínic of Barcelona, Liver Unit, Barcelona, Spain; [2]Institut d'Investigacions Biomèdiques August Pi i Sunyer (IDIBAPS), Chronic liver disease, Barcelona; [3]Centro de Investigación Biomédica en Red, Chronic liver disease, Madrid, Spain; [4]Institut d'Investigacions Biomèdiques August Pi i Sunyer (IDIBAPS), CIF: Q5856414G, Chronic liver disease, Barcelona, Spain; [5]Hospital Clínic of Barcelona, Pathological Department, Barcelona, Spain; [6]Hospital Clínic of Barcelona, Pathology Department and Molecular Biology CORE, Barcelona, Spain; [7]Institut d'Investigacions Biomèdiques August Pi i Sunyer (IDIBAPS), Chronic liver disease, Barcelona, Spain; [8]Mayo Clinic, Division of Gastroenterology and Hepatology, Rochester, United States; [9]Hospital Clínic of Barcelona, Psychiatry, Barcelona, Spain; [10]University of Barcelona, Barcelona, Spain*
Email: EPOSE@clinic.cat

Background and aims: The National Institute of Alcohol Abuse and Alcoholism (NIAAA) clinical criteria for the diagnosis of probable alcoholic hepatitis (AH) are commonly used to select subjects for clinical studies and to diagnose AH in clinical practice. The objectives of this study were to assess the sensitivity and specificity and to improve the diagnostic accuracy of NIAAA clinical criteria for AH.

Method: 268 consecutive patients with Alcohol-related liver disease (ArLD) that underwent liver biopsy were prospectively included: 210 and 58 in the derivation and validation cohorts. NIAAA criteria and histological diagnosis of AH were independently reviewed by clinical investigators and pathologists from Hospital Clínic and Mayo Clinic. Using liver biopsy as gold standard we determined specificity, sensitivity and accuracy of the NIAAA clinical criteria. To improve the diagnostic accuracy of NIAAA criteria the threshold of quantitative variables was optimized and combinations with categorical variables were tested. Factors associated with 1-year transplant-free survival were evaluated.

Results: In the study cohort, NIAAA criteria showed a sensitivity of 63% (95% CI, 52–73) a specificity of 78% (95% CI, 69–84) and an accuracy of 72% (95% CI, 65–78). A significant percentage (37%) of patients with histological-proven AH did not meet NIAAA criteria. These patients had higher MELD score values, higher frequency of cirrhosis decompensation, higher inflammation in terms of C-reactive protein (CRP) levels and lower 1-yr survival compared to subjects without histological AH (63% vs 91%, $p = 0.000$). A new version of the NIAAA criteria, NIAAAs-CRP criteria, was generated by simplifying the current NIAAA criteria and adding a new parameter as follows: bilirubin ≥2.5 mg/dl instead of ≥ 3 mg/dl; AST ≥ 50 UI/L and AST>ALT, instead of AST ≥ 50 UI/L, AST/ALT ratio ≥ 1.5 mg/dl and AST <400 UI/L; active alcohol consumption or alcohol abstinence less than 120 days instead of 60 days before the inclusion; not considering the presence of confounding factors and adding C reactive protein ≥ 1 mg/dl. These modified criteria showed a good combination of sensitivity, specificity and accuracy among all the combinations tested (70%, 83%, 78%, respectively). Factors associated with survival in the study cohort were histological AH, decompensated cirrhosis, MELD score and NIAAAs-PCR criteria, but not NIAAA original criteria. Similar findings were observed in the validation cohort where NIAAA original criteria showed 52% sensitivity, 82% specificity and 69% accuracy, while NIAAAs-PCR showed 56% sensitivity, 91% specificity and 76% accuracy for the clinical diagnosis of AH.

Statistic	NIAAA original (95% CI)	NIAAAs-PCR (95% CI)
Sensitivity	63 % (52-73)	70 % (59-80)
Specificity	78 % (69-84)	**83% (75-90)**
Disease prevalence (*)	39 % (32-46)	39% (32-46)
Positive Predictive Value (*)	64 % (55-72)	**72% (63-80)**
Negative Predictive Value (*)	77 % (71-81)	**82% (76-86)**
Accuracy (*)	71.90 % (65.30-77.90)	**78.10 (71.88-83.49)**

(*) These values are dependent on disease prevalence

Conclusion: A modified version of NIAAA criteria, NIAAAs-CRP criteria, with higher sensitivity, specificity and accuracy, improves non-invasive diagnosis of AH in patients with ArLD and adds prognostic value to NIAAA criteria.

Email: jparab@gmail.com

Background and aims: Severe alcohol-associated hepatitis (HA) has a high morbidity and mortality, however, the information in Latin America is limited. We aimed to characterize patients hospitalized for AH in a multinational cohort in Latin America.
Method: Multicenter prospective cohort study. We included patients admitted with severe AH between 2015–2021. Sociodemographic and clinical information was recorded. The analysis included survival analysis using Kaplan-Meier curves. This study was approved by the institutional ethics committee.
Results: 319 patients from 24 centers (8 countries: Argentina, Bolivia, Brazil, Chile, Colombia, Ecuador, Mexico, Peru) were included. Age 49.9 ± 10.3 years, 84.6% men and 54.1% had a previous diagnosis of cirrhosis. Median MELD at admission 27 [21–32] points. 25.6% met SIRS criteria and 47.6% had acute renal failure on admission. 36.11% were treated with corticosteroids. Survival at 30 days was 77.6% (95% CI: 69.7–83.7%) and at 90 days 71.6% (95% CI: 62.5–78.9%). 39.6% presented infections. The most frequent locations were urinary (34.1%), respiratory (30.7%), spontaneous bacterial peritonitis (17.1%) and skin (11.4%). The most frequent pathogens were Escherichia coli (55.6%), Klebsiella pneumoniae (11.1%) and Enterococcus (7.4%). In the long term, only 2.9% of patients have been transplanted.
Conclusion: This multicenter study shows high morbidity and mortality in patients with severe HA, which is comparable to other centers in the world.

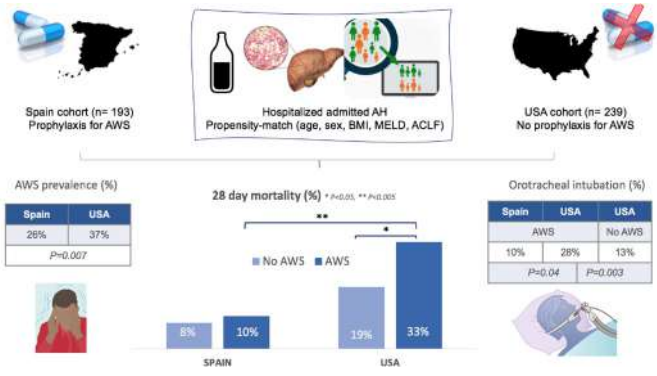
THU035

Prophylaxis of withdrawal syndrome decreases mortality in patients with alcohol-associated hepatitis

David Marti-Aguado[1], Concepción Gómez[1], Amir Gougol[2], Dalia Morales Arraez[3], Alejandro Jiménez Sosa[3], Anjara Hernandez[3], Claudia Pujol[4], Edilmar Alvarado-Tapias[4], Ares Villagrasa[5], Meritxell Ventura Cots[5], Ana Clemente[2], Abo Zed Abdelrhman[2], Keith Burns[2], Aditi Bawa[2], Haritha Gandicheruvu, [2], Vikrant Rachakonda[2], Ramon Bataller[2]. *[1]Clinic University Hospital, Department of Gastroenterology and Hepatology, Valencia, Spain; [2]University of Pittsburgh Medical Center, Hepatology Department, Pittsburgh, Spain; [3]Hospital Universitario de Canarias, Liver Unit, Tenerife, Spain; [4]Hospital de la Santa Creu i Sant Pau, Hepatology Department, Barcelona, Spain; [5]Hospital Vall d'Hebron, Barcelona, Spain*
Email: davidmmaa@gmail.com

Background and aims: Alcohol withdrawal syndrome (AWS) is a serious medical condition that often complicates hospitalized patients with advanced alcohol-related liver disease including alcoholic hepatitis (AH). There are no studies evaluating the prevalence, impact, and effect of AWS prophylaxis in the setting of AH. We aimed at evaluating the incidence and outcomes of AWS in

patients hospitalized with AH from two countries with different AWS management strategies.
Method: A multicenter, international, retrospective, case-control study was performed evaluating consecutive patients hospitalized with AH in Spain (four participating centers) and USA (one center). In Spain, clomethiazole is used as prophylactic therapy for AWS while in USA a symptom-triggered approach is followed. Electronic medical history of all patients hospitalized with the diagnosis code of AH since 2015 were revised. Diagnosis of AWS was based on the clinician criteria and the need for treatment with benzodiazepines to control symptoms. Primary outcome was 28-days mortality. Prescribed benzodiazepine dose expressed in diazepam-equivalent was compared between groups who developed AWS. A propensity score (match by age, sex, BMI, MELD and ACLF score) was performed to compare clinical outcomes between patients who developed WDS in Spain vs. USA, using stratified logistic regression for matched pairs.
Results: Study population included 432 patients (n = 193 from Spain and n = 239 from USA), of whom 63% were women with mean age 48 ± 10 years, median BMI 28 (24–32) kg/m^2 and mean MELD score at admission of 23.7 ± 7.9. Overall prevalence of AWS and mortality was 32% (n = 140) and 17% (n = 74), respectively. Presence of AWS was lower in patients receiving prophylaxis (Spain) than in patients who did not receive it (USA) (26% vs. 37% $P < 0.007$). In patients receiving prophylaxis, the development of AWS was not associated with worse clinical outcomes, including mortality (10% vs. 8%, $P = 0.52$). In patients not receiving prophylaxis in the USA, the development of AWS was associated with higher mortality (33% vs. 19%, $P = 0.009$) [Figure 1]. After propensity matching, a higher mortality was seen among patients presenting AWS in USA vs. Spain (p = 0.003). Importantly, patient with AWS in Spain had similar mortality that those who did not developed AWS in USA (p = 0.35). There were marked differences in several key parameters in patients with AWD with and without prophylaxis, respectively: the diazepam equivalent dose used (87 ± 119 vs. 136 ± 190 mg), ICU admission (16% vs. 48%, $P = 0.02$) and orotracheal intubation rate (10% vs. 28%, $P = 0.04$).



Conclusion: In AH setting, prophylactic therapy for AWS is associated with lower prevalence of both withdrawal symptoms and short-term mortality. This data supports that prophylactic therapy is a better approach than symptom-triggered therapy in patients hospitalized with AH.

THU036
The use of pharmacotherapy in the treatment of alcohol use disorder

Kathryn Allen[1], Tobias Maharaj[1], John Ryan[1]. [1]*Beaumont Hospital, Hepatology, Dublin, Ireland*
Email: kathrynallen123@hotmail.com

Background and aims: Alcohol use disorder (AUD) is an important cause of preventable morbidity and mortality. The prevalence of AUD and alcohol related liver disease is increasing in Ireland. Several medications have been demonstrated to be effective for the treatment of AUD. We wanted to ascertain the current attitude of gastroenterology physicians in Ireland towards pharmacotherapy as a treatment option for AUD.
Method: An anonymous, questionnaire-based survey was sent to gastroenterology physicians nationwide. This survey collected demographic information and assessed prescribing habits towards medications which have been approved to treat AUD (Naltrexone, Disulfiram, Baclofen, Librium, Nalmefene and Acamprosate). Where pharmacotherapy was not routinely utilised, we examined factors which may have led to their avoidance.
Results: We received 60 responses, 56% (n = 32) consultant gastroenterologists, and 40% (n = 23) GI specialist registrars (SpRs). 80% (n = 48) report being frequently (daily/weekly) involved in the management of AUD. 95% (n = 57) of prescribers believe that there is a role for pharmacotherapy in treating AUD, but only 22% (n = 13) routinely use these in clinical practice. Librium was commonly used by 88% (n = 53), while <10% regularly prescribed Naltrexone, Baclofen, or Acamprosate. Prohibitive factors identified were lack of hospital alcohol services (61%) [48% of respondents reported no alcohol service or support in their hospital], side effect profile for patients (26%), lack of compliance (26%), lack of adjuvant psychosocial support in community (47%), and unfamiliarity with medications (61%).
Conclusion: Despite the burden of alcohol on our acute hospitals, there is a clear and significant lack of support for alcohol related conditions. Emanating from this is the underutilisation of pharmacotherapy as a treatment for AUD, despite its evidence base. This survey highlights an urgent need to develop alcohol support services, in conjunction with physician education about the role of pharmacotherapy in treating AUD.

Background and aims: Currently, it is very challenging to distinguish alcoholic steatohepatitis (ASH) and non-alcoholic steatohepatitis (NASH) on liver biopsy alone as they share many of the same histological characteristics. Artificial intelligence (AI) models utilizing deep learning have demonstrated superhuman degrees of accuracy in interpretation of digitized liver histology. The aim of our study was to develop a deep learning algorithm in the form of a convolutional neural network (CNN) to classify ASH and NASH on liver biopsy.
Method: We obtained liver biopsy slides from 38 patients with ASH and 59 patients with NASH. ASH was determined based on the clinical diagnosis of alcohol-associated hepatitis, and patients with NASH were identified from a cohort of morbidly obese patients undergoing bariatric surgery. The slides were digitized into an electronic database with whole-slide diagnosis labels. Each whole-slide image was rescaled and randomly cropped to generate 256 patches of 256 × 256 pixels. Each cropped patch retained the diagnosis label from the original whole-slide image (0 = NASH, 1 = ASH). The patches were randomly split into training and testing sets in an 8:2 ratio. Patches in the training set were used to train a 50-layer CNN (ResNet50), and the CNN's performance as a binary classifier was tested on the patches in the testing set. Gradient-weighted Class Activation Mapping (Grad-CAM) was used as a method to understand the CNN's decisions.
Results: The CNN had an outstanding performance in distinguishing ASH versus NASH with an AUC of 0.962. Using an optimal threshold of 0.504, the CNN had an accuracy of 90.4%, sensitivity of 79.5%, and specificity of 96.3%. The positive predictive value is 92.1% and

negative predictive is 89.7%. Grad-CAM highlighted distinct regions within each patch that the algorithm used to make its decisions.

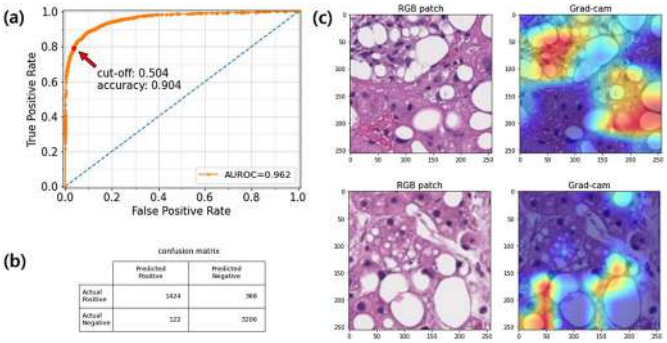

Figure: (a) Receiver operating characteristic (ROC) curve for the CNN's classification of ASH versus NASH. (b) Confusion matrix for the CNN; a diagnosis of ASH is indicated by "Positive" and a diagnosis of NASH is indicated by "Negative." (c) Activation map for classification of ASH patch (top row) and NASH patch (bottom row).

Conclusion: Our deep learning-based AI algorithm had an outstanding performance for patch-level classification of liver biopsy images from patients with ASH and NASH. After further validation on a larger set of liver biopsy images and evaluation of model performance at the level of whole slides, our AI algorithm may prove to be a novel way to distinguish ASH versus NASH histologically.

THU038

Calorie-protein deficit and body mass index are the independent predictors of mortality in severe alcoholic hepatitis

Harshita Tripathi[1], Jaya Benjamin[2], Puja Bhatia[1], Rakhi Maiwall[3], Guresh Kumar[4], Yogendrakumar Joshi[5], Shiv Kumar Sarin[3]. *[1]Institute of Liver and Biliary Sciences, Clinical Nutrition, DELHI, India; [2]Institute of Liver and Biliary Sciences, Clinical Nutrition, New Delhi, India; [3]Institute of Liver and Biliary Sciences, Hepatology, DELHI, India; [4]Institute of Liver and Biliary Sciences, Biostatistics, DELHI, India; [5]Institute of Liver and Biliary Sciences, Clinical Nutrition and Hepatology, DELHI, India*
Email: jayabenjaminilbs@gmail.com

Background and aims: Short term mortality is high in severe alcoholic hepatitis (SAH), which is influenced by multiple factors. We planned to assess the independent predictors of 60 day mortality for optimizing management.
Method: SAH patients with Maddrey's discriminant function (mDF) 32–100 were enrolled; excluding sepsis, AKI and malignancy. Baseline clinical, biochemical parameters, disease severity [MELD, CTP, MDF, FIB-4], BMI, fat free mass index (FFMI), hand grip strength, usual diet [calorie (C) and protein (P) intake] and 60 day mortality were assessed. C and P deficit was the difference of ideal requirement [C (35kcal) and P (1.2 g) per kg ideal body weight] and actual intake. Logistic regression analysis was done.

Table 1: Predictors of Mortality in SAH

Parameter	Death (n = 16)	Alive (n = 44)	P value	Multivariate
Demographic Details				
Age (yrs)	40.6 ± 8.4	39.5 ± 6.2	0.314	
Height (cm)	171 ± 4.7	169 ± 8.9	0.511	
Dry BMI (kg/m^2)	19.7 ± 2.7	22 ± 4.1	**0.051**	**0.048**
Weight reduced (kg)	9.47 ± 7.0	8.9 ± 6.3	0.785	
Duration of weight loss (mo)	4.87 ± 1.6	8.3 ± 1.29	0.257	
Clinical details				
Ascites	32 (53.3%)	12 (20%)	0.676	
Duration of alcohol intake (yrs)	14.47 ± 5.7	13.08 ± 7.3	0.113	
Alcohol Quantity (gm)	571 ± 153	478 ± 194	0.468	
Last intake (days)	24 ± 9.45	36.4 ± 15.7	**0.001**	
Biochemical Parameters				
Total Bil (mg/dl)	21.3 ± 8.9	15.5 ± 7.2	**0.041**	**0.022**
AST (IU/L)	116 ± 54	157 ± 73	**0.040**	
ALT (IU/L)	127 ± 63	162 ± 56	**0.031**	
ALP (IU/L)	91.9 ± 27	157 ± 91	**0.001**	
Total protein (g/dl)	6.28 ± 0.93	6.99 ± 1.09	**0.028**	
Albumin (g/dl)	2.8 ± 0.66	2.8 ± 0.54	0.978	
INR	2.01 ± 0.34	1.96 ± 0.55	0.716	
Urea (mg/dl)	38.5 ± 16	28 ± 06	0.089	
Creatinine (mg/dl)	0.80 ± 0.4	0.73 ± 0.2	0.581	
Sodium (mmol/L)	129.5 ± 4.2	132.3 ± 3.3	**0.039**	
Potassium (mmol/L)	4.07 ± 0.68	4.08 ± 0.68	0.963	
Severity Scores				
MELD	28.3 ± 2.9	28.3 ± 10.8	0.317	
MDF	63.05 ± 18.4	63.05 ± 23.1	0.203	
CTP	10.4 ± 1.06	10.7 ± 1.5	0.115	
FIB-4	8.4 ± 3.6	6.95 ± 1.08	**0.028**	
Body composition parameters				
Fat mass (kg)	18.6 ± 4.8	22.6 ± 5.6	0.118	
Fat free mass (kg)	49.36 ± 13	51.2 ± 13.3	0.720	
FFMI kg/m^2	16.8 ± 4.2	18.02 ± 4.6	0.501	
Hand grip (kg)	22.1 ± 6.17	23.3 ± 6.2	0.986	
Diet				
Energy requirement (kcal)	2289 ± 738	2358 ± 523	0.730	
Protein requirement (g)	85.6 ± 5.7	83.8 ± 10.7	0.511	
Energy intake (kcal)	598.8 ± 231	737.3 ± 278.4	0.643	
Protein intake (g)	26.65 ± 10.6	20.3 ± 9.9	**0.06**	**0.022**
Calorie deficit (kcal)	2035 ± 214	1813 ± 508	**0.05**	**0.045**
Protein deficit (g)	70.7 ± 7.5	60.9 ± 19.2	**0.02**	**0.051**

Data expressed as mean ± SD, n (%). P value ≤0.05 is significant.

Conclusion: High calorie and protein diet with maintained body weight improves survival in SAH.
Results: In 60 patients with SAH [age 40 ± 7.37 yrs; ascites 47 (84%); BMI- 21.3 ± 3.8 kg/m^2; mDF-62.4 ± 21.4, MELD 28 ± 9.3, CTP 10.6 ± 1.4, on steroids 14 (25%)] there was significantly low calorie intake despite >3 weeks of abstinence (Table 1). Those 16 (26.6%) patients who died at 2 mo had significantly lower BMI, higher P and C deficit and total bilirubin compared to survivors; that predicted mortality.

THU039

Alcoholic foamy degeneration: a unique variant of ALD that shows a characteristic pattern of gene expression with upregulation of lipid metabolism and mitochondrial genes and downregulation of fibrosis genes

Jordi Gratacós-Gines[1], Delia Blaya[2], Helena Hernandéz Evole[1], Carla Montironi[3], Emma Avitabile[1], Martina Perez[1], Marta Cervera[1], Marta Carol[1], Ana Belén Rubio[1], Núria Fabrellas[1], Anna Soria[1], Octavi Bassegoda[1], Laura Napoleone[1], Ann Ma[1], Adria Juanola[1], Isabel Graupera[1], Alba Díaz[4], Juan Jose Lozano[5], Pere Ginès[1], Elisa Pose[1]. *[1]Hospital Clínic de Barcelona, Liver Unit, Barcelona, Spain; [2]Institut d'Investigacions Biomèdiques August Pi i Sunyer (IDIBAPS), Barcelona, Spain; [3]Hospital Clínic of Barcelona, Pathology Department and Molecular Biology CORE, Barcelona, Spain; [4]Hospital Clínic de Barcelona, Pathology Unit, Barcelona, Spain; [5]centro de investigación biomedica en red de enfermedades hepáticas y digestivas (CIBERehd), Barcelona, Spain*
Email: EPOSE@clinic.cat

Background and aims: alcoholic foamy degeneration (AFD) is a variant of alcoholic liver disease that is diagnosed based on histology, with a pattern of microvesicular steatosis in the liver biopsy. Recently, in one of the largest series reported to date, we described AFD as an entity with similar clinical presentation to alcoholic hepatitis (AH), but faster improvement of liver function and markedly better long-

term prognosis. Molecular mechanisms underlying AFD are unknown and histological pattern has been scarcely studied. Our aim was to unveil the histological and transcriptional characteristics of AFD in this series.

Method: liver biopsies from 16 patients with AFD and 20 patients with AH diagnosed in the same period, were obtained. Results from RNA sequencing were analyzed with IPA, GO and RA platforms. Moreover, liver biopsies were reviewed by two pathologists to describe steatosis, steatohepatitis, degree of inflammation and fibrosis.

Results: compared to patients with AH, patients with AFD presented with a lower proportion of ascites and had higher levels of transaminases, cholesterol and triglycerides. Bilirubin levels were similar but MELD score was lower in patients with AFD. RNA sequencing analysis revealed that patients with AFD and AH have a differential gene expression pattern. On PCA analysis using gene expression, AFD patients clustered apart from AH patients. Moreover, the analysis of the deregulated gene expression showed that AFD patients have a significant upregulation of pathways associated with lipid metabolism, such as cholesterol and triglycerides biosynthesis, stearate and retinol biosynthesis, mitochondrial function and cell cycle, and a downregulation of pathways related to hepatic fibrosis such as wound healing signaling, integrin signaling and extracellular matrix deposition. Genes involved in senescence, autophagy and inflammation are also downregulated. Half of the cases (n = 8) had predominant microvesicular steatosis, six (37.5%) had a mixed pattern of micro and macrovesicular steatosis and the remaining two cases (12.5%) showed microvesicular steatosis (≥40%) with focally associated steatohepatitis. Fibrosis was uncommon, especially in the cases of predominant microvesicular steatosis.

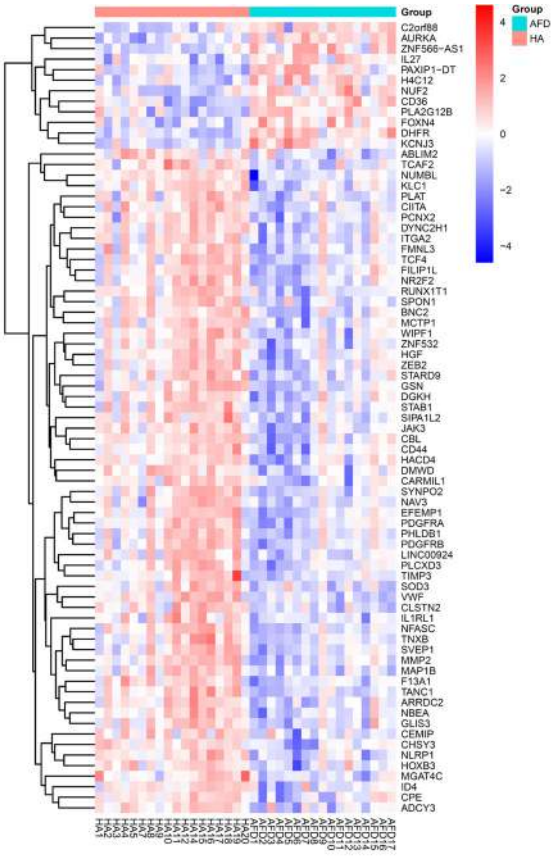

Figure: heatmap of the top upregulated (red) and downregulated (blue) genes in liver biopsies with AFD (green bar) and AH (orange bar).

Conclusion: AFD displays a specific gene signature differentiated from that of AH. Genetic functional pathways associated with lipid metabolism and mitochondrial function are upregulated in patients with AFD. In contrast, there is a downregulation of pathways associated with inflammation, fibrosis and senescence. Histological findings are consistent with genetic profile, with a predominant pattern of steatosis, with scarce fibrosis and steatohepatitis.

THU040

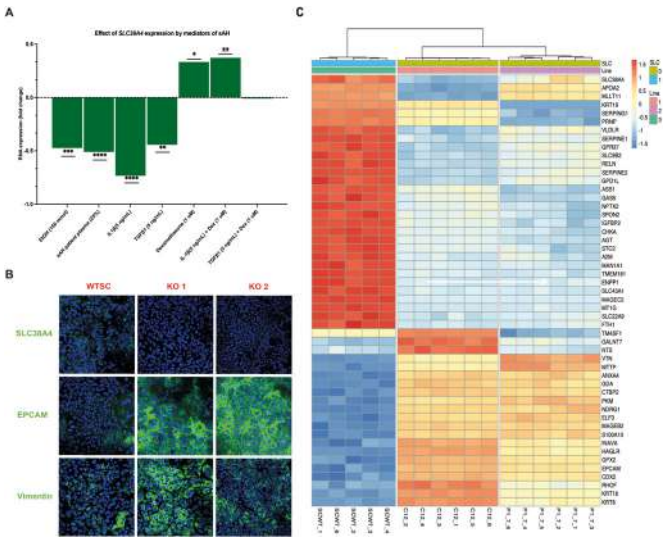
Loss of solute carrier family 38 member 4 (SLC38A4) as a driver for the pathogenesis of severe alcoholic hepatitis

Nchimunya Nelisa Tebeka[1], Stephen Atkinson[1], Luke D. Tyson[1], Josepmaria Argemi[2], Adam Syanda[1], Ramon Bataller[2], Tamir Rashid[1], Mark Thursz[1]. [1]*Imperial College London, Department of Metabolism, Digestion and Reproduction, London, United Kingdom;* [2]*University of Pittsburgh, Medical Center, Pittsburgh, United States*
Email: n.tebeka@imperial.ac.uk

Background and aims: Severe alcohol-related hepatitis (sAH) is a florid presentation of alcohol-related liver disease with very high short-term mortality. A genome-wide association study identified *solute carrier family 38 member 4* (*SLC38A4*) as a potential risk locus for the development of sAH. SLC38A4 is characterised as an amino acid transporter and is predominantly hepatically expressed under the regulation of HNF4a. The aim of this project was to investigate how changes in *SLC38A4* expression may contribute to the pathogenesis of sAH.

Method: *SLC38A4* expression was determined by RNA-seq in whole liver biopsies obtained from patients with alcohol related liver disease, including sAH, from a published study. *In vitro* experiments were conducted to investigate the effects of known disease mediators on *SLC38A4* expression in Huh7.5 cells. *SLC38A4* knock-out lines (aliases P1.7 and C12 *SLC38A4*-KO) were generated by CRISPR/Cas9 editing in Huh7.5 cell lines; a control cell line (SCWT) was generated using a non-targeted scramble guide RNA. The functional impact of *SLC38A4* knock-out was then characterised using gene expression analysis (RT-qPCR and RNA-seq) and protein expression by immunofluorescence (IF). Assays were performed to assess the impact of knock out on cell morphology and proliferation in addition to CYP3A4 activity and ureagenesis.

Results: *SLC38A4* expression was reduced in whole liver tissue from cohorts of patients with sAH compared to their early alcoholic steatohepatitis controls ($p < 0.0001$). *In vitro SLC38A4* expression was downregulated by mediators of alcoholic hepatitis i.e., IL-1b, TGFb1, TNFa and sAH patient plasma but upregulated by dexamethasone (Figure 1A). *SLC38A4*-KO lines demonstrated upregulation in the epithelial-mesenchymal transition markers, EPCAM and Vimentin ($p < 0.0001$ and $p < 0.01$ respectively) (Figure 1B). *SLC38A4*-KO resulted in reduced cell proliferation, ureagenesis, and downregulation of bile acid transporters, *BSEP* ($p < 0.0001$) and *MRP2* ($p < 0.01$). The cell morphology of knock-out cells exhibited stemness like features and the upregulation of the foetal isoform of HNF4a, P2 ($p < 0.001$). *CYP3A4* expression and activity were reduced ($p < 0.001$). RNA-seq confirmed the increase of *EPCAM* and *Vimentin* and the reduction of *CYP3A4* across the *SLC38A4*-KO lines. Additionally, *SLC38A4*-KO resulted in differential expression of other SLC genes and cell growth/differentiation regulating genes (Figure 1C). Pathway analysis indicated changes in amino acid metabolism and cytokine signalling pathways.



Conclusion: *SLC38A4*, a gene identified as a potential risk locus in sAH through genetic studies, demonstrates reduced hepatic expression in patients with disease. This expression is downregulated *In vitro* by recognised disease drivers. *SLC38A4* knock out in cell lines recapitulates several features considered important in disease pathogenesis.

THU041

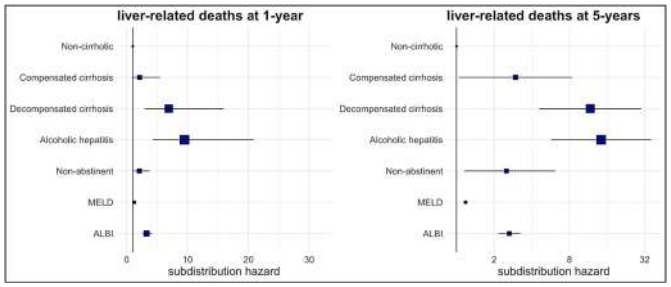
Refining the natural history of alcohol related liver disease: a competing risk analysis

Richard Parker[1], Guruprasad Aithal[2], Michael Allison[3], Juan Pablo Arab[4], Mayur Brahmania[5], Ewan Forrest[6], Hannes Hagström[7], Alisa Likhitsup[8], Steven Masson[9], Anne McCune[10], Neil Rajoriya[11], Ian Rowe[12]. *[1]Leeds Teaching Hospital Trust, Leeds Liver Unit, Leeds, United Kingdom; [2]NIHR Nottingham BRC, Nottingham, United Kingdom; [3]Addenbrooke's Hospital, Hepatology, Cambridge, United Kingdom; [4]Pontificia Universidad Católica de Chile, Departamento de Gastroenterología, Santiago, Chile; [5]Western University, Department of Gastroenterology and Multiorgan Transplant, London, Canada; [6]Queen Elizabeth Hospital, Hepatology, Glasgow, United Kingdom; [7]Karolinska University Hospital, Centre for Digestive Diseases, Stockholm, Sweden; [8]St Luke's Hospital Kansas City, Kansas City, United States; [9]Newcastle Upon Tyne Hospitals NHS Foundation Trust, Liver Unit, Newcastle Upon Tyne, United Kingdom; [10]University Hospitals Bristol NHS Foundation Trust, Department of Liver Medicine, Bristol, United Kingdom; [11]University Hospitals Birmingham NHS Foundation Trust, Liver and Hepatobiliary Unit, Birmingham, United Kingdom; [12]University of Leeds, Leeds Institute for Medical Research, Leeds, United Kingdom*
Email: richardparker@nhs.net

Background and aims: Alcohol-related liver disease (ALD) is common throughout the world and is a frequent cause of ill-health and death. Alcohol consumption affects multiple organs and systems, therefore, increasing the risk of a wide range of conditions. Previous systematic review demonstrated that both liver and non-liver related mortality increased depending on the stages of liver disease. We have analysed a cohort of patients with biopsy-proven liver disease using competing risk analysis to accurately describe the risks of liver and non-liver related outcomes in ALD.

Method: WALDO is an international, retrospective cohort of patients with biopsy-proven liver disease followed up through health records to capture outcome data regarding mortality and morbidity. Competing risk analysis was used to estimate cumulative incidence functions (CIF) of mortality (liver-related or non-liver related deaths), and morbidity. Morbidity was classed as liver-associated clinical events (LACE) and major adverse medical events included cancer, cardiovascular disease or diabetes. Subdistribution hazards were calculated with univariable and multivariable analyses to understand factors affecting outcomes. These analyses were used to describe the cumulative incidence of liver-specific mortality for given MELD scores.

Results: The WALDO cohort includes 710 patients of whom 423 had cirrhosis. Alcoholic hepatitis was present in 184 patients at the time of biopsy, and 216 patients were not cirrhotic and without alcoholic hepatitis. During a median follow-up of 4.6 years (IQR 1.1–9.5 years, totalling over 4 thousand patient-years) there were 381 deaths (54% of the total cohort) and 47 patients (7%) underwent liver transplantation. Deaths were liver related in 144 cases (39% of all deaths). New LACE occurred in 87 patients during follow-up and new medical morbidity occurred in 133 patients (19%). When compared to patients without cirrhosis CIF for liver-related death was significantly higher in patients with cirrhosis (1.87, 1.56–2.18, $p = 0.042$), decompensated cirrhosis (5.88, 5.60–6.165, $p < 0.001$) and alcoholic hepatitis (6.40, 6.12–6.68, $p < 0.001$), whereas the CIF of non-liver related deaths was not significantly different. The strongest baseline predictors of outcomes were stage of disease, MELD or ALBI scores, and abstinence. The cumulative incidence of liver-related deaths at sample baseline MELD scores of 6, 12, and 20 was 8%, 18% and 49% respectively with significant differences between patients who were abstinent or non-abstinent.



Conclusion: Patients with ALD are at risk of multiple causes of ill health. Competing risk analysis takes these into account to give a more accurate analysis of the probability of outcomes. The risk of liver-related mortality increases significantly above that of non-liver related mortality only in decompensated cirrhosis and alcoholic hepatitis.

THU042

Potential biomarkers for differentiating alcoholic hepatitis from decompensated cirrhosis by serum metabolomic analysis

Adelina Horhat[1,2], Fischer Petra[1], Mina Ignat[2], Bogdan Procopet[1,2], Carmen Socaciu[3], Stefanescu Horia[2]. *[1]Iuliu Haţieganu University of Medicine and Pharmacy, Cluj-Napoca, Romania; [2]Regional Institute of Gastroenterology and Hepatology "Prof. Dr. O. Fodor", Cluj-Napoca, Romania; [3]RTD Center for Applied Biotechnology BIODIATECH SC Proplanta, Cluj-Napoca, Romania*
Email: adelinahorhat25@gmail.com

Background and aims: Patients with alcoholic hepatitis (AH) have a high risk of short-term mortality. The diagnosis of AH relies on clinical and biochemical parameters, but it is impossible to differentiate from alcoholic related decompensated cirrhosis (ArDC) without liver biopsy. The main objective of this study was to assess the metabolomic fingerprint of AH; Secondary objective was to identify potential biomarkers to differentiate between the AH and ArDC.

Method: We performed an untargeted metabolomic profiling of blood serum from 36 patients with biopsy proven AH and 36 patients with ArDC, using high performance liquid chromatography and mass spectrometry. More than 300 metabolites were identified; Eighty-

three molecules were selected for further analysis and the most significant biomolecules were selected to discriminate the AH versus ArDC phenotype and infection status.

Results: Seventy-two percent of patients were male and 97% of them had cirrhosis. The main molecules that showed increased levels in AH group comparative to ArDC group were C16 Sphinganine-1-phosphate (S1P), Prostaglandin F1a/b (PGF1a/b), Cerotic acid and arachidic acid while Prostaglandin D2/E2 (PGD2/E2), Prostaglandin E2-ethanolamide (PGE2-EA), dinor cholic acid, 12-ketodeoxycholic acid 2-hydroxy stearic acid, D-Sphingosine decreased (1a).

In the multivariate analysis, PLSDA score plot showed a co-variance of 19.4%, with a good discrimination between AH and ArDC groups (figure 1b)

In the subgroup analysis, (infected AH and ArDC and non-infected AH and ArDC), a good discrimination was showed by S1P, with a p value = 1.49E-15, Mean Decrease Accuracy (MDA) >0.035 and an area value under ROC curve (AUC) of 0.984 (0.943–1) and PGD2/E2, which had a decreased level (p = 2.56E-1, MDA >0.025 and AUC 0.958 (0.898–0.994)) (Figure 1c, d). The semiquantitative analysis of the combination between S1PandPGE2 showed increased (95%) diagnostic accuracy to discriminate AH from ArDC, with 100% NPV and 100% Se.

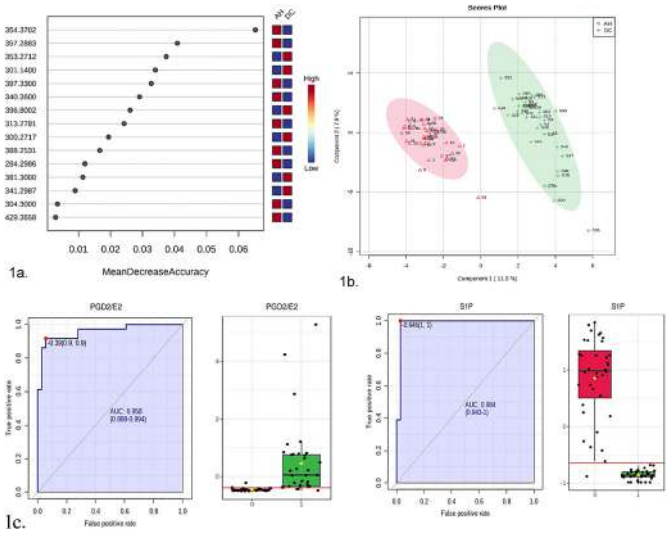


Figure 1: (a) Main molecules that showed good discrimination between AH and ArDC (red – increased, blue -decreased). (b) PLSDA score plot showed a co-variance of 19.4%, with a good discrimination between AH and ArDC groups. (c) AUC curves for S1P 0.984; (0.943-1) and PGD2/E2 0.958 (0.898-0.994).

Conclusion: Sphingolipids are now known to regulate important physiological cellular processes (1). Especially, S1P has an anti-necrotic and anti-inflammatory effects via TNF-a signaling pathway; In an ischemia/reperfusion (I/R) model, plasma S1P levels were noted to be decreased after hepatic I/R injury (2). Prostaglandins have protective effects by inhibiting the generation of reactive oxygen species and regulating the production of inflammatory cytokines. In this study, the prostaglandin levels were decreased in patients with AH showing that beta-oxidation could be a valuable target pathway.

THU043

A phase II, multicenter, open-label, randomized trial of pegfilgrastim for patients with alcohol-associated hepatitis

Timothy Morgan[1], Aliya Asghar[1], John Tayek[2], Danh Nguyen[3], M. Wayne Fleischman[2], John Donovan[4], Joseph Alcorn[5], Daniel Chao[6], Andrew Stolz[4]. *[1]VA Medical Healthcare System, Medicine, Long Beach, United States; [2]Harbor-UCLA Medical Center, Torrance, United States; [3]University of California-Irvine, Irvine, United States; [4]LAC-USC Medical Center, Los Angeles, United States; [5]VA Healthcare System, Albuquerrque, United States; [6]VA Healthcare System, Loma Linda, United States*
Email: timothy.morgan@va.gov

Background and aims: In trials conducted in India, recombinant granulocyte colony stimulating factor (GCSF) improved survival in alcohol-associated hepatitis (AH). The aim of this trial was to determine the safety and efficacy of pegfilgrastim, a long-acting recombinant GCSF, in patients with AH in the United States.

Method: This prospective, open label trial randomized patients with a clinical diagnosis of AH and a Maddrey discriminant function score ≥32 to standard of care (SOC) or SOC+pegfilgrastim (0.6 mg subcutaneously) on Day 1 and Day 8. SOC was 28 days of either pentoxifylline or prednisolone, as determined by the patient's primary physician. The second injection of pegfilgrastim was not administered if the white blood cell count exceeded 30, 000/mm^3 on Day 8. Primary outcome was survival at Day 90. Secondary outcomes included the incidence of acute kidney injury (AKI), hepatorenal syndrome (HRS), hepatic encephalopathy, or infections.

Results: The study was terminated early due to COVID19 pandemic. Eighteen patients were randomized to SOC and 16 to SOC+pegfilgrastim. All patients received prednisolone as SOC. Nine patients failed to receive a second dose of pegfilgrastin due to WBC>30, 000/mm^3 on Day 8. Survival at 90 days was similar in both groups (SOC: 0.83 [95% confidence interval {CI}: 0.57–0.94] vs. pegfilgrastim: 0.73 [95% CI: 0.44–0.89]; p > 0.05). The incidences of AKI, HRS, hepatic encephalopathy, and infections were similar in both treatment arms and there were no serious adverse events attributed to pegfilgrastim.

Conclusion: This phase II trial found no survival benefit at 90 days among subjects with AH who received pegfilgrastim+prednisolone compared with subjects receiving prednisolone alone.

THU044

Trends of alcohol-related liver disease hospitalisation during the COVID-19 pandemic

Oyekoya Ayonrinde[1,2,3], Richard Goodheart[1]. *[1]Fiona Stanley Hospital, Gastroenterology and Hepatology, Murdoch, Australia; [2]The University of Western Australia, Medical School, Crawley, Australia; [3]Curtin University, Faculty of Health Sciences, Bentley, Australia*
Email: oyekoya.ayonrinde@uwa.edu.au

Background and aims: Alcohol-related liver disease (ALD) is a common and potentially serious liver disorder associated with substantial morbidity and mortality. Recent reports have described increased alcohol since the onset of the COVID-19 pandemic. Therefore, the primary aim of this study was to examine trends in ALD hospital admissions prior to and during the Covid-19 pandemic. The secondary aim was to assess patient demographic and clinical characteristics associated with short and medium-term mortality.

Method: We retrospectively analysed data on patients who were admitted with ALD to a quaternary care hospital in Australia. The study population comprised adults hospitalised with International Classification of Diseases, Tenth Revision (ICD-10) principal diagnosis code K70.1 (alcoholic hepatitis), 70.3 (alcoholic cirrhosis), and 70.4 (alcoholic hepatic failure) between January 2018 and December 2021. Data recorded included patient demographics, alcohol history, clinical and laboratory characteristics. The Model for End Stage Liver Disease (MELD) score was calculated.

Results: Amongst 345 hospitalisations with ALD, there was a non-statistically significant rise in cases comparing the two years preceding and during the first two years of the COVID-19 pandemic (Figure 1). There were 104 (30.1%) ARH and 69.9% with decompensated ARC or alcoholic liver failure (ALF). Those with ARH, compared with those with ARC and ALF, had a higher mean [standard deviation] MELD score (22.6 [9.3] vs. 20.3 [7.8], p = 0.02), were younger (47.6 [11.7] vs 54.6 [10.6] years, p <0.001), had longer median [interquartile range] length of hospital stays (7.7 [4.0–13.0] vs. 6.0 [2.0–9.0] days, p = 0.008), and were predominantly male (58.7%).
The in-hospital mortality was 12.8% overall, comprising 17.3% with ARH, 10.8% with ARC/ALF, and 5/47 (10.6%) aged under 40 years. Patients aged <40 years, compared with those ≥ 40 years had a similar 30-day mortality (14.9% vs. 20.5%, p = 0.37) but lower one-year mortality (25.5% vs. 43.0%, p = 0.02). Using multivariable logistic regression analysis, predictors of 30-day mortality were male sex (odds ratio [OR] 2.89, 95% confidence interval [CI] 1.29–6.46, p = 0.02), age (OR 1.06, 95% CI 1.02–1.10, p = 0.004), serum bilirubin (OR 1.006, 95% CI 1.003–1.008, p < 0.001), respiratory failure (OR 3.64, 95% CI 1.62–8.21, p = 0.002, hepatic encephalopathy (OR 6.43, 95% CI 2.91–14.21, p < 0.001), and type 2 hepatorenal syndrome (OR 3.27, 95% CI 1.55–6.87, p = 0.002).

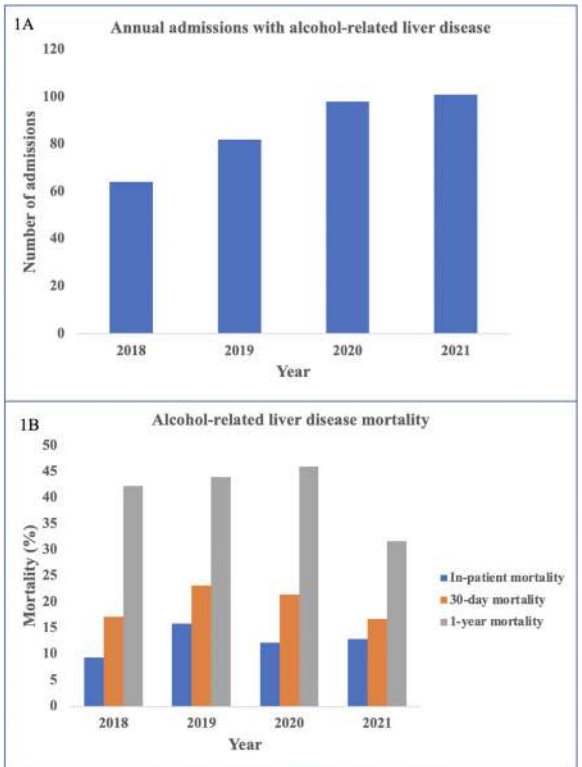

Figure 1: Alcohol-related liver disease (ALD) trends and mortality.
1A: Annual admissions with ALD and 1B: Mortality rates in patients with ALD. * Mortality data for 2021 is incomplete.

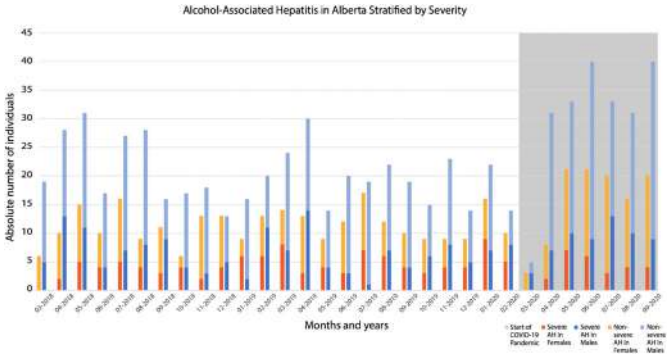
Conclusion: Admissions with ALD have risen during the COVID-19 period. Young adults with severe ALD requiring hospitalisation, have a high mortality that is identical to mortality after a fractured neck of femur in older people. Multi-organ involvement and male sex predict mortality.

THU045

Increased hospital admissions for alcohol-associated hepatitis during the COVID-19 pandemic in Alberta, Canada: a retrospective cohort study

Alexandra Frolkis[1], Meredith Borman[1], Matthew Sadler[1], Stephen Congly[1], Henry Nguyen[1], Samuel Lee[1], Mark G Swain[1], Kelly Burak[1], Carla Coffin[1], Alexander Aspinall[1], Laura Stanton[1], Abdel Aziz Shaheen[1]. [1]*University of Calgary, Calgary Liver Unit*
Email: adfrolki@ucalgary.ca

Background and aims: Alcohol-associated hepatitis (AH) is the most severe and fulminant form of alcohol-related liver disease with females at greater risk of liver injury from alcohol use. Alcohol consumption increased during the COVID pandemic. The aim of our study was to assess the changing epidemiology of hospitalizations for AH by sex before and during the COVID-19 pandemic.
Method: We identified all hospitalizations for adults >18-years-old in Alberta, Canada using a validated algorithm of international classification of disease-10 codes and lab values for AH between March 2018 and September 2020. Severe AH was defined as Model for End-Stage Liver Disease (MELD) >20. Onset of the pandemic was defined as March 2020. Logistic regression was used to identify factors associated with AH severity, and separately mortality, adjusted for age, sex, and pandemic onset. Binomial regression was used to assess changes in frequency of admission for AH with the denominator as all cirrhosis-related admissions over the same time-period.
Results: There were 991 hospitalizations for AH prior to the pandemic (n = 381, 38.5% female) and 417 during the pandemic (n = 144, 34.5% female). Hospitalizations for AH significantly increased during the pandemic (p = 0.04) (Figure 1). Overall, a higher percentage of females (34.5%) had severe AH compared to males (31.0%) however this difference was not statistically significant (p = 0.25) (Figure 1). Though the total number of hospitalizations for AH increased during the pandemic, the odds of severe AH was higher pre-pandemic (odds ratio [OR] 0.73; 95% confidence interval [CI] 0.55–0.98) after adjusting for age and sex. For every year increase in age, the adjusted odds of severe AH increased by 1.02 (95% CI 1.01–1.03). Prior to the pandemic, more females (38.6%) than males (32.2%) had severe AH; during the pandemic, more males (28.4%) than females (24.0%) had severe AH though these differences were not statistically significant (p = 0.1). Median age at admission was significantly lower for both male and female during the pandemic (age 44 and 41, respectively) as compared to prior (age 47 and 45, respectively) p < 0.05. There was no significant difference in mortality between sexes before (10.4% in female, 11.5% in male, p = 0.22) and after the pandemic (9.2% in female, 9.9% in male, p = 0.67).



Conclusion: Hospitalizations for AH rose during the pandemic and occurred at younger ages in both sexes with less severe presentations.

There was no significant difference in mortality by sex before and during the first wave of the pandemic. Advanced age was associated with more severe AH. Public health efforts should continue to educate about the harms of alcohol excess and offer community support.

THU046

The lysosomal enzyme cathepsin D as a new marker for alcoholic liver disease

Mengying Li[1], Tom Houben[1], Mads Israelsen[2], Maria Kjærgaard[2], Marit Westerterp[3], Aleksander Krag[2], Maja Thiele[2], Ronit Shiri-Sverdlov[1]. [1]*School of Nutrition and Translational Research in Metabolism, Maastricht University, Department of Genetics and Cell Biology, Netherlands;* [2]*Center for Liver Research, Odense University Hospital and University of Southern Denmark, Odense, Denmark;* [3]*University Medical Center Groningen, University of Groningen, Department of Pediatrics, Groningen, Netherlands*
Email: r.sverdlov@maastrichtuniversity.nl

Background and aims: Alcohol is the seventh leading cause of premature death worldwide, many of whom die from alcohol-related liver disease (ALD). However, the underlying pathological mechanisms that cause the early stages of ALD are currently under-investigated. Lysosomal cathepsin D (CTSD) was previously shown to be useful in detecting NASH, and circulating CTSD is elevated in advanced liver disease. We therefore investigated plasma CTSD in relation to different histological stages of early ALD.
Method: We conducted a cross-sectional study of 305 asymptomatic ALD patients with a liver biopsy scored according to the NAS CRN system, and compared their plasma CTSD levels with 40 healthy controls, matched for age, gender and BMI. We excluded patients with decompensation at baseline. Next, we determined the correlations between plasma CTSD levels and histology scored for fibrosis, ballooning, lobular inflammation and steatosis. Areas under the receiver operating characteristic curve (AUC) were generated to investigate the accuracy of plasma CTSD levels alone or in combination with known non-invasive markers of fibrosis to predict ALD.
Results: Plasma CTSD levels were significantly higher in ALD patients compared to matched healthy controls (37.7 vs 22.9 ng/ml; AUC 0.84). The highest CTSD levels was measured in ALD patients with no ballooning and lobular inflammation, and a slightly lower CTSD levels were observed in patients with more severe inflammatory activity. Further, plasma CTSD levels exhibited a weak negative correlation with the ELF test and transient elastography, and did not correlate with fibrosis stage. Moreover, transient elastography, ELF, GGT, AST/ALT, and AST independently correlated with plasma CTSD levels. Furthermore, combining plasma CTSD levels with transient elastography and AST/ALT resulted in a high diagnostic accuracy (ROC-AUC: 0.908) for predicting ALD.
Conclusion: Lysosomal leakage of CTSD into the circulation may be a sensitive marker of early stages of ALD.

Ductular bilirubinostasis is a diagnostic biomarker for acute-on-chronic liver failure: results from a well-defined cohort of patients with alcoholic steatohepatitis

Annelotte Broekhoven[1], Tessa Ostyn[2], Lukas Van Melkebeke[3], H.W. Verspaget[1], Schalk van der Merwe[3], Jef Verbeek[1], Minneke Coenraad[1], Tania Roskams[2], Frederik Nevens[3]. [1]*Leiden University Medical Center, Gastroenterology and Hepatology, Leiden, Netherlands;* [2]*Translational Cell and Tissue Research, KU Leuven, Imaging and Pathology, Leuven, Belgium;* [3]*University Hospitals KU Leuven, Gastroenterology and Hepatology, Leuven, Belgium*
Email: a.g.c.broekhoven@lumc.nl

Background and aims: Alcoholic steatohepatitis (ASH) is one of the main precipitating events for the development of acute-on-chronic liver failure (ACLF). Ductular bilirubinostasis (DB) is identified as a marker of ACLF in alcoholic cirrhosis, but overall, the histological features of ACLF are not well characterized. We assessed the diagnostic and prognostic value of DB and other histological features in addition to clinical features for the presence and development of ACLF in a well-defined cohort of ASH patients.
Method: Prospective study in consecutive patients admitted with a diagnosis of ASH to a tertiary referral center between 03–2008 and 04-2021. Diagnosis of ASH was based on clinical presentation and confirmed by transjugular liver biopsy. All biopsies were assessed by a dedicated liver pathologist who was blinded for clinical data and outcome. Clinical and histological data were collected from time of biopsy until 1 year follow-up. Diagnosis of ACLF was based on EASL-CLIF criteria. Differences between patients with and without ACLF at baseline were assessed using chi-square test. Predictors for development of ACLF within 28 days were assessed using Cox regression.
Results: 184 patients with biopsy-confirmed ASH were enrolled, with a median follow-up time of 365 days (IQR 83.5–365). At baseline, ACLF was present in 73 patients (39.7%). Another 30 (16.3%) patients developed ACLF within 28 days (median 7.5 days, IQR 2–20). At baseline, DB was significantly more present in patients with ACLF compared to patients without ACLF (50.7% vs. 30.6%, $p = 0.007$). Presence of DB was not correlated with level of c-reactive protein, level of white blood cell count, presence of infection or positive blood culture (all $p > 0.05$). None of the other histological features, including the histological severity of ASH, was associated with presence of ACLF. The CLIF-C AD score predicted the development of ACLF at 28-days (HR_{cs} 1.09, $p < 0.001$). However, no association between histological features and development of ACLF could be found.
Conclusion: In this well-defined cohort of patients with biopsy-proven ASH, we show that DB is a histological feature of the presence of ACLF. Presence of DB was independent of presence of clinical features of sepsis within this group. The CLIF-C AD score had a high performance in predicting the development of ACLF, while the additional role of histology seems limited.

NAFLD: Clinical aspects except therapy

THU048

The most recent and in-depth meta-analytic assessment of the global epidemiology of non-alcoholic fatty liver disease (NAFLD)

Zobair Younossi[1,2,3], Pegah Golabi[1,2,3], James Paik[1,2,3], Austin Henry[2], Catherine Van Dongen[2], Linda Henry[3,4]. [1]*Inova Fairfax Medical Campus, Center for Liver Disease, Department of Medicine, Falls Church, United States;* [2]*Inova Health System, Betty and Guy Beatty Center for Integrated Research, Falls Church, United States;* [3]*Inova Health System, Inova Medicine, Falls Church, United States;* [4]*Center for Outcomes Research in Liver Disease, Washington, DC, United States*
Email: zobair.younossi@inova.org

Background and aims: NAFLD is a leading cause of liver-related morbidity and mortality. We assessed the global and regional prevalence and incidence of NAFLD using an in-depth meta-analytic approach.
Method: We systematically searched PubMed and Ovid MEDLINE® for population-based studies of NAFLD published 2015–2021 (data collected: 1988–2020). Two reviewers extracted data according to age, sex, race, diagnostic methods, sample size, data collection year, comorbidities, and other study characteristics. Adjustments were applied using prevalence of viral hepatitis and ALD from the Global Burden of Disease study 2019 to approximate prevalence and incidence of NAFLD in general population. The meta-analysis was conducted using a random-effects model. Assessment of bias risk used the Joanna Briggs Institute Critical Appraisal Instrument for studies reporting prevalence data.

Results: Of 1, 857 studies included, 132 studies (N = 9, 945, 423) met the eligibility criteria [106 NAFLD prevalence and 26 NAFLD incidence, high-income North America (H-NA, 19.8%), high-income Asia Pacific (27.4%), East Asia (23.6%), and Western Europe (WE, 11.3%)]. The pooled global prevalence of NAFLD based on a random-effects model was 29.1% (95% confidence interval: 26.8–31.5%). The highest prevalence was reported in Latin America (n = 3, 44.4% [30.7–59.0%]), followed by Middle East and North Africa (MENA) (n = 9, 39.9% [32.6–47.6%]), H-NA (n = 21, 32.9% [27.4–38.9%]) and WE (n = 12, 24.6% [19.1–31.0%]). The prevalence of NAFLD increased over time: 1991–2006 (n = 10, 24.4% [19.6–30.0%]), 2007–2010 (n = 28, 25.7% [22.1–29.7%], 2011–2015 (n = 38, 27.9% [24.1–32.0%]) and 2016–2020 (n = 30, 36.0% [31.6–40.7%]. The global prevalence rate of NAFLD varied between 11.23%–48.61% depending on the diagnostic modality (Table). The incidence of NAFLD ranged from 19.0–99.0 per 1, 000 person-years. Meta-regression showed that diagnostic method/criteria ($p < .001$), data collection year ($p = 0.004$) and geographic location ($p = 0.015$) jointly accounted for 72.1% of the heterogeneity between studies.

Diagnostic Modality	N. of study	Prevalence % (95% CI)	I^2
Ultrasound: mild to severe steatosis	54	32.61 (30.30 to 35.01)	99.74
Ultrasound: moderate to severe steatosis	14	15.36 (13.33 to 17.63)	99.07
Controlled Attenuation Parameter	9	40.78 (32.22 to 49.93)	99.47
CAP of ≥248 dB/m	3	46.76 (37.12 to 56.65)	98.50
CAP of ≥260 dB/m	3	48.61 (43.16 to 54.08)	95.29
CAP of ≥274 dB/m	3	27.71 (16.41 to 42.80)	99.20
Computerized Tomography	3	11.23 (8.37 to 14.89)	93.43
Non-invasive Biomarkers (FLI, US-FLI, HIS)	22	31.11 (26.37 to 36.28)	99.95
Other (ICD-9 or 10)	4	25.23 (23.37 to 27.18)	81.36

Conclusion: The global prevalence of NAFLD is high and growing. Given its impact on the heterogeneity of the reported studies, it is critical to use standardized diagnostic criteria to provide accurate and consistent epidemiologic data across the world.

THU049

Comorbidities and malignancy among NAFLD patients compared to general population

Naim Abu-Freha[1], Bracha Cohen[2], Michal Gordon[3], Alexander Fich[2], Daneila Munteanu[4], David Yardeni[4], Ohad Etzion[5]. [1]*Soroka University Medical Center, Department of Gastroenterology and liver diseases, Beer Sheva, Israel;* [2]*Soroka University Medical Center, Beer-Sheva, Israel;* [3]*Soroka University Medical Center, Beer-Sheva, Israel;* [4]*Soroka University Medical Center, Beer Sheva, Israel;* [5]*Soroka University Medical Center, Beer Sheva, Israel*
Email: abufreha@yahoo.de

Background and aims: Non-alcoholic fatty liver disease (NAFLD) is a common liver disease; we aimed to investigate the frequency of comorbidities and malignancy among NAFLD patients compared to general population.
Method: Retrospective study included all patients older than 18 years with NAFLD diagnosis. A control group was matched in gender and age. The data were extracted using the MDClone platform of the largest health maintenance organization "Clalit" in Israel. Demographics, comorbidities, malignancy and mortality were collected and compared.
Results: 211, 955 NAFLD patients (mean age 42.2 ± 15 years, 47.2% males) were analyzed in comparison to 452, 012 matched general population controls (mean age 42.4 ± 14.8 years, 48.5% males). Significant higher rate of diabetes mellitus (23.2% vs 13.3%), obesity (58.8% vs 27.8%), Hypertension (57.2% vs 39.9%), chronic ischemic heart disease (24.7% vs 17.3%), CVA (3.2% vs 2.8%) and chronic obstructive lung disease (10.1% vs 8.3%) was found among NAFLD patients. Patients with NAFLD have significant higher rate of the following malignancy: prostate (1.6% vs 1.2%) breast cancer (2.6% vs 1.9%), colorectal cancer (1.8% vs 1.4%), uterus (0.4 vs 0.2%) kidney (0.8% vs 0.5%), melanoma (1.6% vs 1.2%), basal cell carcinoma (11.6% vs 8.6%) thyroid (0.7% vs 0.5%) cancer, non-Hodgkin lymphoma (0.7% vs 0.6%) and lower rate of lung cancer (0.9% vs 1.2%), stomach (0.3% vs 0.4%). The all-cause mortality among NAFLD patients was significantly lower in comparison to general population (10.8% vs 14.7%, $p < 0.001$)
Conclusion: Higher rate of comorbidities and malignancy among NAFLD patients was observed, but lower rate of all-cause mortality was found.
Keywords: Fatty liver, comorbidities, malignancy, Israel

THU050

The prevalence of non-alcoholic fatty liver disease in the United Kingdom: a systematic review and meta-analysis

Yusef Alenezi[1], Timothy Card[1,2], Joanne Morling[1,2], Rebecca Harris[2]. [1]*University of Nottingham, Lifespan and Population Health, Nottingham, United Kingdom;* [2]*University of Nottingham, NIHR Nottingham Biomedical Research Centre (BRC), United Kingdom*
Email: msxya10@nottingham.ac.uk

Background and aims: Non-alcoholic fatty liver disease (NAFLD) is a growing cause of cirrhosis and indication for a liver transplant. Since this growth is putting pressure on hepatology services and healthcare systems, up-to-date measures of the size of the problem are needed to plan future services. We have therefore conducted a systematic review of studies in the UK to estimate the prevalence of NAFLD.
Method: We identified studies that investigate NAFLD prevalence among the UK population through a systematic search of electronic databases (PubMed, EMBASE via OVID, CINAHL, Web of Science, and Google). A random-effects meta-analysis was performed on subsets of studies limited to populations with specific conditions and those not so restricted.
Results: Our study included a total of 25, 439 participants from 9 studies. Our results indicate a pooled prevalence of 23.7% in non-disease restricted populations (95% CI 20.6%-26.8%). Of the disease restricted populations, a single study of HIV patients reported a prevalence of 71.2% (CI: 59.7%-82.7%). Two studies of liver-related hospital referral yielded a prevalence of 37.90% (CI: 15.3%-60.5%), a single study of BMI ≥25 (29.6%) (CI: 27.9%-31.3%), and type-1 diabetic patients (1.8%) (CI: 0.0%-3.6%). Our results also included three studies of type-2 diabetic patients with an overall prevalence of 38.6% (CI: 25.5%-51.7%).
Conclusion: Our major finding is that the prevalence of NAFLD within the UK general population is similar to the average global estimate. There is good evidence that adults with T2DM have a higher prevalence of NAFLD. We were unable to determine time trends in prevalence and so updates to this data will be essential to allow ongoing appropriate service planning.

THU051

Health-related quality of life is impaired in people living with HIV and hepatic steatosis

Maurice Michel[1,2], Christian Labenz[1,2], Malena Anders[1,2], Alisha Wahl[1,2], Lisann Girolstein[1,2], Leonard Kaps[1,2], Wolfgang Maximilian Kremer[1,2], Yvonne Huber[1,2], Peter Galle[1,2], Martin Sprinzl[1,2], Jörn Schattenberg[1,2]. [1]*Metabolic Liver Disease Research Program, I. Department of Medicine, University Medical Centre Mainz, Mainz, Germany;* [2] *I. Department of Medicine, University Medical Centre Mainz, Mainz, Germany*
Email: joern.schattenberg@unimedizin-mainz.de

Background and aims: People living with HIV (PLWH) show a high prevalence of hepatic steatosis and non-alcoholic fatty liver disease (NAFLD). NAFLD has been linked to impaired health-related quality of

life (HRQL) and therefore could be an aggravating factor in PLWH. The aim of this study was to determine differences in HRQL between PLWH presenting with and without hepatic steatosis and to identify predictors associated with impaired HRQL.
Method: A total of 245 PLWH were prospectively enrolled at an outpatient clinic. Hepatic steatosis was assessed using vibration controlled transient elastography (VCTE) and defined as a controlled attenuation parameter (CAP) of >275 dB/m. The cohort was then divided into two groups: no steatosis and steatosis. The generic EQ-5D-5L questionnaire was used to determine differences in the HRQL. It consists of an overall value (UI-value) and five dimensions, each addressing different aspects of an individual HRQL. Univariable and multivariable linear regression models were applied to identify predictors with impaired HRQL in both groups.
Results: In this cohort of PLWH, the prevalence of hepatic steatosis was 35% (n = 85) of whom 76.5% (n = 65) had NAFLD and 16.5% (n = 14) alcoholic liver disease. The median age was 52 years (IQR 42; 58) and the majority of PLWH were male (n = 174, 71%). Metabolic risk factors were more prevalent in the steatosis group. The mean UI-value in the total cohort was 0.90 (± 0.15). The HRQL (UI-value) was significantly lower in PLWH and steatosis in comparison to no steatosis (p = 0.013). The most strongly affected dimensions were mobility (p = 0.016) and pain/discomfort (p = 0.012) in the steatosis group, and the dimension anxiety/depression was equally impaired in both groups (p = 0.629) (Figure 1). Unemployment (beta = – 0.270, p = 0.025) and waist circumference (beta = – 0.289, p = 0.017) remained independent predictors of a poor HRQL in the steatosis subgroup. In turn, age (beta = – 0.168, p = 0.045), female sex (beta = – 0.173, p = 0.030), BMI (beta = – 0.214, p = 0.010) and arterial hypertension (beta = – 0.194, p = 0.025) were independent predictors of a low HRQL in the subgroup without steatosis.

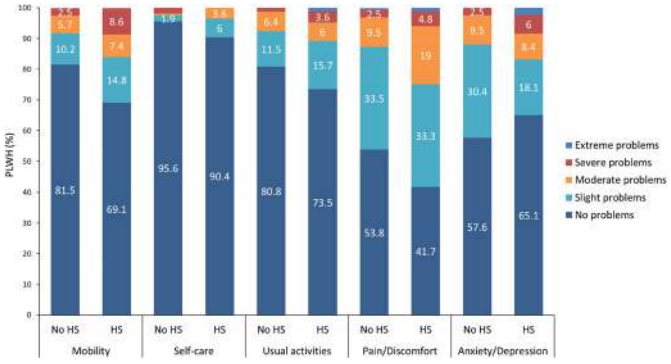

Figure 1: Distribution (%) of the EQ-5D-5L dimensions in PLWH and without hepatic steatosis (no HS) or with hepatic steatosis (HS).

Conclusion: Hepatic steatosis and metabolic comorbidities negatively affect HRQL. Addressing these factors may improve patient reported and liver related outcomes in PLWH.
Funding: This analysis was in parts supported by a research grant from Gilead Sciences.

THU052
Moderate alcohol consumption is associated with significant fibrosis progression in non-alcoholic fatty liver disease-a cohort study with over 17 years of follow-up

Julia Blomdahl[1], Patrik Nasr[1], Mattias Ekstedt[1], Stergios Kechagias[1].
[1]*Linköping University, Department of Gastroenterology and Hepatology, Department of Health, Medicine, and Caring Sciences, Linköping, Sweden*
Email: julia.blomdahl@liu.se

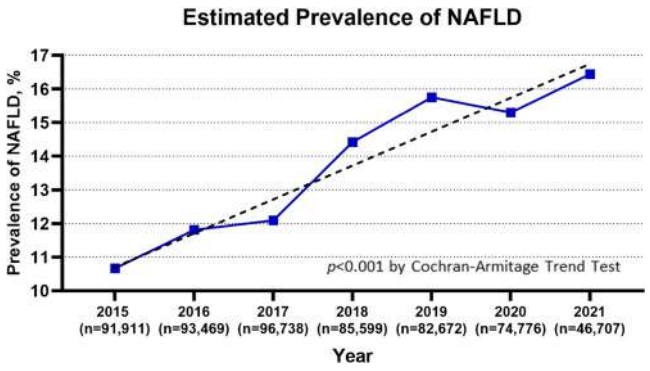
Background and aims: Non-alcoholic fatty liver disease (NAFLD) affects approximately 25% of the adult population worldwide. The effect of moderate alcohol consumption on NAFLD histology is disputed. Assessment of alcohol consumption is commonly performed with interview or questionnaires. A highly sensitive and specific alcohol biomarker is phosphatidylethanol in blood (PEth), which only forms in the presence of ethanol. PEth has hitherto not been evaluated in longitudinal NAFLD studies. This study aimed to examine the impact of moderate alcohol consumption on histologic progression and to evaluate the utility of PEth in NAFLD.
Method: A cohort of NAFLD patients with serial biopsies were reviewed for inclusion in the study. Baseline alcohol consumption was <140 g/week in all patients. Anthropometric and biochemical measurements were performed at baseline and follow-up. Alcohol consumption was measured at follow-up, using three different methods (clinical interview, Alcohol Use Disorder Identification Test-Concise [AUDIT-C], and analysis of PEth). Patients were reviewed for progression of steatosis, ballooning, lobular inflammation, and significant fibrosis progression, defined as progression of fibrosis stage ≥2 stages or development of end-stage liver disease (ESLD).
Results: Eighty-two patients were included. Mean follow-up time was 17.2 years (SD ± 6.0). Twenty-two patients were considered to have fibrosis progression or developed ESLD. Patients with significant fibrosis progression reported higher alcohol consumption and had significantly higher PEth. Progression of other histological parameters (*i.e.*, steatosis, ballooning and lobular inflammation) was unaffected during follow-up and showed no significant associations with alcohol consumption. Consumption >66–96 grams per week (*i.e.*, moderate alcohol consumption) was associated with increased risk for significant fibrosis progression compared with no or low consumption. PEth ≥50 ng/ml and binge drinking showed the highest risk for significant fibrosis progression (aOR 5.2 [95% CI 1.4–19.6], p <0.05, and aOR 5.1 [95% CI 1.4–18.1], p <0.05, respectively).
Conclusion: NAFLD patients consuming moderate amounts of alcohol are at increased risk for significant fibrosis progression and development of ESLD. PEth can be used as a reliable biochemical alcohol marker in NAFLD. Patients reporting moderate consumption or exhibiting PEth ≥50 ng/ml should be advised to reduce alcohol consumption.

THU053
Prevalence trends of non-alcoholic fatty liver disease among young men in Korea: korean military population-based cross-sectional study

Jaejun Lee[1,2], Hyun Yang[1], Si Hyun Bae[2]. [1]*Eunpyeong St. Mary hospital, Department of Internal Medicine, Seoul, Korea, Rep. of South;* [2]*College of Medicine, Eunpyeong St. Mary's Hospital, The Catholic University of Korea, Department of Internal Medicine, Seoul, Korea, Rep. of South*
Email: baesh@catholic.ac.kr

Background and aims: Non-alcoholic fatty liver disease (NAFLD) has become a major concern in Korea since its emergence as a dominant cause of chronic liver disease. However, no study has explored its prevalence in adults under 30 years of age. Therefore, we performed a cross-sectional study to investigate the prevalence of NAFLD in Korean men in their early twenties.
Method: We collected data on 596, 359 Korean soldiers who participated in a health examination between January 2015 and July 2021. A total of 571, 872 individuals were analyzed after excluding those with missing data and hepatitis B antigen positivity. Hepatic steatosis was determined using the hepatic steatosis index (HSI). Participants with an HSI >36 were considered to have NAFLD. The BARD score was used to determine the presence of advanced fibrosis.
Results: All participants were men, and the mean age was 20.9 ± 1.3 years. Of the 571, 872 participants screened, 77, 020 (13.47%) were classified as having NAFLD. The prevalence of NAFLD consistently increased from 2015 to 2021 (10.66% vs. 16.44%, P < 0.001). Increases from 2015 to 2021 were also noted in the prevalence of hypercholesterolemia (1.78% vs. 2.56%, P < 0.001), dysglycemia (10.17% vs. 11.68%, P < 0.001), and hypertension (2.87% vs. 3.51%, P < 0.001). The mean body mass index (BMI) also increased from 23.3 ± 3.0 kg/m^2 to

23.9 ± 3.1 kg/m^2 between 2015 and 2021 (p <0.001). Finally, 24, 092 out of 77, 020 (31.2%) participants with NAFLD had a BARD score of 2 or greater, which was indicative of advanced fibrosis.



Conclusion: The prevalence of NAFLD and of other metabolic dysfunctions (hypercholesterolemia, dysglycemia, and hypertension) in Korean men in their early twenties increased from 2015 to 2021. The Korean society should be alert for an increase in the disease prevalence and continue making efforts to reduce the associated complications.

THU054

Hepatocellular and extrahepatic cancers in non-alcoholic fatty liver disease: a systematic review and meta-analysis

James Thomas[1,2], Bradley Kendall[1,2], Christine Dalais[2], Graeme Macdonald[1,2], Aaron Thrift[3]. [1]*Princess Alexandra Hospital, Woolloongabba, Australia;* [2]*The University of Queensland, Saint Lucia, Australia;* [3]*Baylor College of Medicine, Houston, United States*
Email: aaron.thrift@bcm.edu

Background and aims: Non-alcoholic fatty liver disease (NAFLD) affects approximately one-quarter of the global adult population. Its prevalence is expected to continue to increase with rising rates of obesity and its associated metabolic disorders. Hepatocellular (HCC) and extrahepatic cancers have been associated with NAFLD however the extent and nature of this relationship remain to be clarified. We aimed to estimate the absolute incidence rates of these cancers in adults with NAFLD with respect to key clinical factors.
Method: This systematic review and meta-analysis of published studies reporting the incidence rates of any cancer in adults with NAFLD was registered with PROSPERO (CRD42020164725). The literature search of 4 databases (PubMed, Embase, Cochrane Library and Web of Science) was from inception to 31 August 2020. Teams of independent reviewers assessed each record for inclusion with subsequent extraction of reported data. The main outcomes were pooled incidences of cancers in NAFLD using a random-effects model with subgroup analyses to examine the effects of NAFLD disease stage.
Results: The systematic review returned 10, 042 unique records from which 64 studies including 625, 984 and 41, 027 patients were eligible for analysis of HCC and extrahepatic cancer incidence respectively. The pooled HCC incidence rate was 1.25 per 1000 person-years (95%CI 1.01–1.49; I^2 = 94.8%). In NAFLD patients with advanced liver fibrosis or cirrhosis, the HCC incidence rate was 14.46 per 1000 person-years (95%CI 10.89–18.04; I^2 = 91.3%). The pooled extrahepatic cancer incidence rate was 10.58 per 1000 person-years (95%CI 8.14–13.02; I^2 = 97.1%). The most frequently occurring extra-hepatic cancer sites were uterine, breast, prostate, colorectal and lung. Extrahepatic cancer incidence rates were not higher in NAFLD patients with advanced liver fibrosis or cirrhosis.
Conclusion: The rate of HCC development in NAFLD patients who have progressed to advanced liver fibrosis or cirrhosis supports current HCC surveillance recommendations targeted for this group. The pooled incidence rate of extrahepatic cancers in NAFLD is over eight-fold higher than HCC. Extrahepatic cancer rates are not related to liver fibrosis stage thereby implicating the metabolic dysfunction associated with NAFLD as a risk factor for these malignancies. Given the high and increasing prevalence of NAFLD, these findings support a public health focus on its prevention and the early detection of cancer in adults with NAFLD.

THU055

Association of non-alcoholic fatty liver disease and fibrosis with incident dementia and cognitive function: the Rotterdam Study

Tian Xiao[1], Laurens van Kleef[2], Kamran Ikram[1], Robert De Knegt[2], Arfan Ikram[1]. [1]*Erasmus MC, University Medical Center, Epidemiology, Rotterdam, Netherlands;* [2]*Erasmus MC, University Medical Center, Gastroenterology and Hepatology, Rotterdam, Netherlands*
Email: l.vankleef@erasmusmc.nl

Background and aims: Non-alcoholic fatty liver disease (NAFLD) might affect brain health, via the so-called liver-brain axis. Whether this results in increased risk for dementia remains unclear. Therefore, we investigated the association of NAFLD and fibrosis with incident dementia and cognition among the elderly.
Method: We performed longitudinal and cross-sectional analyses within The Rotterdam Study, an ongoing prospective cohort. Participants visiting between 1997 and 2002 with available fatty liver index (FLI) (set 1; n = 3, 975; FU = 15.5 years) or participants visiting between 2009 and 2014 with abdominal ultrasound (set 2; n = 4, 577; FU = 5.7 years) and liver stiffness (set 3, n = 3, 300; FU = 5.6 years) were included. Exclusion criteria were secondary causes for steatosis, prevalent dementia and missing alcohol data. NAFLD was defined as FLI≥60 or steatosis on ultrasound and fibrosis as liver stiffness ≥8.0kPa. Dementia was defined according to the DSM-III-R. Cox-regression was used to quantify associations for NAFLD, fibrosis, or liver stiffness with incident-dementia and logistic regression for NAFLD and cognitive function.
Results: NAFLD and fibrosis were consistently not associated with increased risk for dementia (NAFLD based on ultrasound, HR:0.84, 95%CI:0.61–1.16; NAFLD based on FLI, HR:0.92, 95%CI:0.69–1.22; fibrosis, HR:1.07, 95%CI:0.58–1.99) in fully adjusted models. Interestingly, NAFLD was associated with a significantly decreased risk for incident dementia until five years after FLI-assessment (HR:0.48; 95%CI:0.24–0.94). Moreover, NAFLD was not associated with worse cognitive function (G-factor, mean difference:0.032; 95% CI:-0.029–0.092).

Table 1: Risk of incident dementia for NAFLD and liver stiffness

			Fully adjusted models	
	cases	FU (year)	HR	95% CI
NAFLD (FLI ≥60)	753/3975	15.5	0.92	0.69–1.22
NAFLD (Ultrasound)	262/4557	5.7	0.84	0.61–1.16
Fibrosis	127/3300	5.6	1.07	0.58–1.99
Liver stiffness (kPa)	127/3300	5.6	1.01	0.92–1.10

Results are given as HR and 95% CI for incident dementia as outcome. NAFLD was either based on FLI ≥60 or on hepatic steatosis assessed with abdominal ultrasound and was compared to participants with FLI <30 or participants without hepatic steatosis.

Conclusion: In conclusion, individuals with NAFLD were not at increased risk of dementia among this general elderly population, nor could an association with fibrosis and dementia be demonstrated. Moreover, NAFLD was associated with a reduced risk of dementia for the first five years after the assessment, suggesting that NAFLD regression is likely before dementia onset, which could be driven by weight loss before dementia onset. As yet, NAFLD may have no clinical implications for dementia awareness. Further studies should focus on NAFLD exposure duration and risk of dementia with longer follow-up durations.

THU056

High meat consumption is prospectively associated with non-alcoholic fatty liver disease and liver fibrosis markers

Dana Ivancovsky Wajcman[1], Naomi Fliss-Isakov[2], Laura Sol Grinshpan[1], Muriel Webb[2], Oren Shibolet[2], Revital Kariv[2], Shira Zelber-Sagi[1,2]. [1]*University of Haifa, School of Public Health, Haifa, Israel;* [2]*Tel Aviv Medical center, Gastroenterology, Tel Aviv, Israel*
Email: danaivanc@gmail.com

Background and aims: Non-alcoholic fatty liver disease (NAFLD) is a chronic disease related to lifestyle. The association of meat consumption with NAFLD has been tested. However, the prospective association between meat consumption and steatosis incidence and remission and liver fibrosis is yet to be tested. Therefore, this study aims to prospectively test the association of meat types consumption with incidence and remission of NAFLD and liver fibrosis markers.
Method: A prospective cohort study among subjects 40–70 years old, participating in two screening days, at least five years apart. NAFLD was determined by ultrasonography or CAP≥294 dB/m. Liver fibrosis was evaluated by Fibrotest (significant fibrosis ≥F2 was defined as a result of ≥0.48) or Fibroscan (significant fibrosis ≥F2 was defined as a result of ≥8.2 Kp). Meat consumption was assessed by a detailed food frequency questionnaire (FFQ), the trajectories of consumption were calculated as the percent of change from baseline (gr/d).
Results: A total of 320 subjects had completed two screening days and had valid FFQ. Mean follow-up of 6.65 ± 0.73 years. In multivariate-adjusted analyses, high consumption of red and/or processed meat (gr/d above the baseline consumption median) was associated with higher risk for NAFLD with elevated ALT incidence (OR = 5.97, 1.84–19.37, P = 0.003). Unprocessed red meat consumption was associated with NAFLD with elevated ALT incidence, lower odds for NAFLD remission, and greater odds for new or persistent significant fibrosis, evaluated by Fibroscan (OR = 3.52, 1.22–10.17, P = 0.020; OR = 0.33, 0.14–0.78, P = 0.012; OR = 4.69, 1.43–15.40, P = 0.011, respectively). Regarding meat consumption trajectories, 10% daily increments in total or processed meat consumption were significantly associated with greater risk for new or persistent NAFLD (OR = 2.09, 1.20–3.65, P = 0.010; OR = 1.90, 1.04–3.46, P = 0.037, respectively).
Conclusion: High consumption of red meat or processed meat is associated with NAFLD and significant fibrosis in a prospective study

THU057

Relevance of diabetes medication on recruitment criteria for clinical studies in patients with non-alcoholic fatty disease and type 2 diabetes mellitus

Michael Holzhey[1], David Petroff[2], Valentin Blank[1], Florian Gerhardt[3], Albrecht Boehlig[3], Toni Herta[3], Florian van Bömmel[3], Thomas Berg[3], Thomas Karlas[1], Johannes Wiegand[3]. [1]*University of Leipzig, Division of Gastroenterology, Germany;* [2]*University of Leipzig, Clinical Trial Center, Germany;* [3]*University of Leipzig, Division of Hepatology, Leipzig, Germany*
Email: johannes.wiegand@medizin.uni-leipzig.de

Background and aims: Guidelines for patients with diabetes mellitus increasingly recommend the use of sodium-glucose cotransporter 2 (SGLT-2) inhibitors and glucagon-like peptide 1 (GLP-1) agonists to prevent cardiovascular end points. Both drugs are promising candidates for treatment of non-alcoholic fatty liver disease (NAFLD). However, pre-existing therapies with SGLT-2 inhibitors or GLP-1 agonists are often an exclusion criterion for clinical trials. Thus, we analyzed use of diabetes medications and their adjustment.
Method: Patients with type 2 diabetes mellitus and NAFLD were prospectively recruited from 2011 to 2018 and followed up in 2021. They were characterized non-invasively by transient elastography (TE) including liver stiffness measurement (LSM), controlled attenuation parameter (CAP) and Fibroscan-AST-score (FAST). Diabetes medication was recorded from patient charts. Data were compared to the time point of the first available TE measurement.
Results: 90 patients were recruited (57% female, age 63.9 ± 9.6 years, BMI 31.3 ± 5.0 kg/m^2, LSM 7.4 kPa [5.3, 14.1], CAP 315 ± 57 dB/m, FAST 0.38 [0.18, 0.65]). After 4.2 [3.7, 7.9] years, follow-up data were available from 78 cases, the remaining 12 individuals had died.
At follow-up, patients received the following diabetes medication:

SGLT-2 inhibitors: 17/78 (22%)
GLP-1 agonists: 13/78 (17%)
Metformin: 42/78 (54%)
Dipeptidyl-Peptidase-4 (DPP-4) inhibitors: 15/78 (19%)
Insulin: 42/78 (54%).

From these five drug classes, patients took a mean of 1.38 substances at baseline compared to 1.65 at follow-up (difference 0.27, 95% CI 0.01 to 0.53, p = 0.046).
The net change compared to baseline was an additional 14 (18%), 10 (13%), and 7 (9%) patients on SGLT-2 inhibitors, GLP-1 agonists, and insulin, whereas metformin and DDP-4 were used in 9 (12%) and one (1%) fewer individuals.
The geometric mean of LSM changed from 8.3 to 7.8 kPa for a relative change by a factor of 0.94 (95% CI 0.85 to 1.03, p = 0.18).
Mean CAP changed from 313 to 306 dB/m for a change of – 7.4 dB/m (95% CI – 22.8 to 7.9, p = 0.34)
The mean of FAST score changed from 0.38 to 0.31 implying an odds ratio of 0.74 (95% CI 0.56 to 0.96, p = 0.027).
Conclusion: A relevant and increasing proportion of NAFLD patients with diabetes mellitus is treated with SGLT-2 inhibitors and GLP-1 agonists in clinical routine. These treatments affect recruitment for clinical studies and should be considered as confounders in case they are continued during the study period.

THU058

Comorbidity severity scores and cardiovascular comorbidities in patients with non-alcoholic steatohepatitis (NASH), with and without cirrhosis, in a real-world setting

Jeffrey Lazarus[1], Abhishek Shankar Chandramouli[2], Kamal Kant Mangla[3], Zobair Younossi[4]. [1]*Barcelona Institute for Global Health (ISGlobal), Hospital Clínic, University of Barcelona, Barcelona, Spain;* [2]*Novo Nordisk Service Centre India Pvt Ltd, Bangalore, India;* [3]*Novo Nordisk A/S, Søborg, Denmark;* [4]*Center for Liver Disease, Inova Medicine, Falls Church, VA, United States*
Email: Jeffrey.Lazarus@isglobal.org

Background and aims: NASH is estimated to be present in 3–6% of the US population and has been linked to end-stage liver disease, type 2 diabetes (T2D), and cardiovascular disease (CVD). The AWARE study aimed to describe the association of NASH with comorbidity severity scores and CVD comorbidities, which has not been well studied previously.
Method: Data were collected from a large US healthcare dataset covering 1 October 2015 to 31 December 2020. Records were included for adult patients diagnosed with NASH (using ICD-10 CM), with no evidence of hepatitis B or C, excessive alcohol use, or liver transplant prior to NASH diagnosis, and with no evidence of pregnancy or cancer in the study period. ICD CM coding was used to identify all diagnoses. Statistical significance of differences in comorbidities and severity scores between cirrhotic patients (CPs) and non-cirrhotic patients (NCPs) was assessed.
Results: Of 4, 989 patients identified, 489 had evidence of cirrhosis prior to NASH diagnosis. CPs were older and more progressed in terms of NASH-relevant biomarkers, glycated haemoglobin (HbA_{1c}), and comorbidities (Table). CVD comorbidities were significantly higher in CPs at baseline, including atherosclerotic CVD, as were severity scores for T2D and comorbidities overall.

Table: Selected baseline characteristics

	NCPs (n = 4, 500)	CPs (n = 489)
Age, years	52.2 (11.0)	59.6 (9.4)
Female, %	55.2	62.4
NAFLD, %	56.5	67.4
Provider, Gastroenterologist: Internist: GP, %	20: 17: 16	28: 11: 7
Aspartate transaminase: platelet ratio index*	586; 0.62 (0.96)	86; 1.09 (1.57)
Fib-4*	493; 1.56 (1.42)	71; 4.68 (5.28)
NAFLD fibrosis score*	454; – 1.13 (1.63)	66; 1.74 (2.04)
Quan-Charlson Comorbidity Index*	1.9 (1.5)	4.4 (1.9)
Adaptive Diabetes Complexity Severity Index*	0.1 (0.4)	0.4 (1.0)
BMI (kg/m^2)	1, 957; 35.0 (5.7)	243; 35.1 (6.1)
Predicted waist circumference, cm	1, 957; 110.4 (15.0)	243; 109.4 (15.9)
HbA_{1c} (%)	485; 6.9 (1.7)	64; 7.1 (1.5)
T2D* %	40.6	73.4
Chronic kidney disease* %	5.9	17.8
Diabetic neuropathy* %	6.8	22.1
CVD* %	29.8	73.0
Atherosclerotic CVD*†	13.1	25.8
Heart failure*	2.2	13.3
Oesophageal varices*	1.2	33.3
Hypertensive disease* %	64.8	81.8

Data are mean (SD) or n; mean (SD) unless stated
BMI, body mass index; NAFLD, non-alcoholic fatty liver disease.
*Assessed by univariate analysis for statistical significance: p <0.001 for NCPs vs CPs.
†Multivariate logistic regression analysis for atherosclerotic CVD, adjusted for demographic factors: odds ratio 1.34 (1.02, 1.78); p < 0.05 for CPs vs NCPs.

Conclusion: This study found that patients with NASH are often not diagnosed until an advanced stage, suggesting the need for greater disease awareness to avoid diagnostic inertia and to better assess the burden associated with NASH. These data also suggest that NASH correlates with a higher risk of developing comorbidities, especially CVD and T2D, particularly as patients progress to cirrhosis.

THU059

NAFLD association with renal impairment in type 2 diabetes patients

Jesús Rivera[1], Monica Pons[1], Alejandra Planas[2], Rafael Simo Canonge[2], Jordi Bañeras[3], Ignacio Ferreira[3], María José Soler[4], Daniel Seron[4], Joan Genesca[1], Juan Manuel Pericàs[1]. *[1]Vall d'Hebron Hospital Universitari, Liver Unit, Spain; [2]Vall d'Hebron Hospital Universitari, Diabetes and Metabolism Research Unit, Spain; [3]Vall d'Hebron Hospital Universitari, Cardiology Department, Spain; [4]Vall d'Hebron Hospital Universitari, Nephrology Department*
Email: jesusriveraest@gmail.com

Background and aims: Non-alcoholic fatty liver disease (NAFLD) and type 2 diabetes (T2DM) frequently coexists in high-risk metabolic patients. NAFLD and T2DM share a multisystemic involvement and the coexistence of both may increase the organ damage, worsening the patient prognosis. The aim of this study was to evaluate the role of NAFLD in the development and severity of extrahepatic conditions in a well-characterized T2DM cohort.
Method: Prospective cohort with case-control analysis comprising 200 T2DM subjects with 60 non-diabetic subjects matched by age with available transient elastography data. Patients were selected from the Outpatient Diabetes Clinic of Vall d'Hebron Hospital and the Primary Healthcare centres within its catchment area. Diabetic nephropathy (DN) was defined as the presence of microalbuminuria >30 mg/dl. According KDIGO guidelines, we defined renal impairment (RI) as a urine albumin:creatinine ratio >30 mg/g and chronic kidney disease (CKD) as an estimated glomerular filtrate rate (eGFR) 60 ml/min per 1.73m^2. NAFLD was defined as Controlled Attenuation Parameter (CAP) ≥275 dB/m and/or Fatty liver index (FLI) ≥60 after exclusion of the other liver diseases and alcohol consumption over 30 gr/day in males and over 20 gr/ay in females. Multivariate regression analysis was performed to identify predictors of extrahepatic diseases.
Results: Patients with T2DM with NAFLD (n = 134) presented higher rates of arterial hypertension (76.1% vs 61.5%, p 0.047) and obesity-BMI ≥30 kg/m^{2-} (61.2% vs 23.1%, p < 0.001) than T2DM-nonNAFLD (n = 52). Distribution for gender, age and presence of dyslipidemia were similar between groups. Respect to T2DM complications, 38.6% of T2DM-NAFLD patients showed DN compared to 19.6% T2DM-nonNAFLD subjects (p 0.014). No statistical differences were found for diabetic retinopathy (25.4% vs 30.8%, p 0.45) or peripheral neuropathy (19.4% vs 17.3%, p 0.74). Of note, T2DM-NAFLD patients showed worse median creatinine and eGFR values (0.85 ± 0.26 vs 0.74 ± 0.14, p 0.001 and 80.1 ± 17.4 vs 86.1 ± 10.1, p 0.004, respectively), and also presented a higher proportion of RI (71.6% vs 49.0%; p 0.004) and CKD (14.2% vs 3.9%, p 0.049) respect to T2DM subjects without NAFLD. Median liver stiffness did not differ among patients with and without RI or CKD. In multivariate analysis the presence of NAFLD (HR = 2.48; 95%CI 1.61–5.32, p 0.019) was associated with the development of RI, independently of well-known risk factors, such as arterial hypertension (HR = 3.23; 95%CI 1.58–6.58, p 0.001) or advanced age (HR = 2.79; 95%CI 1.40–5.56, p 0.003).

Multivariate logistic regression analysis			
	Hazard Ratio	**95% CI**	**p**
NAFLD	2.48	1.61-5.32	**0.019**
Age ≥ 65y	2.79	1.40-5.56	**0.003**
Arterial hypertension	3.23	1.58-6.58	**0.001**
Obesity (BMI ≥ 30 kg/m2)	1.37	0.66-2.73	0.40

Conclusion: Our results suggest that NAFLD poses an increased risk of extrahepatic diseases in T2DM patients, including other metabolic conditions and specially kidney disease. Renal function in diabetic patients with NAFLD should be screened and monitored closely, since NAFLD may lead to further worsening of kidney disease.

THU060

The impact of liver fibrosis on the immune response to SARS-CoV-2 vaccination in metabolic associated fatty liver disease patients

Marta Freitas[1,2,3], Tiago Capela[1,2,3], Vítor Macedo Silva[1,2,3], Sofia Xavier[1,2,3], Joana Teixeira Magalhães[1,2,3], Carla Maria Moura Marinho[1,2,3], José Cotter[1,2,3]. *[1]Hospital da Senhora da Oliveira, Guimarães, Portugal, Gastroenterology Department; [2]School of Medicine, University of Minho, Braga, Portugal, Life and Health Sciences Research Institute (ICVS); [3]PT Government Associate Laboratory, Braga/Guimarães, Portugal, ICVS/3B's*
Email: martaspfreitas@gmail.com

Background and aims: There has been growing concern about the response to severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) vaccination in patients with chronic liver disease, as it may confer an immunosuppression state, potentially being associated with a lower response to vaccination. However, this issue in metabolic associated fatty liver disease (MAFLD) patients remains unestablished. We aimed to assess the impact of liver fibrosis on the immune response to SARS-CoV-2 vaccination in patients with MAFLD.
Method: Prospective cohort study that included MAFLD patients with complete SARS-CoV-2 vaccination. Patients with previous SARS-CoV-2 infection were excluded. Serum SARS-CoV-2 immunoglobulins (Ig), laboratory and transient elastography (TE) data were assessed 1 month after complete vaccination. Significant fibrosis was defined as

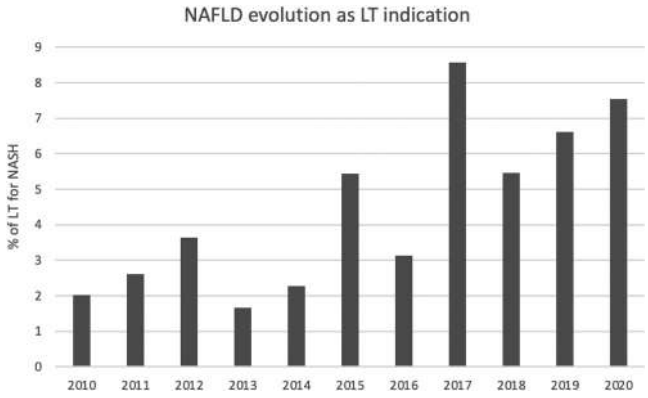
liver stiffness measurement (LSM)≥8.2 kPa, NAFLD fibrosis score≥-1.455, FIB-4 score≥1.45, or FAST score>0.35.
Results: Thirty-seven patients were included, 62.2% of male gender, with a mean age of 55 ± 9 years. The mean LSM was 6.9 ± 2.9 kPa and 32.4% of patients had significant fibrosis in TE. The mean SARS-CoV-2 IgG levels were 10048 ± 9395 U/ml and all patients had response to vaccination (IgG≥50 U/ml). There were no differences in SARS-CoV-2 IgG levels regarding gender (p = 0.93), presence of obesity (p = 0.20), metabolic syndrome (p = 0.26), diabetes (p = 0.70), hypertension (p = 0.52), dyslipidemia (p = 0.96), and tobacco use (p = 0.99). There were no differences in SARS-CoV-2 IgG levels between patients with or without significant fibrosis (p = 0.13) in TE, NAFLD fibrosis score (p = 0.18), FIB-4 score (p = 0.56), or FAST score (p = 0.24).
Conclusion: In our cohort, all MAFLD patients had Ig response to vaccination. Significant liver fibrosis did not compromised response of MAFLD patients to SARS-CoV-2 vaccination. SARS-CoV-2 vaccination is serologically effective in MAFLD patients, regardless of fibrosis.

THU061

Non-alcoholic steatohepatitis is also becoming a major liver transplant indication in Spain, a historically low risk area

Laura Martínez-Arenas[1], Ângela Carvalho-Gomes[2], Fernando Diaz Fontela[3], Sara Lorente Perez[4], Marta Guerrero[5], Jose Ignacio Herrero[6], Marina Berenguer[7]. *[1]Instituto de Investigación Sanitaria La Fe, Hepatology, Hepatobiliopancreatic Surgery and Transplant, Valencia, Spain; [2]Instituto de Investigación Sanitaria La Fe, CIBERehd, Hepatology, Hepatobiliopancreatic Surgery and Transplant, Valencia, Spain; [3]Hospital General Universitario Gregorio Marañón, Liver Unit and Digestive Department, Madrid, Spain; [4]Hospital Clínico Universitario Lozano Blesa, Hepatology and Liver Transplantation Unit, Zaragoza, Spain; [5]Hospital Universitario Reina Sofía, Instituto Maimónides de Investigación Biomédica de Córdoba, CIBERehd, Department of Hepatology and Liver Transplantation, Córdoba, Spain; [6]Clínica Universidad de Navarra, Instituto de Investigación Sanitaria de Navarra, CIBERehd, Department of Internal Medicine, Pamplona, Spain; [7]Hospital Universitario y Politécnico La Fe, Instituto de Investigación Sanitaria La Fe, Universidad de Valencia, CIBERehd, Hepatology and Liver Transplantation Unit, Valencia, Spain*
Email: laura_munera15@hotmail.com

Background and aims: Non-alcoholic fatty liver disease (NAFLD) is becoming one of the most common chronic liver diseases in Spain, particularly in individuals with features of metabolic syndrome, yet its exact prevalence and incidence are not completely known. In fact, non-alcoholic steatohepatitis (NASH) is a growing indication for liver transplantation (LT) in our setting. Our aim was to describe NAFLD evolution as a LT indication and the most frequently found features associated with this indication.
Method: Patients undergoing LT for NASH-related cirrhosis from 2010 to 2020 in five reference LT centers in Spain were included. The medical records of all these patients were reviewed for determining NASH-associated comorbidities. Survival analyses were performed with SPSS to determine survival rates at different follow-up points after LT.
Results: NASH-related cirrhosis was the LT indication in 118 patients from 2010 to 2020. Taking into account the five centers, the percentage of LT for NASH increased 3.8-fold between 2010–2020, from 2.0% to 7.5% (Figure 1). The highest percentage (25.0%) was registered in 2020 in one of the centers. While there were no transplants performed for NASH in some centers in some of the years, mainly in the first years of the study, the number has progressively increased since 2015. Comorbid conditions were found in most patients; 77.1% had obesity, 59.3% type 2 diabetes mellitus (T2DM), 61.9% hypertension (HTN), 37.3% dyslipidemia (DL) and 22.0% a history of prior cardiovascular disease (CVD). While posttransplant complications were frequent, survival was similar to that of other indications with a cumulative proportion surviving of 0.92 and 0.8 at 1- and 5-year post-LT and only 2 cases of graft loss due to recurrence of primary disease. The greatest number of deaths occurred within the first year after transplantation (n = 10), none of them related to primary liver disease.



Conclusion: NAFLD is an increasingly common indication for LT in our country. However, the incidence is still far from that described in countries like the US. As reported, most of these transplant candidates have significant comorbid conditions associated with posttransplant complications and poorer long-term outcome such as obesity, T2DM, HTN, DL and CVD. Yet, in the short-midterm transplant survival is similar to that reported by the Spanish Liver Transplantation Registry, with a survival rate of 87% and 75% at 1- and 5- year post-LT, respectively.

THU062

Total healthcare cost and characteristics associated with higher change in cost in patients with non-alcoholic steatohepatitis

Zobair Younossi[1], Kamal Kant Mangla[2], Abhishek Shankar Chandramouli[3], Jeffrey Lazarus[4]. *[1]Center for Liver Disease, Inova Medicine, Falls Church, VA, United States; [2]Novo Nordisk A/S, Søborg, Denmark; [3]Novo Nordisk Service Centre India Pvt Ltd, Bangalore, India; [4]Barcelona Institute for Global Health (ISGlobal), Hospital Clínic, University of Barcelona, Barcelona, Spain*
Email: zobair.younossi@inova.org

Background and aims: The economic burden in patients with non-alcoholic steatohepatitis (NASH) is often underestimated. The AWARE study collected baseline data on patients with NASH to determine the associated healthcare cost burden.
Method: Data were collected from a large US healthcare dataset (electronic health records linked with claims) from 1 October 2015 to 31 December 2020. Adult patients diagnosed with NASH, with no evidence of hepatitis B or C, excessive alcohol use, or liver transplant prior to NASH diagnosis, and with no evidence of pregnancy or cancer in the study period, were included. All diagnoses were made using ICD CM. Total healthcare follow-up costs and change in total healthcare cost post-NASH are reported as mean (standard deviation). The effect on change in cost by baseline characteristics was assessed using a multivariate generalised linear model.
Results: Of 4, 989 adult patients diagnosed with NASH, 489 had evidence of cirrhosis at baseline. Mean follow-up was 22 months for non-cirrhotic patients (NCPs) and 21 months for cirrhotic patients (CPs). Annualised follow-up costs (US$) were $28, 707 ($140, 814) for NCPs and $84, 582 ($204, 552) for CPs. Among NCPs, approximately 70% had a high annual cost burden (>$5, 000) and 38% had a very high cost burden (>$15, 000) (Figure). Increases in costs following onset of NASH were $13, 202 ($141, 095) for NCPs and $44, 509 ($177, 055) for CPs. For NCPs, the change in costs post-NASH diagnosis significantly increased (in %) with increasing Quan-Charlson Comorbidity Index score (21% per unit increase) and adaptive Diabetes Complexity Severity Index score (36% per unit increase), increasing use of

cardiovascular (CV) drug classes (8%) and anti-diabetes medication classes (12%), and presence (vs absence) of CV disease (71%) and osteoarthritis (51%) at baseline. Female (vs male) patients had higher follow-up costs and a larger change in costs.

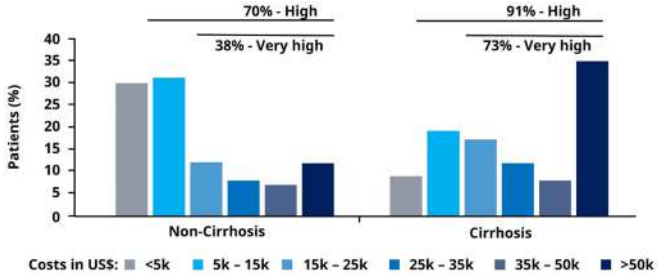


Figure: Annualised follow-up total healthcare cost (US$) for patients with NASH

Conclusion: NASH correlates with noticeable total healthcare cost and increases in costs following onset of NASH for all patients. The costs reported here are reflective of short-term burden. This analysis did not include indirect costs or costs associated with loss of work productivity. Due to the unavailability of approved treatments for patients with NASH, the cost burden is expected to increase with the presence and increasing severity of comorbidities. Therefore, the aim of managing NASH through pharmacotherapy should be to stop progression to cirrhosis and to manage NASH-related comorbidities.

THU063

Non-alcoholic fatty liver disease (NAFLD)/non-alcoholic steatohepatitis (NASH) is associated with worse outcomes in patients hospitalised for COVID-19: a real-world analysis of a large population from the premier healthcare database

Frank Tacke[1], Fady Tanios[2], Lin Xie[2], Deepa Malhotra[2], Simon Dagenais[2], Nino Katchiuri[2], Birol Emir[2]. [1]*Charité University Medical Center, Berlin,* [2]*Pfizer Inc, New York, United States*
Email: frank.tacke@charite.de

Background and aims: NAFLD and NASH contribute to the global burden of liver disease. Previous studies suggest an association between NAFLD/NASH and the severity of COVID-19 illness. This analysis aimed to characterise the impact of NAFLD/NASH on hospitalisation-related outcomes for patients with COVID-19 using hospital administrative data from the United States (US) Premier Healthcare Database Special Release (PHD-SR).
Method: Adults with COVID-19 (primary or secondary International Classification of Diseases [ICD]-10 diagnosis code U07.1) hospitalised for the first time (index event) and discharged between 1 Apr 2020 and 31 Mar 2021 were examined. Pregnant patients and those with human immunodeficiency virus, alcohol dependence/abuse, viral hepatitis, biliary cirrhosis or sclerosing cholangitis were excluded. Cases with NAFLD/NASH (ICD-10: K75.81, K76.0) at index or 3 months pre-index (in- or outpatient) hospitalisation were matched to controls without NAFLD/NASH using exact matching for age; propensity scores were calculated for sex, race and other variables. Outcomes included length of stay (LOS), invasive mechanical ventilator (IMV) use, in-hospital mortality and all-cause network-hospital readmission within 30 days of index event discharge. Linear and logistic regression with inverse probability treatment weight (IPTW) compared outcomes in cases and controls.
Results: The PHD-SR dataset included 513, 623 eligible patients; 14, 672 (2.9%) with a NAFLD/NASH diagnosis. Among 29, 334 patients analysed (14, 667 cases with NAFLD/NASH and 14, 667 matched controls), mean (standard deviation) age was 57.5 (15.0) years, 51.0% were female and 43.8% were white non-Hispanic. Baseline characteristics (eg, age, sex, race) were similar (standard difference <0.10) in cases and controls, except for cirrhosis (9.7% cases vs 0.5% controls) and malignancy (13.6% cases vs 10.2% controls). Regression analysis with IPTW adjusted for cirrhosis and malignancy revealed that patients without NAFLD/NASH had a significantly shorter mean LOS and reduced odds of IMV use with no difference in in-hospital mortality and readmission vs patients with NAFLD/NASH (Table), controlled for age, sex, race and other NAFLD-related comorbidities (eg, diabetes, obesity).

Table: Hospitalisation-related outcomes in matched controls without NAFLD / NASH versus cases with NAFLD / NASH hospitalised with COVID-19

Outcome	Adjusted differences and OR (95% CI) between controls and cases
LOS at index hospitalisation, days	LSM: -1.02 (-1.26, -0.78)
IMV use including ECMO	OR: 0.93 (0.88, 0.99)
In-hospital mortality at index hospitalisation	OR: 1.02 (0.95, 1.10)
Readmission, all-cause within 30 days	OR: 1.06 (0.97, 1.16)

LSM difference for LOS based on linear regression with IPTW adjusted for cirrhosis and malignancy. OR based on logistic regression with IPTW adjusted for cirrhosis and malignancy.

CI, confidence interval; ECMO, extracorporeal membrane oxygenation; IMV, Invasive mechanical ventilator; IPTW, inverse probability treatment weight; LOS, length of stay; LSM, least squares mean; NAFLD, nonalcoholic fatty liver disease; NASH, nonalcoholic steatohepatitis; OR, odds ratio.

Conclusion: Real-world US hospital data suggests that patients hospitalised with COVID-19 who also have NAFLD/NASH have worse hospitalisation-related outcomes than those without NAFLD/NASH.

Estimating the prevalence of advanced fibrosis due to non-alcoholic fatty liver disease in the United States population

Naim Alkhouri[1], Julia Yang Payne[2], Pankaj Aggarwal[1], Prido Polanco[1], Phillip Leff[1], Mazen Noureddin[3], Phuc Le[2]. [1]*Arizona Liver Health, United States;* [2]*Cleveland Clinic, United States;* [3]*Cedars-Sinai Medical Center, United States*
Email: naim.alkhouri@gmail.com

Background and aims: Previous estimates of the prevalence of advanced fibrosis (AF) due to NAFLD in the general US population utilized non-invasive tests that have relatively low positive predictive value leading to potentially overestimating the true prevalence. The AGILE 3+ score was developed by combining routine clinical variables and vibration-controlled transient elastography parameters to specifically increase the PPV of predicting AF. Our aim was to estimate the prevalence of AF due to NAFLD using the AGILE3+ score in the general US adult population.
Method: Our study population included participants aged ≥18 years old who had a complete VCTE exam in the national health and nutrition examination survey (NHANES) 2017–2018 cycle. We excluded pregnant women, patients with excessive alcohol consumption defined as >2 drinks/day for males and >1 drink/day for females, hepatitis B or C, and ALT or AST >500 IU/L.
NHANES used FibroScan model 502 V2 Touch equipped with medium and extra-large probes. The presence of NAFLD was based on having a CAP score >248 dB/m. NAFLD subjects with AGILE3+ score of ≥0.68 were considered to have AF (rule-in), 0.45–0.67 were to be the grey zone, and <0.45 were considered low risk for AF (rule-out).
Results: Our cohort consisted of 1244 subjects with evidence of NAFLD and complete data to calculate the AGILE3+ score. The Median age was 52.5 (50.7–54.2) years, 54.9% were male, median BMI was 32.7 kg/m2 and 36.2% had type 2 diabetes. Based on AGILE3+ score <0.45, 80.3% (95%CI: 77.1–83.2) of the NAFLD population were at low risk for AF. 11.5 (9.2–14.5) of patients were in the grey zone and would have needed another test to determine the presence of AF. The overall prevalence of AF due to NAFLD was 8.1 (6.2–10.6) corresponding to 4.5 million Americans. Patients with AF were older, more likely to be obese and have type 2 diabetes.
Conclusion: Using NHANES 2017–2018, our results suggest that approximately 4.5 million people in the US have AF due to NAFLD based on the AGILE3+ score. Evaluating the cost-effectiveness of using AGILE3+ as a screening tool in high-risk populations is needed before implementing in clinical practice.

THU065

Non-alcholic fatty liver disease associated liver fibrosis is linked with the severity of coronnary artery disease mediated by systemic inflammation

Xianbin Cai[1], Lingzi Chen[1]. [1]*The First Affiliated Hospital of Shantou University Medical College, Department of Gastroenterology, Shantou, China*
Email: cxbin1@qq.com

Background and aims: Non-alcoholic fatty liver disease (NAFLD) is an independent risk factor of cardiovascular disease. Hepatic fibrosis is the most significant determinant of all cause- and liver -related mortality in NAFLD. However, the relationship between NAFLD fibrosis and severe coronary artery disease (CAD) remains unclear.
Method: We conducted a retrospective study of 531 patients with ultrasonogram-confirmed NAFLD who underwent percutaneous coronary intervention (PCI). Then all patients were separated into four categories by Gensini score (0, 0–9, 9–48, ≥48) for use in ordinal logistic regression analysis to determine whether NAFLD fibrosis was associated with increased Gensini scores. Mediation analysis were used to investigate whether systemic inflammation is a mediating factor in the association between NAFLD fibrosis and CAD severity.
Results: FIB-4 >2.67 (OR = 5.67, 95%CI 2.59–12.38) and APRI >1.5 (OR = 14.8, 95%CI 3.24–67.60) remained to be independent risk factors for the severity of CAD after adjusting for conventional risk factors, whereas among the inflammation markers, only neutrophils and neutrophil-to-lymphocyte ratio (NLR) were independently associated with CAD. Multivariable ordinal regression analysis suggested that increasing Gensini score (0, 0–9, 9–48, ≥48) was associated with advanced NAFLD fibrosis. ROC curve showed that either fibrosis markers or inflammation markers, integrating with traditional risk factors, could increase the predictive capacity for determining CAD (Figure 1). Inflammation markers, especially neutrophils and NLR, were mediators of the relationship between NAFLD fibrosis and CAD severity (Figure 2).

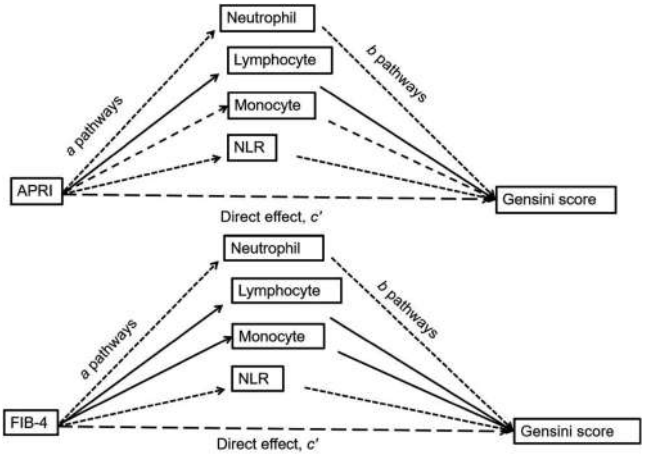

Figure 2: Mediated Model of Fibrosis Markers with Gensini Score.
(1) The coefficient *a* is the effect of fibrosis markers on the inflammation markers; (2) the coefficient *b* is the effect of inflammation markers on Gensini score after controlling the influence of fibrosis markers; (3) the coefficient c' is the direct effect of fibrosis markers on Gensini score after controlling the influence of inflammation markers. Dash line means the pathway is statistically significant.

Conclusion: NAFLD patients with advanced fibrosis are at a high risk of severe coronary artery stenosis, and inflammation might mediate the association between NAFLD fibrosis and CAD severity.

Prevalence of portal vein thrombosis in non-alcoholic fatty liver disease related cirrhossis: a meta-analysis of observational studies

Roberta Stupia[1], Filippo Cattazzo[1], Alessandro Mantovani[2], David Sacerdoti[1], Andrea Dalbeni[1]. [1]*Azienda Ospedaliera Universitaria Integrata Verona, General Medicine, Hypertension and Liver Unit, Verona, Italy;* [2]*Azienda Ospedaliera Universitaria Integrata Verona, Endocrinology, Diabetes and Metabolism, Verona, Italy*
Email: robertastupia1@gmail.com

Background and aims: Portal vein thrombosis (PVT) is a common complication of cirrhosis because of modification in hemodynamics and hemostatic balance, especially in decompensated stage1. Furthermore, patients with non-alcoholic fatty liver disease

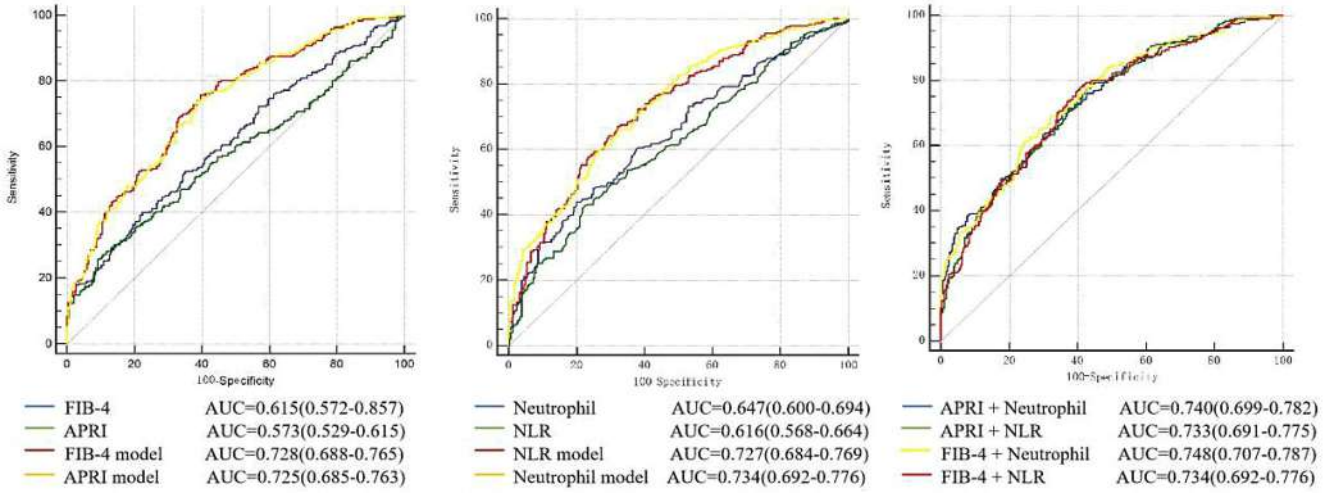

Figure 1: (abstract: THU065): Receiver Operating Characteristics (ROC) Curve Analysis of the Predictive Power of Fibrosis markers, NLR and Neutrophil for CAD.
APRI model, FIB-4 model, NLR model, Neutrophil model, APRI + Neutrophil, FIB-4 + Neutrophil: new models integrating non-invasive markers and recognized risk factors for CAD (gender, age, smoking, hypertension, DM, triglyceride, HDL, LDL).

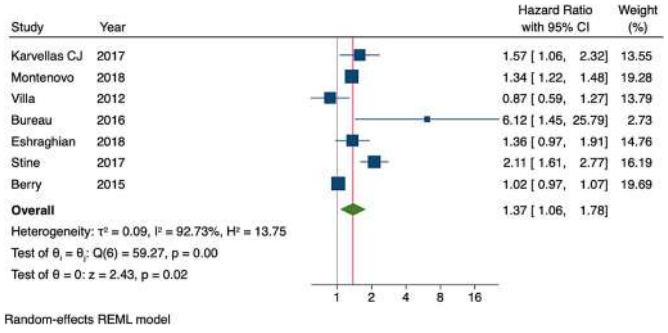
(NAFLD) related cirrhosis seem to be at higher risk of PVT development than patients with cirrhosis due to other causes2. Nevertheless, definitive data in favor of an increased rate of PVT in NAFLD are missing. This meta-analysis attempted to estimate the prevalence of PVT in patients with NAFLD related cirrhosis.

Method: We systematically searched PubMed, Scopus and Web of Science databases from the inception date to November 1st 2021 using predefined keywords to identify observational cohort studies. Meta-analysis was performed using random-effects modelling.

Results: We included seven articles published over the past 10-year period reporting a total of 231.399 cirrhotic patients from five different countries. NAFLD-cirrhosis patients were 26853 (11, 6%), whith a PVT incidence of 6.5% (n = 1748). Meta-analysis demonstrated a significant positive association between NAFLD and PVT (OR 1.37, 95% CI 1.06–1.78 p <0, 001). The between-study heterogeneity was substantial (I2 = 92, 73%).

After stratifying the eligible cohort studies by country, we observed that, compared to other regions, in European patients the incidence of PVT in NAFLD-cirrhosis was higher (OR: 2.03, 95% CI 0.30–13.53) than in North-American patients (OR: 1.42, 95% CI 1.05–1.94) and Arabian patients (OR: 1.36, 95% CI 0.97–1.91).

By a meta regression analysis, neither age nor diabetes seemed to impact on the relationship between NAFLD and PVT.



Conclusion: This meta-analysis suggests that NAFLD-cirrhosis is associated with an increased risk of developing PVT. Further research is required to understand the complex link between NAFLD and PVT development.

Real-world prevalence of metabolic associated fatty liver disease (MAFLD) and fibrotic-non-alcoholic steatohepatitis (NASH) in patients with obesity (PwO) in an outpatient specialist clinic in Italy

Federico Ravaioli[1], Maria Letizia Petroni[1], Francesca Marchignoli[1], Laura Leoni[1], Giulia Bocedi[1], Federica Sacilotto[1], Valentino Osti[1], Dorina Mita[1], Francesca Barbanti[1], Lucia Brodosi[1], Giulio Marchesini Reggiani[1], Loris Pironi[1]. [1]*IRCCS Azienda Ospedaliero-Universitaria di Bologna, Dipartimento di Scienze Mediche e Chirurgiche (DIMEC)*

Email: f.ravaioli@unibo.it

Background and aims: Obesity is a major player of "metabolic dysfunction associated fatty liver disease" (MAFLD); however, scanty data is available on the prevalence of MAFLD and non-alcoholic steatohepatitis (NASH) in patients presenting with obesity to a specialist outpatient clinic; to date, data being available from bariatric surgery patient series only. For this purpose, we aimed to evaluate the prevalence of MAFLD and the applicability of non-invasive tests (NITs) for fatty liver and liver fibrosis identification in an outpatient specialist clinic in Italy.

Method: We consecutively screened patients with obesity (PwO) who attended our outpatient obesity clinic from January 2020 to June 2021. Diagnosis of MAFLD was based on results from abdominal ultrasound (US); the anthropometric and laboratory data of the patients were collected, and the Fatty Liver Index (FLI), Fibrosis-4 (FIB4) and NAFLD (NFS) scores were calculated. Liver fibrosis was assessed within one month of the first visit using liver stiffness measurements (LSM) by transient elastography (FibroScan); Probe-specific LSM cut-offs were used to detect significant (F≥2) and advanced (F≥3) fibrosis and NASH cirrhosis. In a subgroup, hepatic fat was also evaluated through controlled attenuation parameters (CAP) with the FibroScan Expert 630 apparatus; all patients underwent oral glucose tolerance test (OGTT).

Results: Among 249 PwO, according to the WHO obesity classification, obesity I °, II °, III ° was classified in 144 (57.8%), 56 (22.5%), 49 (19.6%), respectively. In addition, about half of the PwO had type 2 diabetes (T2DM) or impaired glucose tolerance (IGT) with a median HOMA index of 3.6 (IQR 2.44–4.94). According to US or FLI definitions, the prevalence of MAFLD was 90.4% and 91.6% and did not differ significantly in the different WHO categories of obesity (p value 0.264). The distribution of hepatic steatosis classification on ultrasound was 25.8%, 38.7%, 35.6% for mild, moderate, and severe steatosis, respectively. The median CAP values were 287 dB/m (IQR 262–337). According to LSM values, 29%, 18% and 9.8% had significant fibrosis, advanced fibrosis, and NASH cirrhosis, respectively. The median LSM value was 5.4 kPa (IQR 4.3–7.5). The liver fibrosis prevalence significantly increased according to WHO categories of obesity (p value <0.0001). Applying the screening with NITs, 10% and 9% of patients are wrongly classified, and this leads to misclassify about 50% and 11.4% of patients with advanced fibrosis using FIB-4 or NFS, respectively; moreover, 34.1% and 54.5% of patients with advanced fibrosis result in the grey area of the two tests respectively.

			Advanced fibrosis (18%)	Cirrhosis-NASH (9.8%)
	Absence of fibrosis (71%)	Significant fibrosis (29%)		
Patients (n.249)	F0-F1 [LSM <7]	F2 [LSM≥ 7 & <8.7]	F3 [LSM≥8.7 & LSM<10.3]	F4 [LSM≥10.3]
Obesity I° [n.144]	117 (81.3%)	13 (9%)	9 (6.3%)	5 (3.4%)
Obesity II° [n.56]	39 (69.6%)	8 (14.3%)	3 (5.4%)	6 (10.7%)
Obesity III° [n.49]	21 (42.9%)	7 (14.3%)	8 (16.3%)	13 (26.5%)
DMT2/IGT (yes) [n.113]	63 (55.8%)	20 (17.7%)	13 (11.5%)	17 (15%)

Conclusion: The results from the present study in a real-world setting strongly advocate for routine screening for MAFLD and NASH by LSM in PwO, regardless of WHO category, attending the outpatient specialist clinic for obesity.

Email: nicolai.albrechtsen@sund.ku.dk

Background and aims: Fatty liver disease has been associated with metabolic disturbances. MAFLD is defined as hepatic steatosis with either overweight, type 2 diabetes (T2D), or at least two metabolic comorbidities. We hypothesized that metabolic disturbances associated with liver disease are pronounced in the postprandial phase and may be identified by a standardized meal. We therefore aimed to study the fasting and postprandial state in biopsy-proven healthy, MAFLD and cirrhosis.

Method: We included 29 participants, 10 healthy controls (age 23 ± 0 years, BMI 25 ± 1 kg/m^2), 9 patients with non-alcoholic fatty liver disease (NAFLD) (age 50 ± 5 years, BMI 35 ± 2 kg/m^2, no/mild fibrosis) and 10 patients with cirrhosis (age 62 ± 3 years, BMI 32 ± 2 kg/m^2, Child A/B). None of the included participants had T2D. The participants were randomized 1:1 to "fasting" or "postprandial" (Nutridrink, Nutricia, 300 kcal). Blood samples were obtained at baseline and 15, 45, 60, 90 and 120 minutes. At time point 60, blood from the liver vein was collected and a transjugular liver biopsy was performed. Levels of glucose, insulin, C-peptide, glucagon, and fibroblast growth factor 21 (FGF21) were measured in peripheral blood, and glucagon and FGF21 as well in liver vein blood. Results are presented as ± SEM. Peak concentrations were calculated as mean ± SEM of individual peaks. The analyses compared controls versus NAFLD and cirrhosis.

Results: 8/9 patients with NAFLD and 9/10 patients with cirrhosis were classified as MAFLD. Postprandial increase in glucose and C-peptide was significantly greater in NAFLD and cirrhosis compared to controls, with peak glucose of 7 and 10 mmol/L (p = .006), and peak C-peptide of 2675 ± 273 and 3340 ± 1048 pM versus 1689 ± 190 pM. Postprandial iAUC for insulin was greatest in patients with NAFLD (p = .037). Patients with NAFLD and cirrhosis had hyperglucagonemia, a phenotype causally related to prediabetes. FGF21 was significantly increased in NAFLD and cirrhosis and correlated to age (r = .61, p = .001) and fasting glucose (r = .54, p = .006). Glucagon was higher in liver vein compared to peripheral blood while FGF21 levels were similar in liver and peripheral blood.

Conclusion: We found significant metabolic dysfunction after a test meal in patients with MAFLD without diabetes compared to healthy controls and that finding that was pronounced in cirrhosis. Patients with MAFLD had impaired glucose tolerance, hyperinsulinemia and hyperglucagonemia, suggesting MAFLD to be a condition of prediabetes.

THU069

Lean non-alcoholic fatty liver disease patients from the global NASH registry

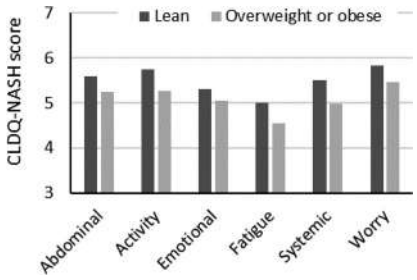
Email: zobair.younossi@inova.org

Background and aims: Although vast majority of patients with NAFLD are overweight and obese, NAFLD can be seen among lean individuals. The aim was to assess prevalence of lean NAFLD in different regions of the world.

Method: The Global NASH Registry enrolled patients with an established diagnosis of NAFLD from real-world practices in 18 countries (Australia, China, Cuba, Egypt, Greece, Hong Kong, India, Italy, Japan, Saudi Arabia, Malaysia, Mexico, Pakistan, Russia, Spain, Taiwan, Turkey, USA) in 6 out of 7 Global Burden of Disease (GBD) super-regions. Clinical and patient-reported outcomes (PRO) data (CLDQ-NASH, FACIT-F, WPAI) were collected. Lean NAFLD was defined as NAFLD in patients with BMI <25 kg/m2, or 23 kg/m2 for patients of East Asian origin.

Results: There were 6096 NAFLD patients included (as of November 10, 2021): 48% from High-Income super-region, 24% Middle East and North Africa (MENA), 12% Southeast Asia, 7% Latin America, 6% from Eastern Europe and Central Asia, and 3% South Asia super-region. Of these, 7.3% were lean. The rates of lean NAFLD were the highest in Southeast Asia (12%) and South Asia (31%), the lowest in Eastern Europe and Central Asia (<2%) and MENA (4%) (p < 0.0001). In comparison to overweight/obese patients, lean NAFLD patients were older (mean age 53 vs. 51 years) and predominantly of Asian race (48% vs. 18%) (p < 0.01). Furthermore, lean patients had lower rates of diabetes (28% vs. 41%), hypertension (35% vs. 52%), hyperlipidemia (40% vs. 50%), sleep apnea (8% vs. 33%), clinically overt fatigue (25% vs. 36%), and histologic cirrhosis (10% vs. 15%), but more abdominal pain (25% vs. 18%) and higher FIB-4 scores (mean 1.8 vs. 1.3) (all p ≤0 .02). In multivariate analysis, having lean NAFLD (as opposed to overweight/obese NAFLD) was independently associated with older age (OR = 1.019 (1.008–1.030) per year), enrollment outside of MENA region (OR = 0.43 (0.31–0.58)) and from South Asia (OR = 5.01 (3.42–7.45)) sites (reference: High-Income), absence of type 2 diabetes

(OR = 0.61 (0.46–0.80)) and hypertension (OR = 0.46 (0.35–0.60)), and presence of regular exercise (OR = 1.55 (1.21–2.00)) (all p < 0.01). Lean NAFLD also had higher PRO scores than overweight/obese NAFLD (all domains of CLDQ-NASH and FACIT-F) (all p < 0.01) (Figure). In multivariate analysis, lower total CLDQ-NASH scores (range 1–7) in lean NAFLD patients were independently associated with enrollment from MENA region, history of anxiety, depression, fatigue, and abdominal pain (beta from – 0.40 to – 0.67 for each condition) (p < 0.01).



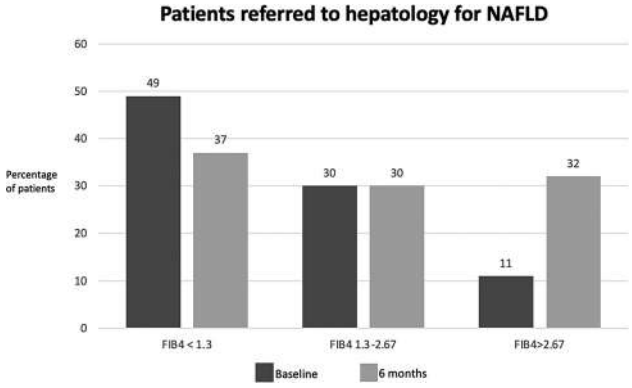
Conclusion: Lean NAFLD patients seen in real-world practices across the world have different clinical and PRO profiles in comparison to NAFLD patients who are overweight or obese.

THU070

Automated FIB-4 calculator and targeted provider education improved referral of at-risk fibrotic NAFLD patients

Cindy Piao[1], Elvis Arteaga[2], Connor Reilly[2], Jesse Simpson[2], Ryan Peck[2], Trevor Pratt[2], Troy Peterson[2], Mopelola Adeyemo[3], Shuai Chen[2], Aili Guo[2], Scott MacDonald[2], Souvik Sarkar[1]. *[1]UC Davis Health-Gastroenterology, Sacramento, United States; [2]UC Davis Medical Center, Sacramento, United States; [3]University of California, Los Angeles, Los Angeles, United States*
Email: ssarkar@ucdavis.edu

Background and aims: Non-alcoholic fatty liver disease (NAFLD) is the leading cause of chronic liver disease with increasing rates globally. Patients with a higher degree of liver fibrosis in NAFLD are at an increased risk for liver-related mortality but get missed easily during the referral process, based on our[1] and other prior data[2]. Our project aims to improve early detection and linkage-to-care of fibrotic NAFLD patients using a combination of automated electronic health record (EHR)-based FIB-4 score and directed provider education within our tertiary care center, serving a large population of Northern California.
Method: We implemented a health-system wide FIB-4 score calculator, embedded in the EHR that providers can easily add to their workflow for NAFLD patient triaging. Subsequently we provided targeted education to all relevant providers taking care of NAFLD patients. All referrals for NAFLD (defined by specific ICD 9/10 codes), to the hepatology from February 2020- August 2021, were retrieved. Patient characteristics were determined with FIB-4 score being essential for determination of fibrotic NAFLD and comparative analysis with prior data[1].
Results: A total of 303 referrals were placed for NAFLD, of which 62% (n = 188) patients had FIB-4 score at the time of referral. Of the 188 patients, 62 patients with diabetes mellitus and 44% of them had FIB-4 ≥1.3. Compared to prior referrals of 49% with FIB-4 score<1.3, in current referrals after a 6-month post-FIB-4 triage implementation, 37% had FIB-4 <1.3 (Fig 1). This suggested a decrease in unnecessary referrals to hepatology. Primary care doctors referred 73% while endocrinology referred 1% of all patients. We noted higher rates of fibrotic NAFLD patients with FIB-4 ≥1.3 in current referrals compared to prior (63% vs 41%). Furthermore, 32% of current referrals were with severe fibrotic disease defined by FIB-4 >2.67 vs 11% previously (Fig 1). This suggested an increase in appropriate referrals for specialty care. Secondary fibrotic testing using imaging modalities such as ultrasound or magnetic resonance elastography was done in 36% of those with FIB-4 ≥1.3, suggesting room for further refinement.



Conclusion: Automated FIB-4 score in EHR can improve appropriate linkage-to-care for at-risk fibrotic NAFLD, especially when coupled with targeted provider education. The durability of such improvement is essential to study along with the need to increase broad acceptance across health systems.

Long term outcomes of non-alcoholic fatty liver disease (NAFLD) and metabolic associated fatty liver disease (MAFLD)

Zobair Younossi[1,2,3], James Paik[2,3], Issah Younossi[4], Pegah Golabi[1,2,3], Michael Harring[1], Linda Henry[1,2,4]. *[1]Inova Health System, Inova Medicine; [2]Beatty Liver and Obesity Research Program, Inova Health System; [3]Center for Liver Disease, Inova Medicine; [4]Center for Outcomes Research in Liver Disease*
Email: zobair.younossi@inova.org

Background and aims: NAFLD and MAFLD are part of the spectrum of fatty liver disease (FLD). Our aim was to compare the outcomes of patients with NAFLD or MAFLD.
Method: Using data from NHANES III and NHANES 2017–2018, FLD was defined as moderate to severe hepatic steatosis by ultrasound (NHANES III) or controlled attenuation parameter (CAP) of ≥285 dB/m (NHANES 2017–2018). Death data were obtained from National Death Index (NDI). NAFLD was defined as FLD without other liver diseases and excessive alcohol consumption (EAC). MAFLD was define as FLD with metabolic dysfunction-one of the following three criteria, overweight/obesity, presence of type 2 diabetes mellitus or metabolic dysregulation (at least two metabolic risk abnormalities).

Table 1. Hazard ratios of risk factors for All-Cause Mortality among Adults with MAFLD and NAFLD: NHANES III

Risk factors	MAFLD		NAFLD	
	HR*(95% CI)	P	HR* (95% CI)	P
Metabolic risk abnormalities				
Central obesity	1.37 (1.05 - 1.78)	0.0217	1.30 (1.05 - 1.63)	0.0192

* HRs and 95% CI were weighted to U.S. population and adjusted for age, sex, race, education, income, marital status, smoking status, and physical activity.
** defined as FIB-4 ≥ 1.30

Results: In NHANES III, 12, 878 adults (age 43.1 years; 49.5% male; 20.3% FLD, 16.5% NAFLD; 18.1% MAFLD, EAC 15.0%) were included. In NHANES 2017–2018, 4, 328 adults (age 48.0 years; 49.1% male; 36.8% FLD; 34.2% NAFLD; 36.3% MAFLD). In both cohorts, there was excellent concordance between diagnosis of MAFLD and NAFLD [Cohen's kappa coefficient of 0.83 (95% CI: 0.82–0.85) in NHANES III and 0.94 (95% CI: 0.93–0.95) in NHANES 2017–2018]. There were no statistical differences in the characteristics of MAFLD as compared to NAFLD except for presence of obesity and EAC. After 19.2 years of follow-up for NHANES III cohort, there were no significant differences in cumulative mortality between MAFLD and NAFLD: all-causes (45.0% [95% Confidence interval, 41.6–48.3] vs 41.5% [38.3–44.8]); cardiovascular disease (15.5% [13.4–17.6] vs 13.9 [11.8–15.9]); extra-hepatic cancer (9.2% [7.5–10.8] vs. 8.6% [6.6–10.5]); liver (3.0% [2.0–4.0] vs. 1.8% [1.0–2.7]) and diabetes (1.4% [1.4–3.5] vs. 2.5% [1.3–3.8]). Furthermore, except for diagnosis of ALD among MAFLD, there were no discernable differences in mortality risk factors between NAFLD and MAFLD. In fact, independent predictors of mortality for both included presence of central obesity, insulin resistance/T2DM, CKD, CVD as well as high triglycerides and low HDL cholesterol ($p < 0.05$). Of 75 liver deaths among MAFLD patients, 66.7% were also classified as NAFLD and 33.3% as ALD. Among MAFLD, the strongest predictor of liver deaths was diagnosis of ALD (HR = 4.50 [1.89–10.75]).
Conclusion: MAFLD and NAFLD diagnostic classifications have excellent concordance. Furthermore, there are similar cause-specific or overall mortality. The strongest predictor of liver mortality among MAFLD is presence of ALD.

THU072

MARC1 and HSD17B13 variants have protective effects on liver injury in the obese: results from a prospective cohort of patients undergoing bariatric surgery

Piotr Kalinowski[1], Wiktor Smyk[2], Małgorzata Nowosad[1], Rafał Paluszkiewicz[1], Łukasz Michałowski[3], Bogna Ziarkiewicz-Wróblewska[3], Susanne N Weber[2], Frank Lammert[2,4], Krzysztof Zieniewicz[1], Marcin Krawczyk[2,5].

Email: marcin.krawczyk@uks.eu

Background and aims: Hepatic steatosis is modulated by genetic variants like *PNPLA3* (p.I148M), *TM6SF2* (rs58542926), and *MBOAT7* (rs641738). Recently, *MARC1* (rs2642438) and *HSD17B13* (rs72613567) polymorphisms were shown to have protective effects in patients with chronic liver diseases. Here, we analyse these fatty liver-related genes in patients undergoing bariatric surgery.
Method: The study cohort was composed of 165 prospectively recruited obese individuals (BMI 43.8 ± 5.7 kg/m^2, 66% women, 48 with diabetes mellitus) who underwent laparoscopic sleeve gastrectomy The *PNPLA3*, *TM6SF2*, *MBOAT7*, *MARC1* and *HSD17B13* polymorphisms were genotyped performed using TaqMan assays. Liver biopsies were performed intraoperatively in all patients.
Results: In total, 70.3% of operated patients presented with hepatic steatosis, whereas NASH was detected in 28.5% of them; none had cirrhosis. Patients carrying the *MARC1* minor allele displayed a lower risk of developing fibrosis stage 1a (OR = 0.54, p = 0.03), 1b (OR = 0.47, p = 0.01), 1c (OR = 0.46, p = 0.01), and 2 (OR = 0.42, p = 0.03). The *PNPLA3* risk allele was associated with increased odds of hepatic steatosis (S2 and S3), fibrosis (1b to 2), and NASH (OR = 2.22, p = 0.04 in multivariate model). This variant was also significantly (p <0.01) associated with increased fasting glucose (p = 0.03) and glycated haemoglobin (HbA1c) levels. Analysis restricted to 48 carriers of the *PNPLA3* risk alleles (29.1%) showed that the *MARC1* polymorphism decreases the odds of developing fibrosis. Furthermore, *MARC1* was an independent protective factor against fibrosis in multivariate analysis (OR = 0.51, 95% CI 0.28–0.92, p = 0.04). Carriers of the *HSD17B13* variant presented, in turn, with lower serum ALT (p = 0.03) and AST (p = 0.04) activities. The *TM6SF2* polymorphism was associated with the risk for S3 steatosis (OR = 17.52, p <0.01) and increased ALT (p = 0.04).
Conclusion: Fatty liver is a frequent condition in patients scheduled for bariatric surgery, but the *MARC1* and *HSD17B13* gene variants diminish hepatic injury in these individuals. Variant *MARC1* might reduce the harmful effects of the major genetic risk factor for fatty liver, namely, *PNPLA3* p.I148M.

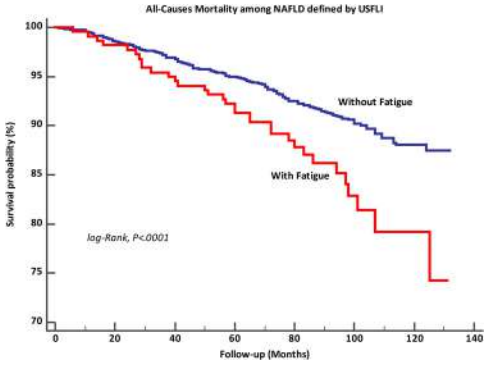
THU073

The impact of fatigue on mortality of patients with non-alcoholic fatty liver disease (NAFLD): data from national health and nutrition examination survey (NHANES) 2005–2018

Zobair Younossi[1,2,3], James Paik[1,2,3], Pegah Golabi[1,2,3], Youssef Younossi[4], Linda Henry[1,3,4], Fatema Nader[4]. *[1]Inova Health System, Medicine Service Line; [2]Center for Liver Disease, Inova Medicine; [3]Betty and Guy Beatty Center for Liver and Obesity, Inova Health System; [4]Center for Outcomes Research in Liver Disease*
Email: zobair.younossi@inova.org

Background and aims: Fatigue is common among patients with NAFLD. Fatigue can negatively impact patient reported outcomes and clinical outcomes.
Aim: To determine the prevalence of fatigue and its association with all-cause mortality for patients with NAFLD.
Method: Data for adults (≥18 years) collected as part of the National Health and Nutrition Examination Survey (NHANES 2005–2010 and 2017–2018) with mortality data via linkage to the National Death Index (through 2015) were used for this study. For NHANES 2005–2010, NAFLD was defined by Fatty Liver Index adjusted for the multiethnic U.S. population (US-FLI). Additionally, transient elastography (TE) with a controlled attenuation parameter (CAP) of ≥285 dB/m was used to define NAFLD for NHANES 2017–2018. Excluded were patients with other liver diseases and excessive alcohol use. Fatigue was assessed through the Patient Health Questionnaire (PHQ-9) question, "Over the last 2 weeks, how often have you been bothered by feeling tired or having little energy?" Significant fatigue was defined as a response of "nearly every day" to the question.
Results: Of the NHANES 2005–2010 study cohort (n = 5, 429, mean age 47.1 years, 49.7% male, 69.9% white), 37.6% had NAFLD. Compared to non-NAFLD group, fatigue was more common in individuals with NAFLD (8.35% vs 6.0%, P = 0.002). Among the NHANES 2017–2018 study cohort (n = 3, 830, mean age 48.3 years, 48.6% male, 62.3% white), 36.9% had NAFLD and 7.2% had fatigue. Compared to non-

NAFLD subjects, those with NAFLD were older (51.4 vs 46.4 years), more likely to be male (55.6% vs 44.6%), and more likely to report fatigue (8.7% vs 6.2%), sleep trouble (ST) (34.0% vs 26.7%), metabolic abnormalities (90.4% vs. 58.4%), asthma (17.3% vs 12.7%), Chronic Obstructive Pulmonary Disease (COPD) (7.7% vs 6.1%), arthritis (34.3% vs 24.1%), thyroid disease (13.0% vs 9.9%), cardiovascular disease (CVD) (10.4% vs. 6.3%), significant fibrosis (liver stiffness >8.0 kPa, 17.9% vs 3.5%), and advanced fibrosis (>13.1 kPa, 5.4% vs 0.9%) (all p <.003). Among NAFLD, multivariate logistic regression analysis showed that presence of depression (Odds Ratio = 16.2, 95% Confidence interval, 6.02–43.6), ST (3.34, 1.85–6.05), arthritis (2.25, 1.29–3.92), COPD (2.91, 1.47–5.77), CVD (3.64, 2.04–6.51) and sleep quantity (+7 hours) (0.52, 0.31–0.88) were associated with presence of fatigue. Multivariable cox model demonstrated that NAFLD patients with fatigue had a 2.3-fold higher mortality than NAFLD without fatigue (HR: 2.31, 95%CI: 1.37–3.89, P = 0.0024).



Conclusion: Fatigue is more common among NAFLD and is driven mainly by depression, sleep trouble, and CVD. Among NAFLD, presence of fatigue is associated increased risk for mortality.

Email: javiercrespo1991@gmail.com

Background and aims: Cardiovascular disease (CVD) is the main cause of mortality among patients with Metabolic dysfunction-Associated Fatty Liver Disease (MAFLD). Currently, clinical evidence shows that MAFLD could be a precursor for future development of metabolic syndrome (MS) components, linked to higher cardiovascular risk (CVR), regardless of classical risk factors. For this reason, our main aim was to determine if patients with MAFLD have a higher CVR as a consequence of liver disease activity.

Method: Cross-sectional study that includes 1, 587 patients with MAFLD, diagnosed by liver biopsy from the HEPAmet Registry, and 1, 587 from the general population (ETHON cohort), age- and sex-matched. The CVR was evaluated with the Systematic Coronary Risk Evaluation (SCORE) model. In addition, the presence of carotid plaques and carotid intima-media thickness were analysed by ultrasound, in a subgroup of MAFLD patients without previous CVD, to establish their use in reclassification of CVR determined by SCORE. Multivariate regression analysis, adjusted for classical CVR factors, was used to evaluate whether CVR is influenced by liver disease activity.

Results: An increased prevalence of cardiovascular events was observed among patients with MAFLD compared to general population (10.3% vs 7.9%; p = 0.02), finding significant differences (p < 0.001) in CVR regarding SCORE categories (low CVR: 32.5% vs 37.3%; very high CVR: 36.9% vs 14.6%). NASH presence (OR 1.490 [IC 95%: 1.037–2.141]) and advanced fibrosis (OR 1.442 [IC 95%: 1.001–2.076]) were independent risk factors associated with high/very high SCORE category, after adjusted by classical CVR factors. The Fibrosis-4 (FIB-4) index was associated with high/very high SCORE category, maintaining as an independent and significant risk factor after adjusting by classical factors (OR 1.423 [IC 95%: 1.238–1.634]; p < 0.001), and showing statistically significant discrimination of high/very high CVR category (AUC: 0.655 [IC 95%: 0.628–0.682], p <0.001). Using carotid ultrasound, it was observed that 20% of patients with low/moderate CVR were reclassified into high-risk category due to the presence of atheromatosis.

Conclusion: The presence of NASH, advanced fibrosis and a higher FIB-4 index were associated with a high/very high CVR in patients with MAFLD, even after considering classical risk factors. The ability of the SCORE model to predict CVD in MAFLD patients may not be as powerful as in the general population.

THU075

Changes in hepatic fat fraction as assessed by MRI-PDFF are correlated with changes in markers of hepatic inflammation, disease activity and fibrosis in biopsy-proven non-cirrhotic NASH with fibrosis

Samuel Daniels[1], Darren Robertson[1], Jose Sanchez[2], Janeli Sarv[2], Antonio Manzur[1], Lutz Jermutus[3], Arun Sanyal[4], Benjamin Challis[5], Sudha Shankar[6]. *[1]Early CVRM, Biopharmaceuticals RandD, Early Clinical Development, Cambridge, United Kingdom; [2]Data Science and Artificial Intelligence, RandD, Early Biometrics and Statistical Innovation, Gothenburg, Sweden; [3]Early CVRM, Biopharmaceuticals RandD, Cambridge, United Kingdom; [4]Virginia Commonwealth University, Division of Gastroenterology, Hepatology and Nutrition, Richmond, United States; [5]Early CVRM, Biopharmaceuticals RandD, Translational Science and Experimental Medicine, Research and Early Development, Cambridge, United Kingdom; [6]Early CVRM, Biopharmaceuticals RandD, Early Clinical Development, Gaithersburg, United States*
Email: samuel.daniels@astrazeneca.com

Background and aims: MRI-PDFF is the gold standard for non-invasive assessment of hepatic fat fraction (HFF) in non-alcoholic steatohepatitis (NASH) and is commonly used within early clinical trials to determine treatment efficacy on steatosis. HFF reduction has been associated with an increased likelihood of NASH resolution. However it is unclear whether reductions in hepatic steatosis bear a relationship with changes in markers of hepatic inflammation, disease activity and fibrosis.
Method: PROXYMO was a 19 week multi-centre phase 2 trial to investigate the safety and efficacy of cotadutide in 74 participants with biopsy confirmed non-cirrhotic NASH with fibrosis (NCT04019561). Post-hoc analysis was performed to investigate whether changes in HFF in the study population were associated with changes in non-invasive markers of hepatic fibrosis, NASH disease activity and inflammation within participants who had baseline and week 19 values. Participants were pooled (active and placebo) and the relative changes in HFF after 19 weeks were assessed against percentage change in non-invasive markers.
Results: Within pooled participants, relative change in HFF was significantly correlated with markers of hepatic inflammation (ALT $R = 0.52$ ($p < 0.0001$)), NASH disease activity (NIS-4 $R = 0.63$ ($p < 0.0001$)) and hepatic fibrosis (PRO-C3 $R = 0.44$ ($p = 0.0012$)). Changes in fibrosis biomarkers were correlated with changes in liver enzymes. Change in body weight was significantly correlated with change in HFF. Relative HFF change was divided into quartiles; those in the quartile of greatest relative HFF reduction had significantly greater reductions in ALT, AST, NIS-4 and PRO-C3.

Spearman Correlation Statistics

Variable correlated to HFF	N	R	95% Confidence Limits		p Value
PRO-C3	49	0.44	0.19	0.64	0.0012
NIS-4	38	0.63	0.39	0.79	<.0001
ALT	51	0.52	0.29	0.70	<.0001

Conclusion: Reductions in HFF as assessed by MRI-PDFF were associated with reductions in non-invasive markers of hepatic inflammation, NASH disease activity and fibrosis. Furthermore, subjects with improvements in HFF had significantly greater reductions in ALT, AST, NIS-4 and PRO-C3.

THU076

The metabolic dysfunction-associated fatty liver disease definition, regardless of its clinical subclassification, identifies patients at high risk for liver disease progression

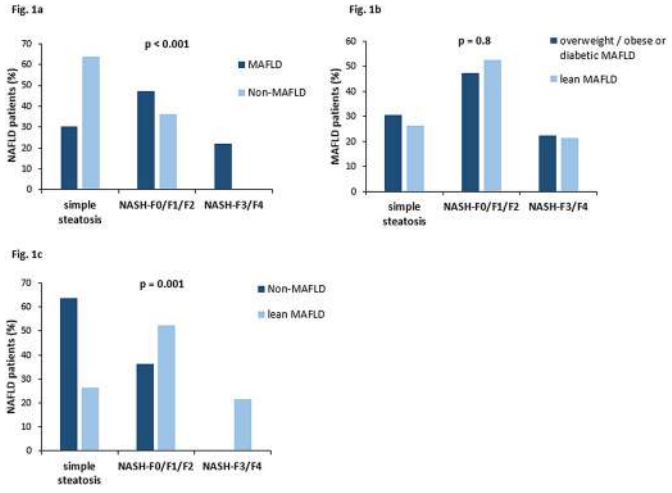
Email: javiercrespo1991@gmail.com

Background and aims: Several population studies indicate that Metabolic dysfunction-Associated Fatty Liver Disease (MAFLD) diagnostic criteria better identify which patients are at high risk for liver disease progression. However, the impact of this new definition on specialized clinical practice is still unknown. Here, our aim was to compare, MAFLD vs non-MAFLD patients, from a cohort of Non-Alcoholic Fatty Liver Disease (NAFLD) patients with liver biopsy.
Method: A cross-sectional multicenter study with 2, 148 NAFLD patients from the HEPAmet Registry with liver biopsy, with no other causes of chronic liver disease and with the necessary clinical data to reach MAFLD diagnosis. Clinical, analytical and elastographic data, close to liver biopsy date, were collected. The Non-Alcoholic Steatohepatitis (NASH) diagnosis was based on the presence at once of steatosis, ballooning and lobular inflammation.
Results: Only 1.5% of patients did not fulfill MAFLD diagnostic criteria. Compared to non-MAFLD, MAFLD patients showed a higher mean value of Fibroscan (12.5 ± 9 vs 6.5 ± 2.3; $p = 0.002$) and had more ballooning, lobular inflammation and significant/advanced fibrosis

(38.6% vs 9.1%; p = 0.001); as well as, NASH (Fig. 1a). Among MAFLD patients, there were no differences in histological diagnosis between lean MAFLD and the remaining of patients (Fig. 1b). Differences in liver affectation between lean MAFLD and non-MAFLD maintained significant (Fig. 1c). The most powerful independent risk factors for advanced fibrosis in MAFLD patients were Type 2 Diabetes Mellitus (OR 2.37; IC 95% 1.79–3.15; p <0.001) and Arterial Hypertension (OR 1.47; IC 95% 1.09–1.99; p = 0.01). Alcohol consumption (10–30 g/d) was the only factor associated with the presence of advanced fibrosis in lean MAFLD (OR 8.44; IC 95% 1.57–45.39; p = 0.01).



Conclusion: The metabolic dysfunction that defines MAFLD better identifies patients at risk for advanced liver disease, regardless of whether they are overweight/obese or diabetic.

THU077

Assessment of the prevalence of non-alcoholic fatty liver disease, its severity, and comorbidities in lean americans: national health and nutrition examination surveys (NHANES) with transient elastography assessment from 2017 to 2018

Emily Truong[1], Galen Cook-Wiens[2], Naim Alkhouri[3], Mazen Noureddin[4]. *[1]Cedars Sinai Medical Center, Internal Medicine, Los Angeles, United States; [2]Cedars Sinai Medical Center, Los Angeles, United States; [3]Arizona Liver Health, Phoenix, United States; [4]Cedars Sinai Medical Center, Karsh Division of Gastroenterology and Hepatology, Comprehensive Transplant Center, Los Angeles, United States*
Email: emily.truong@cshs.org

Background and aims: Previous studies examined lean non-alcoholic fatty liver disease (NAFLD), which affects 10–20% of non-obese or lean Americans and is associated with lower rates of hyperlipidemia, hypertension, diabetes, and cirrhosis. We described characteristics and NAFLD prevalence and severity in the lean population in National Health and Nutrition Examination Surveys (NHANES) from 2017 to 2018 by using Fibroscan to directly assess steatosis and fibrosis.

Method: We analyzed NHANES data from 2017–2018. Inclusion criteria were age ≥18 years and completion of interview, laboratory testing, and FibroScan®. Exclusion criteria were excessive alcohol use (≥7 or 14 drinks/week for females or males, respectively) or viral hepatitis. Non-lean NAFLD was defined as body mass index (BMI) ≥25 kg/m^2, and lean NAFLD was defined as BMI <25 kg/m^2. NAFLD was defined as controlled attenuation parameter >274 dB/m.

Results: Of 3899, 120 (3.1%) respondents were lean NAFLD, and 1453 (37.3%) respondents were non-lean NAFLD. Overall NAFLD prevalence was 40.34% (non-lean 37.27% vs lean 3.08%). Compared to non-lean NAFLD, lean NAFLD had significantly lower prevalence of prediabetes, though not significantly different prevalence of diabetes or hypertension. Lean NAFLD had lower mean CAP, FAST score, and median stiffness than that of non-lean NAFLD. Lean NAFLD had lower prevalence of fibrosis stage 2 or 3 and higher (≥F2 or ≥F3) and Fibroscan-AST (FAST) score compared to non-lean NAFLD. Neither fibrosis stage 4 (F4) nor FAST score ≥0.67 were significantly different between lean and non-lean NAFLD.

	CAP≥274		
Mean or percent (95% CI)	Non-lean NAFLD (unweighted n = 1453, weighted n = 66070260)	Lean NAFLD (unweighted n = 120, weighted n = 3807897)	p value
Severity of steatosis			
Mean CAP	324.17* (321.27 ; 327.07)	304.11* (299.32 ; 308.91)	<0.0001
Prevalence of fibrosis			
≥F2	15.72* (11.75 ; 20.32)	6.03* (2.21 ; 12.5)	0.0137
≥F3	10.31* (7.86 ; 13.16)	3.49* (1.07 ; 8.04)	0.0061
F4	5.08 (3.48 ; 7.09)	1.57 (0.1 ; 6.59)	0.1364
FAST ≥0.67	3.06 (2.27 ; 4.01)	1.04 (0.04 ; 5.06)	0.2496
Severity of fibrosis			
Mean FAST score	0.17* (0.16 ; 0.18)	0.11* (0.08 ; 0.13)	0.0002
Median stiffness (kPa)	6.88* (6.39 ; 7.38)	5.4* (4.27 ; 6.52)	0.0095

*Statistically significant. ≥F2, ≥F3, and F4 were defined by median stiffness ≥8.2, ≥9.7, and ≥13.6 kPa. F2/F3/F4 = fibrosis stage 2/3/4.

Conclusion: Compared with non-lean NAFLD, lean NAFLD had significantly higher prevalence of prediabetes and severity of hyperlipidemia. Although lean NAFLD had significantly decreased prevalence of ≥F2 and ≥F3 and lower FAST score compared to non-lean NAFLD, neither fibrotic non-alcoholic steatohepatitis nor cirrhosis prevalence were significantly different between lean and non-lean NAFLD. The largest to date to examine this subpopulation, this study highlights important implications for monitoring disease progression in the lean NAFLD population.

THU078

Coagulation imbalance is associated with hepatic fibrosis and vascular complications in patients with type2 diabetes and NAFLD

Francesca Alletto[1,2], Paolo Francione[1,2], Gabriele Maffi[1,2], Giordano Sigon[1,2], Annalisa Cespiati[1,2], Daniela Bignamini[1], Mariagrazia Clerici[3], Veena Chantarangkul[3], Armando Tripodi[3], Flora Peyvandi[2,4], Silvia Fargion[1,2], Anna Ludovica Fracanzani[1,2], Rosa Lombardi[1,2]. *[1]Fondazione Ca' Granda IRCCS, Policlinico Hospital of Milan, Unit of Internal Medicine and Metabolic Diseases, Milan, Italy; [2]University of Milan, Department of Pathophysiology and Transplantation, Milan, Italy; [3]Fondazione Ca' Granda IRCCS, Policlinico Hospital of Milan, Angelo Bianchi Bonomi Hemophilia and Thrombosis Center and Fondazione Luigi Villa, Milan, Italy; [4]Fondazione Ca' Granda IRCCS, Policlinico Hospital of Milan, Unit of Internal Medicine Hemostasis and Thrombosis, Milan, Italy*
Email: rosa.lombardi@unimi.it

Background and aims: Both non-alcoholic fatty liver disease (NAFLD) and type 2 diabetes mellitus (T2DM) are characterized by a pro-coagulant state and expose patients to vascular complications. The interaction between pro-coagulant state, vascular complications and advanced liver disease has not been defined yet. Aim: to evaluate in a cohort of patients with T2DM and NAFLD if alterations in coagulation tests are associated with high prevalence of hepatic fibrosis and vascular complications.

Method: 96 consecutive outpatients with T2DM and ultrasound fatty liver and an age and sex matched control group of 156 healthy individuals were enrolled. For all subjects, determination of serum pro- (i.e factor II-FII, factor VIII-FVIII) and anti-coagulant factors (i.e protein C-PC, antithrombin-AT) and test of thrombin generation (ETP ratio, peak ratio, FVIII/PC) were obtained. In the T2DM cohort, significant liver fibrosis (≥F2) was diagnosed by Fibroscan (i.e liver stiffness measurement-LSM>7.0/6.2 kPa M/XL probe). Evaluation of microvascular (i.e retinopathy, nephropathy and neuropathy) and macrovascular complications (i.e carotid plaques and history of cardiovascular (CV) events) was assessed.

Results: In the T2DM group mean age was 65 ± 7 years, 66% male. Mean FII was 95.9 ± 12.8, FVIII 130.3 ± 33.2, PC 112.8 ± 20.8, AT 106 ± 14.4, ETP ratio 0.64 ± 0.09, peak ratio 0.93 ± 0.05, FVIII/PC 1.2 ± 0.3. Despite only 5% of the cohort had increased transaminases, significant hepatic fibrosis was present in 14% by LSM. Microvascular complications were present in 29 (30%) patients (retinopathy in 8%, nephropathy in 23% and neuropathy in 4%) whereas plaques in 70 (73%) and CV events in 23 (24%). Compared to the control group, T2DM patients presented a pro-coagulant imbalance (ETP ratio 0.64 ± 0.09 vs 0.59 ± 0.18, p = .0.12; FVIII/PC 1.2 ± 0.3 vs 1.02 ± 0.3, p = 0.03). In the T2DM cohort, indexes of procoagulant imbalance as AT and FVIII/PC were independently associated with significant fibrosis by LSM>7.0/6.2 kPa with M/XL probe (multivariate analysis for AT corrected for age, sex, T2DM duration, HbA1c, overweight, hypertension: OR 0.89; CI 95% 0.80–0.98) and microvascular complications (multivariate analysis corrected for age, sex, smoking, T2DM duration, HbA1c, overweight, hypertension, use of statins, uric acid for AT: OR 0.93; CI 95% 0.88–0.98; and for FVIII/PC ratio: OR 8.0; CI 95% 1.00–65.8).
Conclusion: In patients with T2DM and NAFLD a pro-coagulant imbalance was found compared to healthy controls and it was associated with both hepatic and vascular complications, speculating on a possible common pathogenetic pattern. Further studies and a wider cohort are warranted to define the clinical application of these coagulation alterations. However, our results point on the need of a careful evaluation also of hepatic complications in diabetics.

THU079

Presence of two or more metabolic risks regardless of fatty liver is a risk factor for significant hepatic fibrosis

Huiyul Park[1], Dae Won Jun[2], Eileen Yoon[2], Sang Bong Ahn[3], Hyo Young Lee[4], Hyunwoo Oh[4], Bo-Kyeong Kang[5], Mi Mi Kim[5], Chul-min Lee[5], Joo Hyun Sohn[6]. *[1]Uijeongbu Eulji Medical Center, Department of Family medicine, Gyeonggi-do, Korea, Rep. of South; [2]Hanyang University College of Medicine, Department of Medicine, Seoul, Korea, Rep. of South; [3]Nowon Eulji Medical Center, Eulji University School of Medicine, Department of Medicine, Seoul, Korea, Rep. of South; [4]Uijeongbu Eulji Medical Center, Department of Medicine, Gyeonggi-do, Korea, Rep. of South; [5]Hanyang University College of Medicine, Department of Radiology, Seoul, Korea, Rep. of South; [6]Hanyang University Guri Hospital, Hanyang University College of Medicine, Department of Medicine, Gyeonggi-do, Korea, Rep. of South*
Email: mseileen80@gmail.com

Background and aims: Metabolic syndrome and diabetes are well-known risk factors for hepatic fibrosis. However, hepatic fibrosis screening strategies for subjects with these risks have not yet been established. We aimed to identify the high-risk group for hepatic fibrosis screening, according to the type and number of metabolic risk factors.
Method: This was a retrospective cross-sectional cohort study using data from 13 nationwide centres. A total of 5, 111 subjects who underwent both magnetic resonance elastography and abdominal ultrasound as part of their health check-up were included. Subjects with viral hepatitis and/or a history of significant alcohol consumption were excluded.
Results: The prevalence of significant hepatic fibrosis was 7.3%. Among subjects with significant hepatic fibrosis, 41.3% did not have fatty liver. Hepatic fibrosis burden increased according to the number of metabolic abnormalities. Nearly 70% of subjects with significant hepatic fibrosis also had two or more metabolic risks and/or diabetes. However, significant fibrosis prevalence did not differ between the groups with and without fatty liver among those with healthy metabolic conditions. The presence of two or more metabolic abnormalities was an independent risk factor for significant hepatic fibrosis, even when the presence of fatty liver was corrected.
Conclusion: Health check-up examinees who have two or more metabolic risks and/or diabetes are at risk of hepatic fibrosis, regardless of fatty liver status. Thus, active screening for hepatic fibrosis in the setting of health check-up centres should be extended to subjects with two or more metabolic risks and/or diabetes, beyond those with fatty liver.

Pregnancy as a unique opportunity to identify NAFLD in women: a prospective assessment

Tatyana Kushner[1], Shaelyn O'Hara[1], Marcia Lange[1], Carin Carroll[2], Emma Rosenbluth[1], Pamela Argiriadi[1], Rachel Meislin[1], Joanne Stone[1], Keith Sigel[1], Rhoda Sperling[1], Scott Friedman[1], Norah Terrault[3]. *[1]Icahn School of Medicine at Mount Sinai; [2]University of Miami School of Medicine; [3]University of Southern California Keck School of Medicine*
Email: tatyana.kushner@mssm.edu

Background and aims: Non-alcoholic fatty liver disease (NAFLD) in U.S. women of reproductive age is rising and recent administrative claims-based data suggest a significant association of NAFLD with adverse pregnancy outcomes. We evaluated the prevalence and associated risk factors of NAFLD at a high-volume obstetrics center.
Method: In this prospective study, a liver ultrasound at time of routine pregnancy anatomy scan at 18–22 weeks' gestation was performed to assess for presence of NAFLD. Obstetric sonographers were trained to obtain liver images that were subsequently graded for hepatic steatosis by a radiologist blinded to clinical status. The proportion having elevated hepatic steatosis index (HSI) and meeting recently defined metabolic associated fatty liver disease (MAFLD) criteria was evaluated. A multivariable logistic regression model assessed independent predictors of NAFLD among pregnant women.
Results: Among 749 women approached for participation, satisfactory liver ultrasounds were obtained on 560 (75%) pregnant individuals; median age 28, 58% Hispanic ethnicity, 65% with pre-pregnancy BMI ≥25, 22% nulliparous. Seventy-eight (14.3%) had steatosis on ultrasound; 83% grade 1, 14% grade 2 and 3% grade 3. Overall, 36% had HSI ≥36; 11% satisfied MAFLD criteria. Only 4 of 560 (0.71%) carried a previous diagnosis of NAFLD. Women with steatosis were more likely to be of Hispanic ethnicity, have diagnoses of chronic hypertension and diabetes and have a pregnancy history of gestational diabetes (p < 0.05; see Table). Women with grade 2/3 steatosis were more likely to have a history of preeclampsia (30% vs 10%, p = 0.05). In multivariable analyses, Hispanic ethnicity (OR 2.57; 95% CI 1.30–5.09) and BMI (OR 1.06; 95% CI 1.01–1.11) were independently associated with NAFLD.
Conclusion: In this first time U.S. based prospective study of pregnant women, integration of ultrasound into obstetric care was feasible and effective in identifying women with NAFLD. NAFLD prevalence was 14%, similar to reports in non-pregnant women of reproductive age with Hispanic and elevated pre-pregnancy BMI women being at highest risk of NAFLD. Most had no prior diagnosis of NAFLD, highlighting a unique opportunity to identify and link women to specialized care.

N-terminal propeptide of type III collagen (PRO-C3) based risk for liver fibrosis predict cardiovascular events in non-alcoholic fatty liver disease

Francesco Baratta[1], Giulia Tozzi[2], Daniele Pastori[1], Alessandra Colantoni[1], Nicholas Cocomello[1], Stefano Cecchi[2], Mattia Coronati[1], Francesco Angelico[1], Maria Del Ben[1]. [1]*Sapienza-University of Rome;* [2]*Children's Hospital Bambino Gesù*
Email: francesco.baratta@uniroma1.it

Background and aims: N-terminal propeptide of type III collagen (PRO-C3) is cleaved off during the process of collagen III deposition. Serum levels of PRO-C3 properly correlate to biopsy-proven liver fibrosis stage and PRO-C3 was included in some risk scores, namely ADAPT, FIB-C3 and ABC3D to predict advanced liver fibrosis. While the association between other liver fibrosis risk scores (FIB4 and NAFLD fibrosis score) and cardiovascular events (CVEs) has been demonstrated, the association between PRO-C3 derived scores and CVEs has never been investigated. Aim of the study was to investigate the association between scores including PRO-C3, and CVEs incidence in a large prospective cohort of NAFLD patients.
Method: The present study is a post hoc analysis of the Plinio Study (ClinicalTrials.gov: NCT04036357). PRO-C3 detection was performed in plasma using ELISA commercial kit (Novus Biological). ADAPT, FIBC3 and ABC3D were calculated. Data on CVEs were prospectively collected with periodical phone calls (every six months) and visits (every 12 months).
Results: The median follow-up was 47.8 [25.3–72.8] months yielding 2786.5 person-years of observation. During the follow-up, 41 patients (1.5% year) experienced CVEs. Patients who experienced CVEs were more frequently males ($p = 0.010$) and had higher prevalence of type 2 diabetes ($p = 0.006$), metabolic syndrome ($p = 0.002$) and of prior CVE event ($p < 0.001$). The prevalence of impaired ADAPT ($p = 0.038$), FIBC3 ($p = 0.015$) and ABC3D ($p < 0.001$) were higher in patients with CVEs. At multivariate Cox regression analyses, the association with CVEs was confirmed for ABC3D>3 (HR: 2.29 [1.17–4.47]) in the whole population and for FIBC3 (HR: 1.40 [1.06–1.85]) and ABCD3 (HR: 1.40 [1.06–1.84]) only in patients who did not experience a CV event before enrollment (in primary prevention) (Table 1). In all the analyses performed in the whole cohort, prior-CVE was the strongest predictor of new onset CVEs during the follow-up (data not shown).

Table 1. Multivariate cox regression analysis in the whole population (Panel A) and in patients in primary prevention (Panel B)

Panel A.	CVEs aHR (95% C.I. for aHR)	CHD aHR (95% C.I. for aHR)
ADAPT[2]	1.24 [0.93-1.64]	1.19 [0.83-1.69]
ADAPT>6.3287[2]	1,23 [0.42-3.63]	0.50 [0.07-2.93]
FIBC3[3]	1.22 [0.97-1.55]	1.21 [0.90-1.61]
FIBC3>0.4[3]	1.40 [0.66-2.98]	1.04 [0.38-2.86]
ABC3D[3]	1.24 [0.98-1.57]	1.27 [0.95-1.70]
ABC3D>3[3]	2.29 [1.17-4.47]*	2.38 [1.04-5.43]*
Panel B.	**CVEs aHR (95% C.I. for aHR)**	**CHD aHR (95% C.I. for aHR)**
ADAPT[2]	1.34 [0.91-1.99]	1.39 [0.87-2.21]
ADAPT>6.3287[2]	1,98 [0.46-8.54]	1.35 [0.18-10.15]
FIBC3[3]	1.40 [1.06-1.85]*	1.41 [1.01-1.95]*
FIBC3>0.4[3]	1.22 [0.44-3.39]	1.07 [0.30-3.85]
ABC3D[3]	1.40 [1.06-1.84]*	1.27 [0.95-1.70]
ABC3D>3[3]	1.69 [0.69-4.18]	1.27 [0.89-1.83]

[1]Adjusted for age, sex, prior CVEs, smoking habits, BMI, diabetes, platelets; [2]Adjusted for sex, prior CVEs, smoking habits and BMI; [3]Adjusted for sex, prior CVEs, smoking habits; *p<0.05. CVEs: cardiovascular and cerebrovascular events; composite: CVEs + new onset atrial fibrillation: CHD: coronary heart disease; HR: Hazard ratio; aHR: adjusted HR; C.I: confidence interval. PRO-C3: N-terminal propeptide of type III collagen; ADAPT: age, of diabetes, PRO-C3, and platelet algorithm; FIBC3: FIBC3 diagnostic panel; ABC3D: age, BMI, platelet count, PROC3, diabetes derived score.

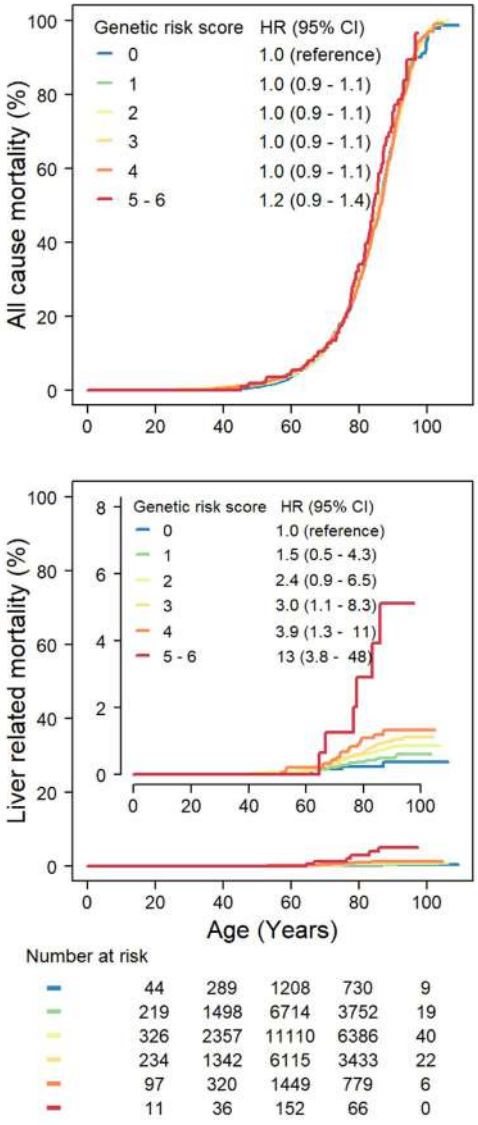
Conclusion: This from the Plinio cohort study is the first evidence of an association between ADAPT, FIBC3, ABC3D and cardiovascular events in NAFLD. These scores detect high-risk patients for both liver and cardiovascular complications, may contribute to better identify a sub-population of NAFLD patients who deserve a more holistic approach.

THU082

Genetic risk of fatty liver disease and mortality in the general population

Helene Gellert-Kristensen[1], Børge Nordestgaard[2], Anne Tybjaerg Hansen[1], Stefan Stender[1]. [1]*Rigshospitalet, Clinical Biochemistry, København, Denmark;* [2]*Herlev Hospital, Clinical Biochemistry, Herlev, Denmark*
Email: stefan.stender@regionh.dk

Background and aims: Fatty liver disease associates with increased mortality due to extrahepatic causes, as well as increased all-cause mortality. However, it remains unclear if these associations reflect a causal effect of fatty liver disease rather than confounding due to coexisting comorbidities. The aim of this study was to use genetic variants (which are less susceptible to confounding) to assess if fatty liver disease *per se* is likely to causally influence mortality.
Method: We included participants from two prospective studies of the general Danish population, the Copenhagen City Heart Study and the Copenhagen General Population Study, totaling 110, 913 persons. All participants were genotyped for six variants with known effects on fatty liver disease: *PNPLA3* rs738409, *TM6SF2* rs58542926, *HSD17B13* rs72613567, *MBOAT7* rs641738, *MTARC1* rs2642438, and *GCKR* rs1260326.



Results: During a median of 9.5 years of follow-up, 16, 119 individuals died, hereof 201 due to liver-related causes, 1, 736 to ischemic heart disease, and 4, 973 to extrahepatic cancer. The variants at *PNPLA3*, *HSD17B13, TM6SF2,* and *MBOAT7* (but not those at *MTARC1* and *GCKR*) were individually associated with liver-related mortality, with per-allele hazard ratios of 1.3 to 1.6 (p values <0.06). The strongest effect was seen for the *PNPLA3* variant, for which homozygous carriers had a three-fold higher risk of liver-related death compared to non-carriers. A previously developed genetic risk score comprised of the variants at *PNPLA3*, *TM6SF2* and *HSD17B13* was robustly associated with stepwise increased liver-related mortality, with a maximum hazard ratio of 13 (95% CI: 3.8 to 48) for those with 5 or 6 versus 0 risk-increasing alleles (p for trend = 9 × 10E-7, see Figure, bottom panel). The fatty liver disease variants, individually or combined into risk scores, did not associate with ischemic heart disease-related, extrahepatic cancer-related, or all-cause mortality (Figure, top panel).
Conclusion: High genetic risk of fatty liver disease increased liver-related mortality but did not influence the risk of death due to ischemic heart disease or extrahepatic cancer, nor all-cause mortality in the general population. These data support that fatty liver disease is causally associated with liver-related mortality, but not with mortality due to other causes.

THU083

Role of NAFLD-associated genetic variants on renal function in patients with non-alcoholic fatty liver disease

Laura D'Erasmo[1], Francesco Baratta[1], Alessia Di Costanzo[1], Ilaria Umbro[1], Alessandra Colantoni[1], Nicholas Cocomello[1], Daniele Pastori[1], Marcello Arca[1], Francesco Angelico[1], Maria Del Ben[1]. [1]*Sapienza, University of Rome*
Email: laura.derasmo@uniroma1.it

Background and aims Previous studies demonstrated the association between non-alcoholic fatty liver disease (NAFLD) and chronic kidney disease (CKD). Recent studies focused the attention on the role of Patatin-like Phospholipase domain-containing 3 (PNPLA3) rs738409 polymorphism in the association between NAFLD and CKD in non-metabolic adults and children, but the genetic impact on NAFLD-CKD association is still matter of debate. Aim of the study was to investigate the impact of *PNPLA3*, Transmembrane 6 Superfamily Member 2 (*TM6SF2*), Membrane Bound O-Acyltransferase Domain Containing 7 (*MBOAT7*) and Glucokinase Regulatory Protein (*GCKR*) genes on renal function in a large population of NAFLD patients.
Method: The present study is a post hoc analysis of the Plinio Study (ClinicalTrials.gov: NCT04036357). *PNPLA3, TM6SF2, MBOAT7* and *GCKR* genes were analyzed by using Real Time PCR with TaqMan probes. Glomerular filtration rate (GFR) was estimated with CKD-epi formula. The effect of the NAFLD genetic background on eGFR was estimated both including each gene individually and considering the NAFLD genetic risk score (wGRS). The effect of NAFLD on renal function was assessed by analyzing two end points: 1) eGFR <90 ml/min (rGFR) or 2) eGFR <60 ml/min (moderate-to-severe CKD).
Results: This analysis was conducted on 564 NAFLD patients with available renal function data. Among these, the 48.0% had an eGFR below 90 ml/min while only 6.6% had moderate-to-severe CKD. The distribution of genotypes was superimposable if considering the entire group of patients with eGFR <90 ml/min or only those with eGFR <60 ml/min. At multivariate regression analyses (table 1), we did not observe any correlation between genotypes and renal function. Conversely, we found that metabolic syndrome was highly associated with rGFR (Odds ratio (OR): 1.52 (1.07–2.18)), whereas prior Atherosclerotic Cardiovascular Disease (ASCVD) with moderate-to-severe CKD (OR: 3.54 (1.22–10.24)). When introduced in the model, arterial hypertension emerged as the strongest risk factor for eGFR decline (OR: 1.45 (1.02–2.06) and OR: 2.85 (1.20–6.79) respectively for rGFR and moderate-to-severe CKD) (table 1).

Table 1. Multivariate regression analyses

Panel A. Factors Associated with eGFR < 90 ml/min				
	Model A OR (95% C.I.)	**Model B OR (95% C.I.)**	**Model C OR (95% C.I.)**	**Model D OR (95% C.I.)**
Metabolic Syndrome[#]	1.52* (1.07-2.18)	-	-	1.53* (1.07-2.18)
Arterial Hypertension	-	-	1.45* (1.02-2.06)	-
Panel B. Factors Associated with moderate-to-severe CKD				
	Model A OR (95% C.I.)	**Model B OR (95% C.I.)**	**Model C OR (95% C.I.)**	**Model D OR (95% C.I.)**
Prior ASCVD	3.54* (1.22-10.24)	3.55* (1.19-10.55)	-	3.44* (1.19-9.90)
Arterial Hypertension	-	-	2.85* (1.20-6.79)	-

[#]According to ATP III modified criteria; *p<0.05
Model A: including BMI, metabolic syndrome, prior ASCVD, PNPLA3 GG/CG and FIB4 -.
Model B: including component of the metabolic syndrome (namely high blood glucose, high waist circumference, high blood pressure, low HDL cholesterol, high triglycerides) instead of the composite score, prior ASCVD, PNPLA3 GG/CG genotype and FIB4 -.
Model C: including arterial hypertension instead of high blood pressure, diabetes instead of high blood glucose, high waist circumference, low HDL cholesterol, triglycerides, prior ASCVD, PNPLA3 GG/CG genotype and FIB4 -.
Model D: including BMI metabolic syndrome, prior ASCVD, weighted GRS and FIB4 -.

Conclusion: In our cohort of adult patients with NAFLD, we found no association between CKD and *PNPLA3, TM6SF2, MBOAT7* and *GCKR* gene variants. Hypertension was the stronger predictor of eGFR impairment. Based on these findings, the association between NAFLD and CKD might be due to the shared metabolic risk factors rather than the genetic NAFLD background.

THU084

The association between non-alcoholic fatty liver disease and insulin resistance within normal glucose level population

Chun-Yi Wang[1], Kuan-Yu Lai[1], Wen-Yuan Lin[1], Tsung Po Chen[1]. [1]*China Medical University Hospital, Department of Community and Family Medicine, Taichung, Taiwan*
Email: tsungpo88@gmail.com

Background and aims: The study of non-alcoholic fatty liver disease (NAFLD) with association of type 2 diabetes (T2DM) reveals rapid growth of prevalence and incidence in recent years. The mechanism of NAFLD shows connection between insulin resistance (IR) and T2DM. The aim of this study was to investigate the association between NAFLD and IR in normal glucose level population.
Method: We recruited participants from community and outpatient department in a hospital from central and northern Taiwan. Those with impaired fasting glucose or with diagnosis of T2DM were excluded from our study. We screened the items of body max index (BMI), systolic/diastolic blood pressure (SBP/DBP), body fat ratio (%) and social factors. We performed serum test after 8 hours overnight fasting. NAFLD was diagnosed based on an abdominal ultrasonography measurement. The calculation of IR used HOMA-IR formula and was shown by tertile (T1, T2, and T3). The method of statics counted through analysis of variance (ANOVA) and multivariate logistic regression.
Results: A total of 485 subjects (mean age 42.0 ± 11.4 years) were involved. The prevalence of NAFLD increased significantly among increasing level of IR (34.1%, 40.1%, 47.8%, p <0.001). Although fasting plasma glucose were within normal range among three groups, higher level of IR presented higher glucose value (81.9 ± 7.4 mg/dL, 85.1 ± 7.6 mg/dL, 87.3 ± 6.5 mg/dL, p < 0.0001). After adjusting for age, sex, BMI, exercise, alcohol consumption and cigarette smoking, the risk of NAFLD was increased with the increment of IR (T3 v.s. T1: Odd ratio [OR] 3.87, 95% confidence interval [CI], 2.08 to 7.21; T2 v.s. T1: OR 1.83, 95% CI, 1.11 to 3.00) after adjusting for confounding factors.

Conclusion: This study shows that in normal sugar level groups, the significant increasing risk of NAFLD if IR presented even in normal glucose level groups. The mechanism of NAFLD influenced hepatic enzymes production and further IR involved. We should take early intervention if abnormal IR present.

THU085

Chronic pruritus represents a major burden in non-cholestatic hepatobiliary disorders

M. Düll[1,2], Vanessa Karlen[1,2], Marcel Vetter[1,2], Peter Dietrich[1,2,3], Jörg Kupfer[4], Markus F. Neurath[1,2], Andreas E Kremer[1,2,5]. *[1]Deutsches Zentrum Immuntherapie (DZI), Erlangen, Germany; [2]Friedrich-Alexander-University Erlangen-Nürnberg, Department of Medicine 1, Erlangen, Germany; [3]Friedrich-Alexander-University Erlangen-Nürnberg, Institute of Biochemistry, Emil-Fischer-Zentrum, Erlangen, Germany; [4]Justus-Liebig-University Giessen, Institute of Medical Psychology, Giessen, Germany; [5]University Hospital Zürich, Department of Gastroenterology and Hepatology, Germany*
Email: andreas.kremer@usz.ch

Background and aims: While previous data indicated a high prevalence of pruritus in patients with immune-mediated liver disorders, there is only limited data on pruritus in hepatobiliary diseases in general. This study therefore aimed at further investigating epidemiology, clinical features, and influence on quality of life (QoL) in a large cohort of patients with different liver diseases.
Method: We performed a prospective, cross-sectional study in a large Hepatology outpatient clinic from August 2020-May 2021. We collected extended clinical data including characteristics of pruritus (e.g. mean/worst itch intensity on a numeric rating scale, NRS) and questionnaires containing validated scores such as ItchyQoL and SF12. Statistical analyses were performed using Mann-Whitney-U-test and Spearman`s rank correlation. Data are given as mean ± SEM.
Results: In total, 609 patients participated in this study of whom 27.3% (N = 166) presented with liver cirrhosis. 24.1% (N = 147) of all patients reported on pruritus with 61.9% (N = 91) being female. In the pruritus group 52.7% (N = 79) of all patients suffered from non-cholestatic liver diseases such as (non)alcoholic fatty liver disease, (non)alcoholic steatohepatitis (N)ASH, viral hepatitis, and associated liver cirrhosis. Immune-mediated and cholestatic liver diseases such as primary biliary cholangitis, primary and secondary sclerosing cholangitis, and genetic disorders represented 46.3% (N = 68). The majority of all pruritic patients reported on chronic itch with a duration >6 weeks (80.9%; N = 119). Only 17.7% (N = 26) received oral anti-pruritic therapy with fibrates being most commonly prescribed (30.5%, N = 8). Mean and worst itch intensity during the last week were rated at moderates intensities of 3.7 ± 0.2 and 4.2 ± 0.3 on a NRS, respectively. The QoL of affected patients quantified by ItchyQoL correlated with the mean and worst itch intensities ($r_s = 0.34$; $p < 0.001$; $r = 0.40$; $p < 0.0001$). SF-12 analyses exhibited significantly lower median physical ($p < 0.0001$) and mental scores ($p < 0.01$, Mann-Whitney-U-test) in the pruritus group.
Conclusion: Pruritus affected almost every fourth patient with hepatobiliary diseases and reduced their QoL. A significant number of patients remain treated insufficiently. Our findings underscore the need to increase awareness of chronic itch in hepatobiliary disorders and to study this symptom in clinical trials beyond the classical cholestatic liver disorders.

THU086

Mortality prediction in non-alcoholic fatty liver disease using SteatoSITE: an integrated gene-to-patient data commons for high-definition non-alcoholic fatty liver disease research

Maria Jimenez Ramos[1], Frances Turner[2], Prakash Ramachandran[1], Donald R. Dunbar[2], Lynn McMahon[3], Marian McNeil[3], Tim Kendall[1,4], Jonathan Fallowfield[1]. *[1]The Queen's Medical Research Institute, Centre for Inflammation Research, Edinburgh, United Kingdom; [2]Edinburgh Genomics, Edinburgh, United Kingdom; [3]Precision Medicine Scotland-Innovation Centre (PMS-IC), Glasgow, United Kingdom; [4]Edinburgh Pathology, Edinburgh, United Kingdom*
Email: jonathan.fallowfield@ed.ac.uk

Background and aims: Studies have correlated liver gene expression to pathological and clinical features of NAFLD cross-sectionally, but there is a paucity of longitudinal data using molecular features to predict patient outcomes. Such data is critical for accurate risk stratification and identification of novel treatments for specific subphenotypes of NAFLD. Using SteatoSITE (https://steatosite.com/), a resource containing integrated genetic, clinical and pathological data, we studied hepatic RNA-sequencing (RNA-seq) and linked electronic health record (EHR) data to identify gene expression patterns across the full histological NAFLD spectrum and to determine transcriptomic signatures that are associated with adverse clinical outcomes. Bulk tissue cell-type deconvolution was also performed using published single-cell RNA-seq (scRNA-seq) data to elucidate changes in cellular composition to inform rational biomarker and drug development.
Method: Bulk RNA-seq data was analysed from 692 liver samples (normal liver controls (n = 28), isolated steatosis (n = 43), steatosis with inflammation and/or hepatocyte ballooning (n = 621), including samples from all fibrosis stages). Time until death or censoring was retrieved for each patient. Differentially expressed genes (DEGs) between alive and dead patients at 1, 2, 3 and 5 years were used to generate a transcriptional signature predictive of mortality. Multi-subject Single-cell Deconvolution (MuSiC) was used to compare counts from each bulk RNA-seq sample with scRNA-seq data from healthy and cirrhotic livers to estimate proportions of liver macrophage, mesenchyme, endothelial, B- and T-cell subtypes across discrete NAFLD stages.
Results: RNA-seq identified 45 DEGs in early NAFLD (i.e., isolated steatosis) and 9826 DEGs in advanced NAFLD (i.e., fibrosis stage F4), compared with controls. KEGG analysis showed enrichment of inflammatory pathways in early-stage disease (e.g., cytokine-cytokine receptor interactions; $q < 0.01$), whilst pathways linked to extracellular matrix were only enriched in advanced disease ($q < 0.0001$). Linkage of RNA-seq with EHR data identified DEGs associated with mortality including potential biomarkers such as growth/differentiation factor 15 (GDF15) and fibroblast growth factor 21 (FGF21). Deconvolution analysis revealed statistically significant correlations between histological fibrosis scores and expanded populations of scar-associated macrophages, myofibroblasts, endothelial cells and B-cells.
Conclusion: Using SteatoSITE, the world's first data commons for NAFLD, we defined hepatic gene signatures across the full disease severity spectrum. Linkage to EHR-derived outcomes enables identification of liver transcriptional features associated with increased mortality. This work will underpin future studies aimed at developing a stratified medicine approach for NAFLD.

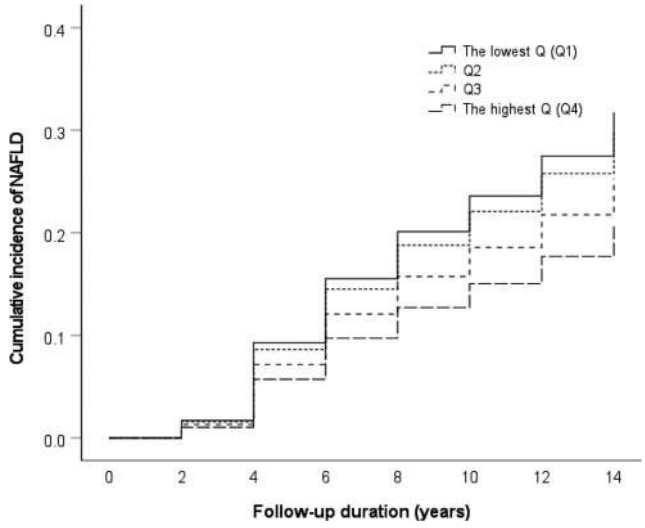
Different effects of low muscle mass on the risk of non-alcoholic fatty liver disease and liver cirrhosis in a prospective cohort

Hun Jee Choe[1,2], Hyunsuk Lee[1,2], DongHo Lee[1,2], Soo-Heon Kwak[1,2], Bo Kyung Koo[2,3]. *[1]Seoul National University Hospital, Internal Medicine, Seoul, Korea, Rep. of South; [2]Seoul National University College of Medicine, Internal Medicine, Seoul, Korea, Rep. of South; [3]Seoul, Boramae Medical Center, Seoul, Korea, Rep. of South*
Email: bokyungkoomd@gmail.com

Background and aims: As non-alcoholic fatty liver disease (NAFLD) and sarcopenia share insulin resistance as a common pathophysiology and have overlapping clinical manifestation of metabolic derangement, it is hard to differentiate the independent effect of sarcopenia on the development of NAFLD from concomitant metabolic disorders. Using a community-based prospective cohort study, the contributions of low muscle mass and genetic risk factors,

to the development of NAFLD and NAFLD-related liver cirrhosis were investigated in the Korean population.
Method: This prospective community-based cohort study included 40–70-year-old adults, followed-up biennially from 2001–2002 to 2017–2018. NAFLD was defined as a hepatic steatosis index of 36 or higher, and liver cirrhosis was defined based on the fibrosis-4 index. Sex-specific quartiles of body mass index (BMI)-adjusted muscle mass were calculated, and low muscle mass was defined as the lowest quartile (Q1). Cox proportional hazard models for incident NAFLD or liver cirrhosis incorporating age, sex, BMI of 25 kg/m^2 or higher, metabolic syndrome, and *PNPLA3* and *TM6SF2* risk alleles were used to assess the independent determinants for incident NAFLD and liver cirrhosis among individuals with NAFLD at baseline.
Results: Among the 4, 038 participants without NAFLD at baseline (mean age, 51.5 ± 8.8 years), 920 (22.8%) developed NAFLD during the follow-up period of 12 years. As muscle mass decreased, the risk of NAFLD increased even after adjustment for age, sex, obesity, metabolic syndrome, and *PNPLA3* and *TM6SF2* risk alleles (hazard ratio [HR] per quartile, 1.18, 95% confidence interval (CI), 1.11–1.27, p <0.001). TM6SF2 also affected the risk of NAFLD (HR 1.19, [95% CI, 1.00–1.40].
Of the 1, 176 patients with NAFLD but without hepatic fibrosis at baseline, incident liver cirrhosis was found in 51.8%, 44.7%, 42.6%, and 41.0% in Q1, Q2, Q3, and Q4 of BMI-adjusted muscle mass, respectively, during the follow-up period (p for trend = 0.006). However, this trend lost its statistical significance when adjusted for confounders. The *PNPLA3* risk variant and not the *TM6SF2* genotype, was an independent risk factor for developing liver cirrhosis among NAFLD patients (HR 1.17, 95% CI 1.04–1.32, p = 0.010).



Conclusion: Both lower muscle mass index and genetic risk variants are important contributors to the development of NAFLD. In patients already diagnosed with NALFD, however, *PNPLA3* conferred a greater risk for progression to liver cirrhosis than did lower muscle mass.

THU088
Age and the relative importance of liver-related deaths in non-alcoholic fatty liver disease
Huapeng Lin[1], Terry Cheuk-Fung Yip[1], Xinrong Zhang[1], Guanlin Li[1], Yee-Kit Tse[1], Vicki Wing-Ki Hui[1], Yan Liang[1], Che To Lai[1], Stephen Chan[1], Henry LY Chan[1], Grace Wong[1], Vincent Wai-Sun Wong[1]. [1]*The Chinese University of Hong Kong, Hong Kong*
Email: linhuapeng5@163.com

Background and aims: It is unclear if the leading causes of death in patients with non-alcoholic fatty liver disease (NAFLD) differ by age. In particular, we aim to investigate if the relative importance of liver-related deaths is lower in the elderly population such that screening is no longer meaningful.
Method: We conducted a territory-wide retrospective cohort study of adult NAFLD patients between 2000 and 2021 in Hong Kong. The outcomes of interest were all-cause and cause-specific mortality. Age at time of death were studied by subgroups of 10-year intervals.
Results: During 662, 471 person-years of follow-up of 30, 943 NAFLD patients, there were 2, 097 deaths. The top 3 causes of death were pneumonia, extrahepatic cancer and cardiovascular diseases. Extrahepatic cancer was the leading cause of death, followed by pneumonia and cardiovascular diseases before the age of 80. Pneumonia became the leading cause of death after the age of 80. Liver disease was the sixth leading cause of death in patients aged 70–79 and 80–89 years, accounting for 5.1% and 5.9% of deaths, respectively, but only accounted for about 3% or less of the deaths in the other age groups. The incidence of liver-related death was higher in men before the age of 70 but higher in women afterwards. The incidence of liver-related death in women increased from 0.62 to 7.14 per 10, 000 person-years from age 60–69 to 70–79 years.
Conclusion: The relative importance of liver-related death increases with age in NAFLD patients, especially among women. Thus, detection of NAFLD and advanced liver disease should be continued in the elderly population so far if they remain candidates for treatment.
Key words: non-alcoholic fatty liver disease, liver-related deaths, age

THU089
Hepatic fat as a novel marker for high-risk coronary atherosclerosis in familial hypercholesterolaemia: a CT-based study
Gavin Huangfu[1], Biyanka Jaltotage[1], Jing Pang[2], Nick Lan[1], Arun Abraham[1], Jacobus Otto[3], Abdul Ihdayhid[1,4], Jamie Rankin[1], Benjamin Chow[5], Gerald Watts[2,6], Girish Dwivedi[1,2,4], Oyekoya Ayonrinde[2,7]. Email: oyekoya.ayonrinde@uwa.edu.au

Background and aims: The liver is a transducer of cardiovascular risk factors through central regulation of lipid and glucose metabolism, insulin signalling and the production of inflammatory and thrombogenic factors. Individuals with heterozygous familial hypercholesterolaemia (FH) have accelerated but variable progression of coronary artery disease (CAD). We investigated the association between hepatic steatosis (HS) and coronary atherosclerosis, including plaque burden, composition, and morphology in adults with FH.
Method: High-risk plaque (HRP) features (low attenuation, positive remodelling, spotty calcification), plaque volume (PV) and pericoronary adipose tissue (PCAT) attenuation were assessed using coronary computed tomography angiography (CCTA). From concurrently captured upper abdominal images, severity of HS was computed, as liver minus spleen computed tomography attenuation (HU_{L-S}) and stratified into quartiles. Associations were assessed using logistic regression, adjusting for cardiometabolic and conventional risk factors, lipid-lowering treatment use, coronary artery calcium (CAC) and obstructive CAD (≥50% stenosis).
Results: Of 213 patients with FH (median age 54.0 [46.0–59.5] years, 58.7% female), median HU_{L-S} was 13.17 [6.58–18.33], 59% had CAC score >0, 36% obstructive CAD and 77% HRP features. Increasing HS

was associated with higher CAC score (p = 0.008), number of HRP features (p = 0.007) and presence of obstructive CAD (p = 0.01) and CAC (p = 0.02) as demonstrated in Figure 1. HS was associated with the presence of both HRP (odds ratio [OR]: 1.48; 95% confidence interval [CI]: 1.09–2.00; p = 0.01) and proximal HRP features (OR: 1.52; 95% CI: 1.18–1.96; p = 0.001). Associations persisted when controlling for cardiovascular risk factors, features of metabolic syndrome, lipid-lowering treatment use, presence of obstructive CAD and CAC score. HS was associated with a higher PV (Q4: 499 mm^3 vs Q1: 414 mm^3, p = 0.02), driven by low attenuation (p = 0.03) and non-calcified (p = 0.03) plaques. No differences in PCAT were observed.

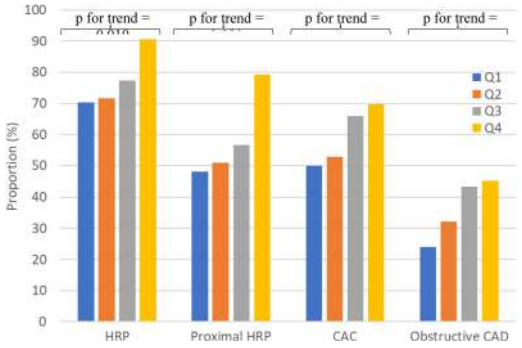

Figure 1: Coronary Artery Disease Characteristics, Stratified by HU_{L-s} Quartile

Conclusion: HS is associated with multiple indices of coronary atherosclerosis, particularly HRP features, in patients with FH. This appears to be independent of conventionally measured risk factors and may involve additional mechanisms related to HS.

Non-alcoholic fatty liver disease impcat on cardiovascular disease death: a population-based study

Chaonan Jin[1], Sheng Bi[1], Mei Deng[2,3,4], Jifang Sheng[1]. [1]*The First Affiliated Hospital, College of Medicine, Zhejiang University, State Key Laboratory for Diagnosis and Treatment of Infectious Diseases, National Clinical Research Center for Infectious Diseases, Collaborative Innovation Center for Diagnosis and Treatment of Infectious Diseases, Hangzhou, Zhejiang Province, China;* [2]*Guangxi Key Laboratory of Molecular Medicine in Liver Injury and Repair, Affiliated Hospital of Guilin Medical University, Guilin, Guangxi, China;* [3]*Department of Radiation Oncology, Affiliated Hospital of Guilin Medical University, Guilin, Guangxi, China;* [4]*Guangxi Health Commission Key Laboratory of Basic Research in Sphingolipid Metabolism Related Diseases, Affiliated Hospital of Guilin Medical University, Guilin, Guangxi, China*
Email: jifang.sheng@zju.edu.cn

Background and aims: Non-alcoholic fatty liver disease (NAFLD) represents a common risk factor for cardiovascular disease (CVD). However, the impact of NAFLD on CVD mortality remains to be defined. We aimed to investigate whether NAFLD has a negative influence on CVD mortality.

Method: 11035 participants who were aged 20–74 years, completed both interview and examination in mobile examination centers, with 'confident or absolute confident' reports from clear and gradable ultrasound images, from US Third National Health and Nutrition Examination Survey (NHANES III: 1988–94) with follow-up of mortality to 2015 were included.

NAFLD was defined as moderate or severe steatosis grade. Mortality and follow-up data were obtained from NHANES III public-use linked mortality file with underlying cause of death 113 (UCOD_113, 001 or 005 as CVD) recorded. Weighted demographic and clinical characteristics from non-NAFLD and NAFLD participants were compared. Weighted survival was analyzed using univariate and multivariate Cox proportional hazards model.

Results: A total of 2299 (weighted 2^*10^7 subjects) NAFLD and 8736 (weighted 108 subjects) subjects without NAFLD were included. NAFLD individuals were older (age 20–39 years 34.8% (standard error (SE) (1.9) vs 52.5% (1.1), p <0.001), male dominant (54.0% (SE (1.5) vs 45.3% (0.7), p <0.001), had more often a lower education level (<9 years 15.6% (1.2) vs 9.6% (0.7), p <0.001), hypertension (33.0% (1.8) vs 18.3% (0.7), p <0.001), type 2 diabetes (10.8% (0.8) vs 3.4% (0.3), p <0.001) and CVD history (7.3% (0.7) vs 3.5% (0.3), p <0.001) comparing to no-NAFLD participants.

Multivariate analysis showed that after adjusting age and gender, NAFLD was not associated independently with CVD mortality (adjusted hazard ratio (aHR) 1.079, 95% confidence interval (CI) 0.911–1.279, p = 0.369). This did not differ (aHR 1.109 95% CI 0.892–1.378, p = 0.345) after adjustment for putative risk factors including age, gender, race, education, poverty income ratio, hypertension, diabetes, smoking status and CVD history.

Conclusion: This prospective cohort suggests that the presence of NAFLD is not associated with CVD mortality among US adults.

THU091

Sarcopenia is associated with the severity of metabolic associated fatty liver disease in elderly residents

Xiaohui Liu[1], Jingjing Song[1], Shuang Zhang[1], Shan Liang[1], Zhang Jing[1]. [1]*Beijing Youan Hospital, Capital Medical University, The Third Unit, The Department of Hepatology, Beijing, China*
Email: zjyouan@ccmu.edu.cn

Background and aims: It has been proved that sarcopenia was associated with the metabolic associated fatty liver disease (MAFLD), but their relationship in elderly patients has not been studied in which sarcopenia is more prevalent.

Method: A cross-sectional survey was conducted among 1353 elderly residents over 65 years old in a community in Beijing. Demographic data, medical history, physical examination and laboratory examination results were collected for all subjects. Fatty liver was detected by B type ultrasound. Body composition was detected by Inbody720 (Bios pace, Korea). Liver fat content and liver stiffness was examined by Fibro Scan. Sarcopenia index (SI) was calculated as total ASM (kg)/BMI (kg/m^2). Sarcopenia was defined as SI<0.789 for men and<0.521 for women.

Results: Among the 1353 elderly residents, the mean age is 70.5 ± 5.0 years old and women account for 66.0%. There were 755 (55.8%) patients were diagnosed as MAFLD. The BMI, waist circumference, hip circumference, waist-to-hip ratio, upper arm circumference, body fat percentage and visceral fat area in MAFLD group were significantly higher than those in the non-MAFLD group (all $p < 0.05$). The proportion of patients with sarcopenia (20.3%) was significantly higher than in non-MAFLD group (15.6%, $p = 0.026$). MAFLD patients with sarcopenia had higher BMI, waist circumference, hip circumference, waist-to-hip ratio, upper arm circumference, body fat rate, visceral fat area, glucose and lipid metabolism indexes than those without sarcopenia (all $p < 0.05$). They also had higher liver fat content [(300.6 ± 43.5) vs. (295.1 ± 40.3), $p<0.001$] and liver stiffness scores [5.3 (4.3, 7.0) vs. 5.0 (4.1, 6.3), $p<0.001$] when compared to non-sarcopenia group. According to quartile stratification, Serum creatinine, HbA1c, HOMA-IR, hs-CRP, CAP and LSM increased significantly from subjects with non-MAFLD to subjects with non-sarcopenia in MAFLD group and subjects with sarcopenia in MAFLD group (all p for trend <0.001).

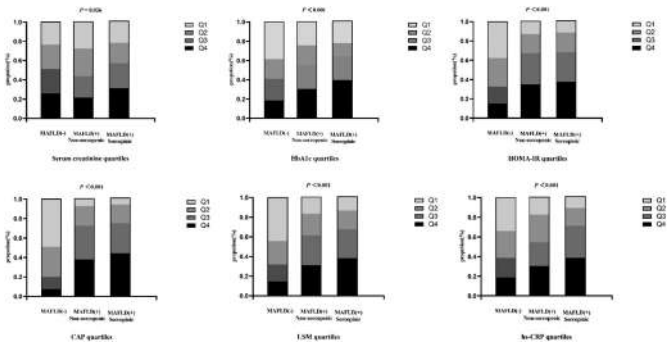

Figure 1: Association between the status of metabolic dysfunction-associated fatty liver disease (MAFLD)/sarcopenia and SCr, HbA1c, HOMA-IR, CAP, LSM, hs-CRP by quartile stratification.

Conclusion: We found that in elderly MAFLD patients, sarcopenia is closely correlated with liver fat content and fibrosis. We should pay more attention to the system metabolic abnormal in elderly population.

THU092

NAFLD patients scheduled for bariatric surgery present with a milder disease phenotype as compared to not morbidly obese NAFLD patients: analysis of a large real-world cohort

Monika Rau[1], Sarah Kaps[1], Hans Benno Leicht[1], Florian P Reiter[1], Marcin Krawczyk[2], Andreas Geier[1]. [1]*University Hospital Würzburg, Department of Internal Medicine II, Würzburg, Germany;* [2]*Saarland University Medical Center, Department of Medicine II, Homburg, Germany*
Email: rau_m@ukw.de

Background and aims: Non-alcoholic fatty liver disease (NAFLD) is the leading chronic liver disease worldwide associated with the metabolic syndrome. Based on recent findings, one can speculate that patients with morbid obesity might present have a milder NAFLD than those without. Aim of this study is to analyze the clinical phenotype of NAFLD in patients with and without (w/o) bariatric surgery (BarSur).
Method: In total, 814 patients were prospectively included (10/12–04/21) in a single-center study at a tertiary hospital. NAFLD was diagnosed either clinically by Fibroscan/CAP (n = 413) or histologically (n = 348). Routine laboratory parameters were available for all patients and 351 patients were genotyped for *PNPLA3* p.I148M variant.
Results: 761 NAFLD patients were included (n = 512 with and n = 249 w/o BarSur) in this cohort. A case-control matching for age, sex, and diabetes mellitus (T2DM) was performed to analyse different disease phenotypes (n = 202 with and n = 201 w/o BarSur). Patients with BarSur had more often arterial hypertension (82% vs. 52%; p < 0.001), hypertriglyceridemia (16% vs. 9%; p < 0.01) and coronary heart disease (9% vs. 3%; p < 0.01) compared to NAFLD patients w/o BarSur. However, BarSur NAFLD patients were characterized by significantly lower disease specific serum profile including ALT (32 vs. 55U/l; p < 0.001), AST (28 vs. 39U/l; p < 0.001), gGT, ferritin and FIB-4 (1, 00 vs. 1, 17; p < 0, 001). Although higher frequency of *PNPLA3* p. I148M genotype was observed in NAFLD patients w/o BarSur compared to BarSur NAFLD patients (CC: 46% vs. 58%; CG: 39% vs. 38%; GG: 15% vs. 4%;p < 0.01), an additional matching for the *PNPLA3* genotype showed the same significantly lower serum ALT, AST, GGT and ferritin in BarSur NAFLD patients. Differences in histology were analysed by case-control matching for age, sex and T2DM only in patients with available histology (n = 74 for each patient group). NAFLD patients w/o BarSur had significantly higher frequency of NASH (74% vs. 49%; p < 0.01), steatosis, ballooning and fibrosis (F2-F4 46% vs. 8%; p < 0.001). Non-invasive liver stiffness assessment by Fibroscan was also significantly higher in NAFLD patients w/o BarSur (8.4 vs. 6.6kPa; p < 0.01).
Conclusion: NAFLD Patients with BarSur present a clinically milder disease phenotype in terms of serum profile and histology in our large cohort of NAFLD patients after case-control matching and independently of PNPLA3 genotype. Our observation warrants further pathophysiological studies in this special subpopulation of NAFLD.

THU093

Effects of SARS-CoV2 pandemic in a cohort of italian NAFLD patients

Bernardo Stefanini[1,2], Simona Leoni[1], Roberta Capelli[1,2], Alice Secomandi[1,2], Luca Muratori[1,2], Fabio Piscaglia[1,2], Silvia Ferri[1]. [1]*IRCCS Azienda Ospedaliero-Universitaria di Bologna, Division of Internal Medicine, Hepatobiliary and Immunoallergic Diseases, Bologna, Italy;* [2]*University of Bologna, Department of Medical and Surgical Sciences (DIMEC)*
Email: silvia.ferri@aosp.bo.it

Background and aims: SARS-Cov2 wide and uncontrolled spread in Italy in winter 2020 forced the authorities to declare an emergency status characterized by a complete lock-down and a massive temporary conversion of medical resources into COVID-positive patients care. Some of the consequences were a great limitation to physical activity and a reduced possibility to regularly follow outpatients in hospital.
Aim of our study was to evaluate the effect of COVID pandemic on subjects with stable NAFLD followed in our outpatient liver clinic.
Method: we enrolled 43 patients (58% females, median age 59 years, mean BMI 29) with defined NAFLD in charge to our liver outpatient unit with these characteristics: a first visit in 2017–2018, a pre-pandemic visit in 2019, a programmed visit between March and June 2020 not performed due to the pandemic condition and a post-pandemic visit after September 2020.
At first visit all patients were given dietary advice following the Mediterranean approach and encouraged to increase physical activity up to 150 minutes/week of aerobic and/or anaerobic activity of moderate intensity. Medications were prescribed when needed. At the three time points a complete anamnestic, physical, laboratory and ultrasound evaluation was performed.
Patients with advanced disease (decompensated cirrhosis and/or hepatocellular carcinoma) were excluded from the study as they were seen in outpatient clinic also during the lock-down period.
Results: compared to first visit, post-pandemic evaluation in our cohort of patients revealed stable BMI, HOMA index, transaminases, lipid profile, NAFLD fibrosis score (NFS), FIB-4, B-mode hepatorenal ratio (BMHRR) and liver stiffness (2D:SWE:SSI), whereas a reduction was detected in gammaGT levels (p = 0.02).
We then considered separately patients that at pre-pandemic visit had lost >5% of their basal weight (10 patients, mean weight –7.2%, mean BMI 27, 0) and those who had not (33 patients, mean weight +1.4%, mean BMI 29, 4). At post-pandemic control, patients in both groups maintained their weight trend (mean BMI 27, 3 and 29, 6 respectively; weight change compared to first visit –6.0% and +2, 1% respectively, p <0.0001). Weight variations were associated to NFS (but not FIB-4, BMHRR and liver stiffness) modifications (in weight losers: –19.4%, in weight maintainers +55.9%, p = 0.034).
Surprisingly, all patients, especially those in the latter group, reported an increase in their physical activity after the first visit that was maintained also during the pandemic phase (from scarse-moderate to moderate-good p = 0.004).
Conclusion: in patients with NAFLD, when the behavioral approach (in which physical activity may exert an independent protective role) had been well consolidated in the pre-pandemic phase, it was maintained also during COVID pandemic even without a strict medical follow-up, thus allowing a preservation of the results obtained.

THU094

A higher Fibrosis-4 (FIB-4) score is associated with higher healthcare costs and hospitalizations in patients with non-alcoholic steatohepatitis (NASH)

Elliot Tapper[1], Jesse Fishman[2], Stephen Dodge[2], Keith Miller[2], Ni Zeng[3], Alina Bogdanov[3], Machaon Bonafede[3]. [1]*University of Michigan, United States;* [2]*Madrigal Pharmaceuticals, United States;* [3]*Veradigm*
Email: alina.bogdanov@gmail.com

Background and aims: The cost and complexity of care for patients with Non-alcoholic Steatohepatitis (NASH) increases with disease stage. we aimed to study the Fibrosis-4 (FIB-4) score as a proxy for disease severity and test its association with increased disease burden.
Method: The Veradigm Health Insights Electronic Health Record Database and linked Komodo administrative claims data were used to identify adult patients with coded NASH with aspartate aminotransferase (AST), alanine aminotransferase (ALT) and platelet results and age to compute a FIB-4. The index date was the first coded NASH encounter between 2016 and 2020 with at least 6 months of database activity pre- and post-encounter and a FIB-4 score. We excluded patients coded with viral hepatitis, alcoholism, or alcoholic liver disease. Inpatient hospital admissions and log-transformed costs for pharmacy, hospital inpatient, emergency department, and outpatient services were measured in the 12-month period surrounding index. Multivariate logistic regression for any hospitalization and linear regression for log total cost was performed, controlling for patient demographics (age, race, sex, and geography), smoking status, Charlson comorbidity index (CCI), and diabetes complications severity index (DCSI).
Results: 6, 743 patients met the study criteria; mean age was 56.1 ± 13.3, patients were 62.9% female and 53.6% of patients were diagnosed with Type 2 Diabetes. Mean FIB-4 at index was 1.79 ± 1.88. A 1 unit increase FIB-4 at index was associated with a 4.2% increase in mean total annual cost (p < 0.0001 CI 2.2% to 6.3%) and with an odds ratio of 1.12 (p < 0.0001 CI 1.08 to 1.15) for hospitalization. CCI and DCSI were also significantly associated with higher odds ratios for hospitalization (OR 1.27, p <0.001 CI 1.23 to 1.31 and OR 1.27, p <0.001 CI 1.22 to 1.33).

Figure 1. Summary of Modeling results for log total cost and hospital admissions

	Log Total Cost			Hospital Admission		
Item	e^{β}	$e^{Lower\ CI}$	$e^{Upper\ CI}$	Odds Ratio	Lower CI	Upper CI

Email: rosa.lombardi@unimi.it

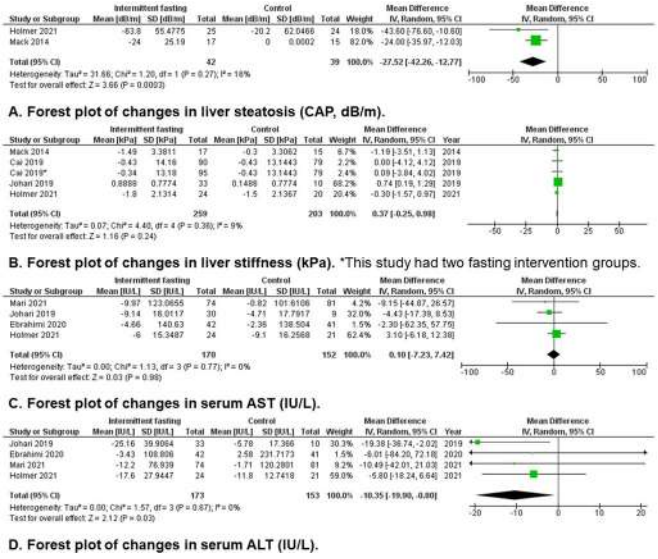
Background and aims: People living with HIV (PLWH) develop metabolic alterations and hepatic steatosis (HS), exposing them to increased cardiovascular (CV) risk. However, if presentation of HS in this category of patients is different from that of non-alcoholic fatty liver disease (NAFLD) is unknown. Aim: to evaluate metabolic, hepatic and CV alterations in PLWH and to compare them with those observed in primary NAFLD subjects.
Method: forty-two HIV mono-infected patients (mean age 46 ± 12 ys, male 81%; 90% with viral suppression) were enrolled. The cohort of PLWH underwent hepatic ultrasound (US) and those with evidence of HS were compared to a sex and age matched NAFLD control group (1:2). For all enrolled subjects, anthropometric parameters (BMI, waist circumference-WC), metabolic comorbidities, CV damage by carotid ultrasound (plaques, arterial stiffness by radiofrequency as pulse wave velocity-pWv) and heart ultrasound (systolic and diastolic function and epicardial adipose tissue-EAT) were assessed. All patients underwent transaminases determination, Fibroscan to detect advanced fibrosis (LSM >8.9/7.2 kPa M/XL probe) and bioimpedance (BIA) to quantify sarcopenia (SMI ≤10.75/6.75 kg/m2 male/females) and fat mass. CV risk was assessed according to ESC guidelines. Genotyping for PNPLA3 was determined by Taqman assay.
Results: Thirty (63%) PLWH presenting HS were compared with 60 NAFLD patients. PLWH with HS presented no difference in the prevalence of metabolic alterations (type 2 diabetes 13% vs 13%, p = 1.0; hypertension 47% vs 42%, p = 0.82; dyslipidemia 83% vs 85%, p = 1.0) and sarcopenia (40% vs 52%, p = 0.81) compared to NAFLD, despite lower BMI (27.1 ± 4 vs 29.1 ± 4.3 kg/m^2, p = 0.04), WC (98 ± 9 vs 103.1 ± 10.3 cm, p = 0.03) and trunk fat mass (9.8 ± 3.3 vs 12.4 ± 4.7 kg, p = 0.02). No difference in the prevalence of increased transaminases (17% vs 20%, p = 0.78) and advanced fibrosis (17% vs 12%, p = 0.53) was found, as well of high CV risk (84% vs 83%, p = 0.86), pWv (7.4 ± 2 vs 6.9 ± 1.4 m/s, p = 0.18), carotid plaques (39% vs 28%, p = 0.33), increased EAT (20% vs 17%, p = 0.77) and systolic (6% vs 5%, p = 1.0) and diastolic dysfunction (7% vs 6%, p = 1.0). PNPLA3 distribution was not significantly different between groups (p = 0.16).
Conclusion: Hepatic steatosis and fibrosis are highly prevalent in patients with HIV. Interestingly, in PLWH metabolic alterations, liver and cardiovascular damage are superimposable with those observed in a primary NAFLD cohort, although in presence of lower visceral adiposity. Therefore, screening for liver disease in HIV patients is mandatory independently of obesity, as the increased risk of metabolic and CV complications.

THU096

Impact of intermittent fasting on anthropometric and clinical outcomes in non-alcoholic fatty liver disease: systematic review and meta-analysis

Marcia Lange[1], Devika Nadkarni[1], Lily Martin[1], Carolyn Newberry[2], Sonal Kumar[2], Tatyana Kushner[3]. [1]*Icahn School of Medicine at Mount Sinai, New York, United States;* [2]*Weill Cornell Medicine, Division of Gastroenterology and Hepatology, New York, United States;* [3]*Icahn School of Medicine at Mount Sinai, Division of Liver Medicine, New York, United States*
Email: marcia.lange@icahn.mssm.edu

Background and aims: Currently, weight loss through caloric restriction is the cornerstone of initial non-alcoholic fatty liver disease (NAFLD) management. However, there remains a lack of evidence-based guidelines on the benefits of intermittent fasting (IF) for NAFLD. In this systematic review with meta-analysis, we evaluated the effect of IF on anthropometric and clinical markers of NAFLD.
Method: We conducted a comprehensive search of MEDLINE, EMBASE, and Cochrane Central databases as well as trial registries and conference abstracts up to January 31, 2022. The search strategy included all appropriate controlled vocabulary and keywords for NAFLD and fasting. No date, language, or article type restrictions were included in the search strategy. Studies of adults with NAFLD or non-alcoholic steatohepatitis (NASH) undergoing an intermittent fasting intervention reporting at least one anthropometric or clinical outcome were included in our review. A random effects model was used for meta-analysis to estimate mean differences between intervention and control group for various outcomes.
Results: Initial literature search yielded 16 294 studies, of which 10 772 were duplicates, leaving 5517 studies to screen for title/abstract. An additional 5367 studies were excluded after title/abstract review with moderate concordance (k = 0.53). The remaining 150 studies were assessed for full text review with fair concordance (k = 0.24). Twelve studies were included in the systemic review and meta-analysis, totaling 908 participants with NAFLD, combined mean age of 42.50 years (SD 14.54), 50% male. Meta-analysis of anthropometric outcomes showed that the effect of IF on BMI and body weight was statistically significant (Mean difference (MD) −0.69 kg/m2, 95% CI −1.29 to −0.09, p < 0.05; MD −2.51 kg, 95% CI −4.44 to −0.58, p < 0.05) with moderate though statistically significant heterogeneity for both (I^2 = 47%, p = 0.07; I^2 = 62%, p = 0.02). Clinical outcome analysis showed that the effect of IF on liver steatosis (CAP, dB/m) and ALT levels was also statistically significant (MD −27.52 dB/m, 95% CI −42.26 to −12.77, p < 0.01; MD −10.35 IU/L, 95% CI −19.9 to −0.8, p < 0.05) with zero to low heterogeneity for both outcomes (I^2 = 16%, p <0.01; I^2 = 0%, p < 0.05). IF did not have a significant effect on AST levels or liver stiffness (kPa).



Conclusion: Intermittent fasting interventions may improve BMI and body weight as well as reduce both liver steatosis and serum ALT levels in adults with NAFLD. Studies with varying types of IF interventions and varying intervention durations likely contributed to meta-analysis heterogeneity. This data suggests that IF likely provides a benefit in NAFLD, but future randomized controlled studies are needed to validate the use of IF for NAFLD treatment.

THU097

The burden of liver fibrosis in the obese population

Gres Karim[1], Dewan Giri[1], Andrea Delgado Nieves[1], Caileen Sennett[1], Andre Khazak[1], Bo Hyung Yoon[2], Amreen Dinani[3]. [1]*Icahn School of Medicine at Mount Sinai Beth Israel, Department of Medicine, New York, United States;* [2]*Icahn School of Medicine at Mount Sinai Beth Israel, Mount Sinai Morningside, and Mount Sinai West (MSBIMW), Department of Gastroenterology, New York, United States;* [3]*Icahn School of Medicine, Division of Liver Diseases, New York, United States*
Email: gres.karim@mountsinai.org

Background and aims: The impact of obesity extends beyond non-alcoholic fatty liver disease (NAFLD). It is an independent risk factor for hepatocellular carcinoma (HCC), cirrhosis and liver decompensation. Liver fibrosis (LF) is linked to overall and liver-related mortality. The impact of obesity and LF is not as well established. Identifying LF in a high risk population with obesity is crucial to prevent disease progression and implement early intervention. We aim to describe the burden of LF in a population with obesity (BMI ≥30 kg/m^2) and understand the variables that contribute to the development of LF.
Method: Patients with a body mass index (BMI) ≥30 kg/m^2 and no chronic liver diseases (CLD) were identified using electronic medical records from a tertiary care clinic between 01/2019 to 01/2020. Demographic information, markers of liver inflammation and synthetic function, medical conditions, imaging and histology were recorded. The Fibrosis Index 4 (FIB-4) was calculated to determine the stage of liver fibrosis; FIB-4 ≥1.3 indicated significant fibrosis. A univariate and multivariate logistic regression analysis was performed to identify factors contributing to the stage of fibrosis. Other outcomes of interest were complications of cirrhosis, development of HCC and mortality.

Demographic and laboratory characteristics of Patients			
Patient Characteristics	All patients [N (%)]	FIB-4 ≤1.3 [N (%)]	FIB-4 >1.3 [N (%)]
Sex Male : Female :	 361 720	 218 (20%) 478 (44%)	 361(13%) 720(22%)
BMI (kg/m²)	34.5	34.9	33.9
Ethnicity Hispanic Non-Hispanic	 185 (17%) 520 (48%)	 107 (10%) 350 (32%)	 78 (7%) 170 (16%)
Race: White Black Other	 322 (30%) 236 (22%) 293 (27%)	 212 (20%) 158 (15%) 186 (17%)	 110 (10%) 78 (7%) 107 (10%)
Hypertension	518 (48%)	287 (27%)	231 (21%)
CAD	123 (11%)	52 (5%)	71 (7%)
DM2	264 (24%)	158 (15%)	106 (10%)
AST Mean ≤30 IU/L >30IU/L	 23 955 (88%) 127 (12%)	 21 647 (60%) 50 (5%)	 27 308 (28%) 77 (7%)
ALT Mean ≤30 IU/L >30 IU/L	 24 886 (82%) 196 (18%)	 23 571 (53%) 126 (12%)	 26 315 (29%) 70 (6%)
GFR ≥60mL/min <60 mL/min	 895 (84%) 165 (16%)	 604 (57%) 76 (7%)	 291 (27%) 89 (8%)
Outcomes Cirrhosis HCC Death	 7 62 3	 0 40 (6%) 1 (33%)	 7 (100%) 22 (35%) 2 (67%)

Results: A total of 2999 patients with BMI ≥30 kg/m^2 were identified, of which 1082 patients had no documentation of CLD during the study period. Majority were female (66%), mean age 57 years (SD 13), and mean BMI 35 kg/m^2 (SD 4.9). One third were white and 17% Hispanic. Mean ALT and AST were 23 IU/L (3–671). Approximately 40% (385/1082) had a FIB-4 ≥1.3, of which 80% had normal aminotransferases (≤30IU/ml). Those with FIB-4 ≥1.3 were likely to be female, Hispanic or black. Coronary artery disease (2.8[1.9, 4.1]), hypertension (2.1[1.6, 2.7]), impaired renal function (GFR <60) (2.4 [1.7, 3.4]), elevated low density lipoprotein (0.99[0.98, 0.99]) and total cholesterol (0.993 [0.990, 0.997]), were associated with liver fibrosis in univariate analysis, p < 0.001. No association was seen with diabetes. An inverse association was found between BMI and liver fibrosis (0.96[0.93, 0.99], p = 0.03) in univariate analysis, but not statistically significant in the multivariate analysis (0.96[0.92, 1.00], p = 0.08). In the multivariate model, female, older age, black, elevated AST and low platelet count were found to be associated with significant LF.

Conclusion: In our analysis of an obese population we found a high 40% degree of significant liver fibrosis in those without known CLD. The presence of CAD, HTN, and GFR <60 appear to be significantly associated with liver fibrosis. Sex, ethnicity may have a role in development of LF in obesity. Majority of these patients would not have been assessed for liver disease due to normal liver enzymes. People with obesity should be pro-actively assessed for CLD and NAFLD.

THU098

Impact of screening and treatment of obstructive sleep apnea in non-alcoholic fatty liver disease

Kelsey Collins[1], Amreen Dinani[1], Horacio Romero Castillo[1], Brooke Wyatt[1], Indu Ayappa[1], Anne Mooney[1]. [1]*Mount Sinai Medical Center, New York, United States*
Email: kelsey.collins@mountsinai.org

Background and aims: Obstructive sleep apnea (OSA) has been recognized as a risk factor for non-alcoholic fatty liver disease (NAFLD). Oxidative stress and chronic intermittent nocturnal low oxygen state promotes liver injury, inflammation, and liver fibrogenesis. It is estimated that persons with OSA are 2–3 times likely to have NAFLD. Treatment of NAFLD is based around managing co-morbidities and weight loss. The aim of our study is to prospectively screen patients with NAFLD for OSA and evaluate the impact of OSA treatment on NAFLD.

Method: Patients with NAFLD (defined by presence of hepatic steatosis on imaging, controlled
attenuated parameter [CAP] ≥240 dB/m, or histology) were prospectively screened for OSA using STOP-BANG (SB) and Epworth Sleepiness Score (ESS) in an outpatient liver clinic. SB ≥3 or ESS ≥10 were characterized as 'high risk' for OSA and referred to Sleep Medicine for home sleep testing with a WatchPAT device. Patients confirmed with OSA were followed in Sleep Medicine and Hepatology. Baseline characteristics, demographics and severity of liver disease were collected and students t test as well as logistic regressions were used to assess differences. Patients with NAFLD and OSA were followed over time to determine the impact of OSA treatment on NAFLD.

Results: Sixty-eight patients with NAFLD from a tertiary hospital system were screened for OSA from; 41% were male, mean age 49 years, 21% were White Non-Hispanic, 32% Hispanic, 26% Other/Unknown. The median BMI was 32.8 kg/m^2 with 68% ≥30 kg/m^2 consistent with obesity. At baseline, 53% had ALT above the upper limit of normal (ALT ≥30IU/L). Forty patients (59%) screened positive for OSA (mean SB = 5 and ESS = 7). There were no differences observed in BMI, ALT, AST, liver stiffness (LF), or CAP scores for patients that screened positive and negative for OSA, however, the group that screened negative for OSA, on average had higher high-density lipoprotein (HDL) (44.1 mg/dL vs 52.4 mg/dL, p = 0.01), low-density lipoprotein (LDL) (99.1 mg/dL vs 116.9 mg/dL, p = 0.03), and cholesterol (176.4 mg/dL vs 200.7 mg/dL, p = 0.01). Compared to patients with no diabetes (DM) (p = 0.015), preDM and DM showed statistically significant increased odds of screening OSA positive (OR = 5.3 [CI:1.535–18.15]; OR = 4.6 [CI:1.12–18.80]). Of those referred for formal OSA testing, n = 20 (55%) complied, and n = 17 (85%) patients were subsequently diagnosed with OSA and underwent treatment (mean AHI4 = 19.6/hr). Due to lack of OSA treatment acceptance/adherence, overall impact could not be assessed.

Conclusion: Screening for high risk OSA with a combination of STOP-BANG and ESS was reliable for identifying subjects with OSA confirmed by sleep test. Closer attention to lipid profile and insulin resistance (preDM and DM) were risk factors identified contributing to the diagnosis of OSA. Impact of treatment for OSA needs further evaluation.

THU099

Undiagnosed NAFLD in the obese population: in sight, out of mind

Dewan Giri[1], Gres Karim[2], Andrea Delgado Nieves[2], Andre Khazak[2], Caileen Sennett[2], Bo Hyung Yoon[3], Ilan Weisberg[4], Amreen Dinani[5]. *[1]Icahn School of Medicine at Mount Sinai Beth Israel, Department of Medicine, New York, United States; [2]Mount Sinai Beth Israel, Internal Medicine, New York; [3]Mount Sinai Beth Israel, Morningside and West, Department of Gastroenterology, New York, United States; [4]New York Presbyterian-, Brooklyn Methodist, Department of Gastroenterology and Hepatology; [5]Icahn School of Medicine, Division of Liver Diseases, New York, United States*
Email: gres.karim@mountsinai.org

Background and aims: Obesity is a leading risk factor for non-alcoholic fatty liver disease (NAFLD), with estimated prevalence rates as high as 50–90%. There is a strong correlation between obesity and hepatocellular carcinoma (HCC), cirrhosis and advanced liver disease. Despite the rising burden of NAFLD in obesity, no concrete guidance exists for screening in this high-risk population. Early detection can facilitate early intervention and development of pathways to specialty care. Herein, we describe the burden of NAFLD in an obese population and affirm the need to proactively assess patients that would otherwise be undiagnosed.

Method: Patients with a diagnosis of obesity (body mass index [BMI] >30 kg/m^2) and no documented chronic liver diseases (CLD) were identified using electronic medical record (EMR) from a tertiary care clinic between 01/2019 to 01/2020. Patients who met the criteria for NAFLD (as per AASLD guidelines) were also identified from the same cohort with attention to those who had documentation of NAFLD diagnosis in EMR (ICD-10 codes and review of notes) and those who did not. Demographic information, markers of liver inflammation and synthetic function, medical conditions, imaging and histology were recorded. Fibrosis Index 4 (FIB4) was calculated to determine the stage of liver fibrosis. We reviewed the reason for referrals, differences in the two groups of patients with NAFLD who were and were not diagnosed.

Results: A total of 2999 patients with BMI >30 kg/m^2 were identified, 586 (20%) had a diagnosis of NAFLD (D-NAFLD) and 1350 had no diagnosis of CLD. One-fifth (268/1350, 20%) of patients without diagnosis of CLD met diagnostic criteria for NAFLD (UD-NAFLD). Baseline characteristics of D-NAFLD and UD-NAFLD were comparable. Majority of UD-NAFLD had normal (<30IU/L) alanine transaminase (ALT) and aspartate transaminase (AST), 65% and 69% compared to 48% and 60% in D-NAFLD, respectively. Mean AST and ALT were higher in D-NAFLD (38 IU/L and 46 IU/L, respectively) versus UD-NAFLD (33 IU/L and 33 IU/L, respectively). Mean FIB4 was similar, 1.62 and 1.64. FIB4 in the UD-NAFLD group with normal ALT and AST was 1.17 compared to 1.34 in D-NAFLD. Hypertension (55%), coronary artery disease (15%) and diabetes mellitus (30%) were more common in patients in the undiagnosed cohort. Presence of CAD or DM in both groups was associated with a higher FIB4. Majority of patients in D-NAFLD were referred to the specialty clinic for either elevated liver tests (24%), radiographic evidence of steatosis (26%) or both (19%).

Demographic and Laboratory Characteristics of Patients

Patient Characteristics	Undiagnosed NAFLD (UD-NAFLD) (N=268) Mean or N/%	Diagnosed NAFLD (D-NAFLD) (N=586)
Sex		
Male :	90 (34%)	243 (41%)
Female :	178 (66%)	343 (59%)
Mean Age (SD)	57 (12.6)	56 (12.7)
BMI (kg/m^2) (SD)	35.5 (5.5)	35.6 (5.5)
Ethnicity		
Hispanic	73 (27 %)	137 (23%)
Non-Hispanic	112 (42%)	279 (48%)
Race:		
White	84 (31%)	225 (38%)
Black	48 (18%)	85 (14%)
Other	91 (34%)	153 (26%)
Comorbidities		
Hypertension	148 (55%)	294 (27%)
CAD	39 (15%)	64 (6%)
DM	81 (30%)	211 (20%)
FIB-4		
Mean	1.62	1.64
FIB-4 ≤ 1.3	147 (55%)	321 (55%)
FIB-4 > 1.3	131 (45%)	247 (45%)
AST		
Mean	33	38
≤30 IU/L	184 (69%)	347 (60%)
>30IU/L	84 (31%)	239 (40%)
ALT		
Mean	33	46
≤30 IU/L	174 (65%)	283 (48%)
>30 IU/L	94 (35%)	303 (52%)
GFR		
≥60mL/min	223 (83%)	507 (89%)
<60 mL/min	38 (14%)	61 (9%)
Outcomes		
Cirrhosis	18 (7%)	71 (12%)
HCC	3 (1%)	3 (0.5%)
Death	2 (0.7%)	5 (0.9%)
Lifestyle Changes recommended	112 (42%)	478 (44%)

Conclusion: We have demonstrated that obesity continues to be an underrecognized risk factor for NAFLD. In our cohort, 20% of patients with obesity had missed diagnosis of NAFLD. Based on current guidelines, 70% of these patients would not have been worked up for NAFLD with normal liver enzymes. NAFLD should be considered as a comorbidity when evaluating patients with obesity.

THU100

Prevalence of non-alcoholic steatohepatitis in patients undergoing laparoscopic cholecystectomy for gallstone with non-alcoholic fatty liver disease

Utpal Anand[1,1], Aaron John[1], Ramesh Kumar[1], Rajeev Priyadarshi[2]. *[1]All India Institute of Medical Sciences, Patna, Surgical Gastroenterology, Patna, India; [2]All India Institute of Medical Sciences, Patna, Radiodiagnosis, Patna, India*
Email: utpalanand2@gmail.com

Background and aims: Gallstone disease (GSD) and non-alcoholic fatty liver disease (NAFLD) shares common risk factors. Non-alcoholic steatohepatitis (NASH) is a more progressive form of NAFLD and is among the most frequent causes of cirrhosis. There is a lack of prospective studies utilizing liver biopsy during laparoscopic cholecystectomy in patients of gallstones and NAFLD for assessing the prevalence of NASH and factors associated with it. The aim of the study was to assess the usefulness of liver biopsy for patients with gallstones and NAFLD who underwent laparoscopic cholecystectomy.

Method: Among the 250 patients with symptomatic GSD, 55 had associated NAFLD diagnosed by ultrasound. These patients underwent liver biopsy during laparoscopic cholecystectomy between June 2021 to Feb 2022.

Results: The mean age of patients was 41.6 ± 11.69 years and 60% of patients were female. The mean BMI of subjects was 26.43 ± 3.84 kg/m^2. Eight patients had hypothyroidism, 7 patients had diabetes mellitus, and 6 patients had hypertension as comorbidities. The histopathology of NAFLD patients revealed no significant steatosis in 7 patients, NAFLD in 38 patients and NASH in 10/55 (18.1%). Higher AST (44 ± 22.15 vs 31.5 ± 13.0; p = 0.02) and controlled attenuation parameter (CAP) (294 ± 58.5 vs 202.9 ± 69.6; p <0.001) were significantly associated with NASH in GSD patients with NAFLD

Table: Clinical characteristics of NASH and non-NASH patients

	Non-NASH	NASH	P value
Age (years)	40.9 ± 10.6	44.8 ± 12.0	0.34
Female	31 (68%)	8 (80%)	0.48
Body mass index (kg/m2)	26.46 ± 3.96	26.33 ± 3.46	0.92
Laboratory parameters			
INR	0.97 ± 0.10	0.94 ± 0.07	0.49
ALT (U/L)	31.3 ± 17.9	40.8 ± 24.67	0.18
AST (U/L)	31.5 ± 13.0	44 ± 22.15	0.02*
ALP (U/L)	88 (72.5–102)	76.5 (74–84.5)	0.23
Total bilirubin (mg/dL)	0.61 (0.45–0.8)	0.75 (0.48–0.94)	0.23
Albumin (g/dL)	4.09 ± 0.37	4.10 ± 0.32	0.93
Cholesterol (mg/dL)	164.9 ± 36.64	169.22 ± 33.89	0.73
Triglyceride (mg/dL)	137.24 ± 60.9	161.37 ± 53.7	0.25
HDL (mg/dL)	39.08 ± 11.08	42.78 ± 6.53	0.31
CAP	202.9 ± 69.6	294 ± 58.5	<.001*
LSM (kPa)	5.3 ± 1.8	6.1 ± 1.8	0.19

ALP: Alkaline phosphatase; ALT: Alanine aminotransferase; AST: Aspartate aminotransferase; INR: International normalized ratio; HDL: high-density lipoprotein; LSM: Liver stiffness measurement; CAP: controlled attenuation parameter

Conclusion: The high prevalence of NASH in patients of GSD with NAFLD may justify the need of routine liver biopsy during laparoscopic cholecystectomy in these patients.

THU101

Lack of awareness of a NAFLD pandemic in a high risk group. Is it time to act in primary care?

Maria Guerra Veloz[1], Kosh Agarwal[1], Marck Chamley[2], Saima Ajaz[1].
[1]*Institute of Liver Studies. King's College Hospital, London, United Kingdom;* [2]*Partner, North Wood Group Practice, Lambeth Diabetes Intermediate Care Team, United Kingdom*
Email: maria.guerraveloz@nhs.net

Background and aims: Non-alcoholic fatty liver disease (NAFLD) includes a wide spectrum of conditions and is currently the leading cause of chronic liver disease. NAFLD is intrinsically associated with obesity and is particularly common in people with type 2 diabetes (T2D) with a prevalence ranging from 70 to 80%. As NAFLD is mostly a silent disease, early diagnosis and the accurate staging of fibrosis is crucial for patients who are at risk. The complex relationship between NAFLD and T2D, the risk of cardiovascular disease, raises the question of the cost effectiveness of screening for NAFLD in the general population. With current guidelines discouraging screening in the general population, early recognition and intervention are important in high-risk groups in order to improve clinical outcomes.
The aim of our project was to evaluate the awareness of NALFD knowledge, the prevalence of NAFLD, and the prevalence of advanced fibrosis in patients with T2D who regularly attend a secondary diabetes clinic.
Method: Patients with T2D that have a regular follow-up at the Lambeth Diabetes Intermediate Care Centre were invited to participate in the NAFLD screening using a Fibroscan. A structured diet, exercise activity and NAFLD knowledge ***questionnaires*** were provided by a liver doctor to all patients that agreed to participate in this project. Anthropometric measures, medical history, LSM and CAP were recorded for each patient. The presence of steatosis was defined with a CAP cut off ≥ 275 dB/m and advanced fibrosis ≥ 8kpa.
Results: We screened 90, 47.3% were male with a median age of 59 years (IQR 52 – 66), most were of black African descent 55.6% (50) with a median BMI of 31.8 kg/m2 (26 – 37). Comorbidities, such as hypertension, coexisted in 61.1% and 58.9% had dyslipidaemia. (Baseline characteristics Figure 1)
The Fibroscan data was valid in 96.7% (87), 56.3% (49/87) had steatosis and 27.6% (24/87) had advanced fibrosis.
14.4% (13) were aware of NAFLD/NASH, 33.3% were aware that they were overweight or obese and 88.9% stated that they had received guidance about having a healthy lifestyle. Of the patients who were not aware of NAFLD (85.6%), 58% of these had steatosis and those who were not aware of being overweight/obese (66.7%), 40.6% of these were overweight and 25% were obese.
38% of patients who had steatosis and 47.8% who had advanced fibrosis were on GLP-1 analogue (24.4% of all patients).

Demographic variables	n= 90
Males n (%)	43 (47.8)
Age (years), median (IQR)	59 (52 -66)
Race n (%)	
White	18 (20)
Black African/Caribbean	50 (55.6)
Asian	1 (1.1)
Mediterranean	9 (10)
Hispanic	5 (5.6)
Weight Kg median (range)	89.5 (74 – 104)
BMI kg/m2 median (range)	31.8 (26.7 -37.2)
Normal weight	14 (15.6)
Overweight	19 (21.1)
Obese	49 (54.4)
Comorbidities (%)	
Hypertension	55 (61.1)
Dyslipidaemia	53 (58.9)
OH consumption (yes %)	2 (2.3)
Active smokers (yes %)	30 (33.3)
GLP-1 treatment (yes %)	22 (24.4)
Diet evaluation (yes %)	
Daily vegetables/fruits	48 (53.3)
Daily olive oil/nuts	17 (18.9)
Ultra-processed food weekly	19 (21.1)
Daily carbohydrates	40 (44.4)
Exercise n (%)	
No	44 (48.9)
Low activities	18 (20)
Moderate activities	28 (31.1)
Fibroscan	(n=87)
Median Kpa (range)	5.4 (4 – 8.1)
Advanced Fibrosis (%)	24 (27.6)
*Median Kpa (range)	12 (9 -14)
CAP	
Median dB/m (range)	295 (235-338)
Steatosis (%)	49 (56.3)

Conclusion: T2D patients are mostly unaware of this silent epidemic, and so do not recognise themselves as being overweight/obese, which is intrinsically linked with NAFLD. Preliminary data suggests that the screening of NAFLD in patients with T2D can yield important information regarding the prevalence of advanced fibrosis and factors affecting the progression of NAFLD in this *multi-ethnic high-risk group*. It is particularly important to screen the patients who are already in our healthcare system due to other pre-existing conditions.

THU102

Non-alcoholic fatty liver disease and type 2 diabetes: low referral rate of patients at increased risk of progressive liver disease

Lucy Gracen[1,2], Kelly Hayward[1,2], Melanie Aikebuse[1,2], Anthony Russell[3,4], James O'Beirne[5], Katharine Irvine[6], Suzanne Williams[7], Patricia Valery[8], Elizabeth Powell[1,2]. Email: lucy.gracen@hotmail.com

Background and aims: Routine assessment of liver fibrosis in people with non-alcoholic fatty liver disease (NAFLD) is recommended. The aim of this study was to determine whether a community-based NAFLD diagnosis, risk-stratification and referral pathway for people with type 2 diabetes (T2D) provides targeted detection of advanced fibrosis and appropriate referral to liver clinics.

Method: People with T2D were screened for NAFLD when they attended a diabetes clinic appointment in the community, using FibroScan (VCTE) as a point-of-care test to assess steatosis (CAP score ≥248) and fibrosis (liver stiffness measurement, LSM). A letter to participants' general practitioners (GPs) provided the LSM result and guidance on appropriate management/follow-up of their patients in primary care, as well as investigation of abnormal liver enzymes. Referral to a liver clinic was advised if LSM ≥8.0kPa. Patients were advised to discuss their liver health and FibroScan result with their GP. A monthly audit of GP referrals to liver clinics was provided by the central referral hub to assess whether GPs pursued the recommended referral.

Results: To date, 129 people with T2D (61.9% male, 58.8 ± 9.7 years) were assessed and VCTE met quality criteria in 126 (97.7%). Referral to a liver clinic for further assessment was advised for 28 (22.2%) patients with LSM ≥8.0kPa and 8 patients with other indications (Figure). 68 (54.0%) of 126 patients had abnormal liver function tests and 13 (10.3%) had LSM ≥12.0kPa suggestive of advanced chronic liver disease (CLD). 34 (27.0%) of 126 patients had a prior liver ultrasound (US) of which two-thirds (n = 23) showed steatosis and 2 had clear signs of CLD. None of these patients had been referred for fibrosis assessment reflecting the need to embed this in routine clinical pathways. A greater proportion of people with LSM ≥8kPa had a prior US compared to those with LSM <8kPa (46.4% vs. 21.4%, p = 0.009), suggesting GPs are identifying patients that need investigation but not pursuing further management. A GP referral was received for 13 (36.1%) of the 36 patients with a recommendation for referral.

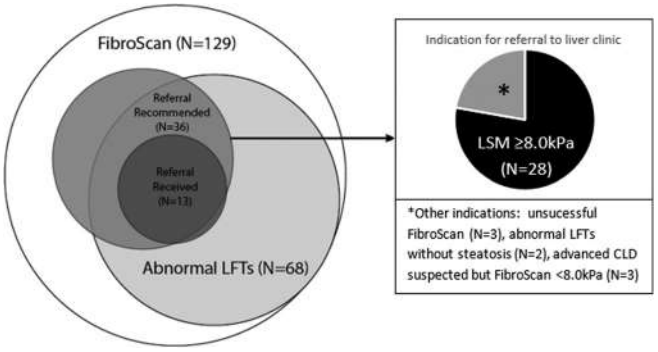

Figure: Proportion of patients with type 2 diabetes recommended for referral to liver clinic following FibroScan assessment. Circles proportionate to group size; liver function tests (LFTs).

Conclusion: VCTE as a point-of-care test provides a well-validated real-time assessment of liver fibrosis as well as steatosis and allows for timely delivery of the diagnosis and fibrosis risk category (low or increased risk) to the patient's healthcare team. The high detection rate of people requiring specialist assessment supports this screening approach. However the low GP referral rate in a cohort at increased risk of progressive liver disease calls attention to the need for improved education, guidelines and referral pathways for NAFLD to embed fibrosis assessment in the patient workflow.

Hypertension and diabetes mellitus are associated with high FIB-4 index in a health checkup examination cohort without known liver disease

Shunsuke Sato[1], Hidehiko Kawai[2], Sho Sato[1], Hirohiko Iwasaki[2], Yuji Kita[1], Yuji Ikeda[1], Ayato Murata[1], Yuji Shimada[1], Takuya Genda[1]. [1]*Juntendo University Shizuoka Hospital, Gastroenterology and Hepatology, Shizuoka, Japan;* [2]*Fuji Town Medical Center, Shizuoka, Japan*
Email: syusato@juntendo.ac.jp

Background and aims: Non-alcoholic fatty liver disease (NAFLD) is usually asymptomatic and lacks a specific biomarker; therefore, many individuals might remain undiagnosed even with advanced liver fibrosis. The aim of this study was to clarify the prevalence and clinical features of subjects with a high risk of advanced liver fibrosis in the general population, using the Fibrosis-4 (FIB-4) index.

Method: We retrospectively investigated 6, 183 subjects without known liver disease who had participated annual health checkup examination. We analyzed the factors associated with high FIB-4 index (≥2.67) using a logistic regression analysis.

Results: Among 6, 183 subjects, 76 (1.2%) had high FIB-4 index. Multivariate analysis identified hypertension (odds ratio [OR] = 8.926; 95% confidence interval [CI] 4.031–19.768; P < 0.001) and diabetes mellitus (OR = 4.045; 95% CI 1.694–9.660; P = 0.002) as important risk factors for high FIB-4 index. The rates of hypertension and diabetes mellitus in subjects with high FIB-4 index were 78.9% and 23.7%, respectively. No significant association was observed between obesity or large waist circumference and a high FIB-4 index. A history of cardiovascular disease was significantly more common in subjects with high FIB-4 index. These results were also observed in the subjects with normal aminotransferase (ALT) levels.

Conclusion: The present study revealed that approximately 1% of the general Japanese population has a high risk of advanced liver fibrosis. Many of these patients had hypertension and/or diabetes mellitus. The findings suggest that there are many undiagnosed NAFLD patients with risk of advanced liver fibrosis in the general population.

THU104

Statins, but not aspirin, reduce the risk of hepatocellular carcinoma and mortality in Danish patients with cirrhosis due to alcohol-related liver disease: a nationwide causal study

Frederik Kraglund[1], Diana Hedevang Christensen[2], Peter Jepsen[1]. [1]*Aarhus University Hospital, Department of Hepatology and Gastroenterology, Aarhus N, Denmark;* [2]*Aarhus University Hospital, Department of Clinical Epidemiology, Aarhus N, Denmark*
Email: frekra@clin.au.dk

Background and aims: Observational studies have shown a strong association between use of statins or aspirin and a lower risk of hepatocellular carcinoma (HCC). We emulated a trial assessing the causal link between statin and aspirin use and HCC development and mortality in Danish patients with cirrhosis due to alcohol-related liver disease (ALD cirrhosis).

Method: Using nationwide Danish healthcare registries, we identified all patients diagnosed with ALD cirrhosis, 2000-2018. We determined their statin and aspirin use through reimbursed prescriptions. A target trial was designed in which patients were randomised to initiate and adhere to statins (and, in a separate analysis, aspirin) or to not initiate treatment. The primary end point

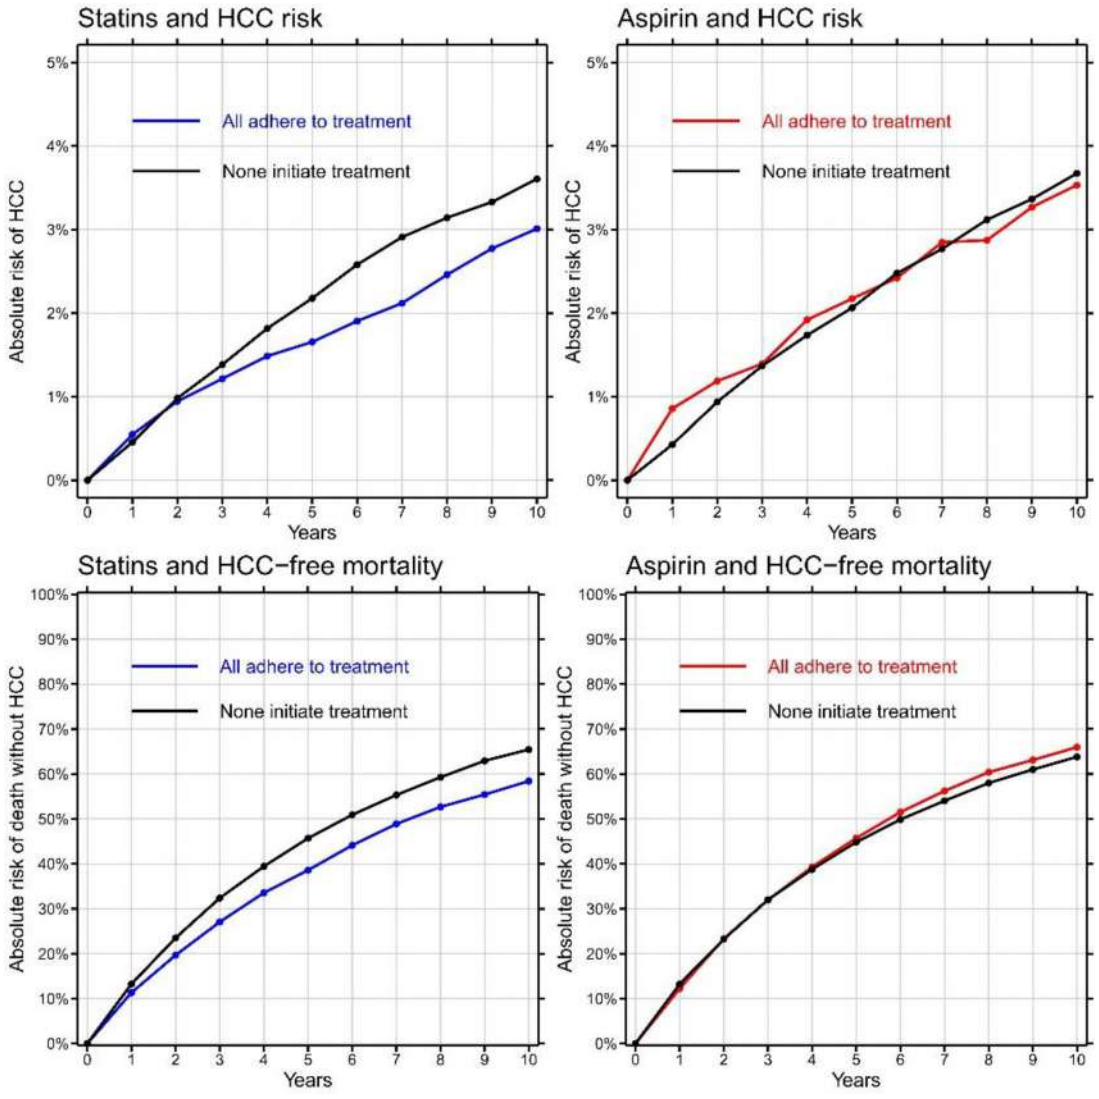

Figure: (abstract: THU104)

was HCC development, and the secondary end point was death without HCC. The target trial was emulated using inverse probability of treatment and censoring weights to create a marginal structural model adjusted for comorbid diseases, prescription drugs, procedures, hospital contacts, and prior use of statins among other covariates. Based on this model we estimated the average treatment effect (ATE) of statin use (and aspirin use) on the cumulative risk of HCC and of death without HCC.

Results: Of 16, 811 patients with ALD cirrhosis, 4, 540 used statins at some point during follow-up, 4, 647 used aspirin, and 899 were diagnosed with HCC. The ATE of statin use was 0.74 (95% confidence interval [CI] 0.47 to 1.02) for HCC and 0.77 (95% CI 0.70 to 0.83) for death without HCC. The ATE of aspirin use was 1.08 (95% CI 0.73 to 1.44) for HCC and 1.10 (95% CI 1.02 to 1.19) for death without HCC. The cumulative HCC incidence functions and corresponding relative risk estimates reflected the ATEs (Figure).

Conclusion: Statin use reduces the risk of HCC and death without HCC in patients with ALD cirrhosis. Conversely, aspirin use does not reduce the risk of either HCC or death without HCC in patients with ALD cirrhosis. Thus, statins, but not aspirin, likely have a chemopreventive effect in patients with ALD cirrhosis. While we wait for truly randomized studies, studies such as ours provide the strongest possible evidence in favour of statins.

Gut microbiota and liver disease

Altered fecal microbiome and metabolome in hepatitis B related chronic liver diseases

Wei Jiang[1], Yue Shen[1], Wu ShengDi[1], Jian Wu[2,2,2]. [1]*Zhongshan Hospital, Fudan University;, Shanghai Institute of Liver Diseases, Department of Gastroenterology and Hepatology, Xuhui District, Shanghai, China;* [2]*Fudan University Shanghai Medical College, Dept. of Medical Microbiology and Parasitology, MOE/NHC/CAMS Key Laboratory of Medical Molecular Virology, School of Basic Medical Sciences, Shanghai, China*
Email: jiang.wei@zs-hospital.sh.cn

Background and aims: It is well accepted that microbiota is a major modulator of liver diseases and is associated with severe clinical outcomes. However, the influence of gut dysbiosis on chronic hepatitis B (CHB) progression as well as the interplay between microbiota shift and antiviral treatment remains to be clarified. The present study aims to provide a comprehensive profile of gut microbiome and metabolomics in CHB patients at different disease stages. Taking advantage of a cohort of CHB patients with entecavir

therapy for five years, influence of antiviral treatment on the characteristics of microbial composition and function in CHB patients was investigated.

Method: Fecal samples from subjects with CHB (n = 64) and healthy controls (n = 17) were sequenced with 16 s rRNA analysis. Fecal metabolomics was measured via untargeted LC-MS in subgroups of 58 subjects (Fig. 1A).

Results: Compared to healthy controls, community richness, diversity and evenness of gut microbiota were decreased during CHB progression (Fig. 1B and 1C). Overall gut microbial community was shifted (Fig. 1D). Four genera: Faecalibacterium, Streptococcus, Sutterella and Ruminiclostridium_9 were enriched in CHB patients. Eight genera including Blautia, Escherichia-Shigella, Klebsiella, Bifidobacterium, Parasutterella, Eubacterium hallii group,

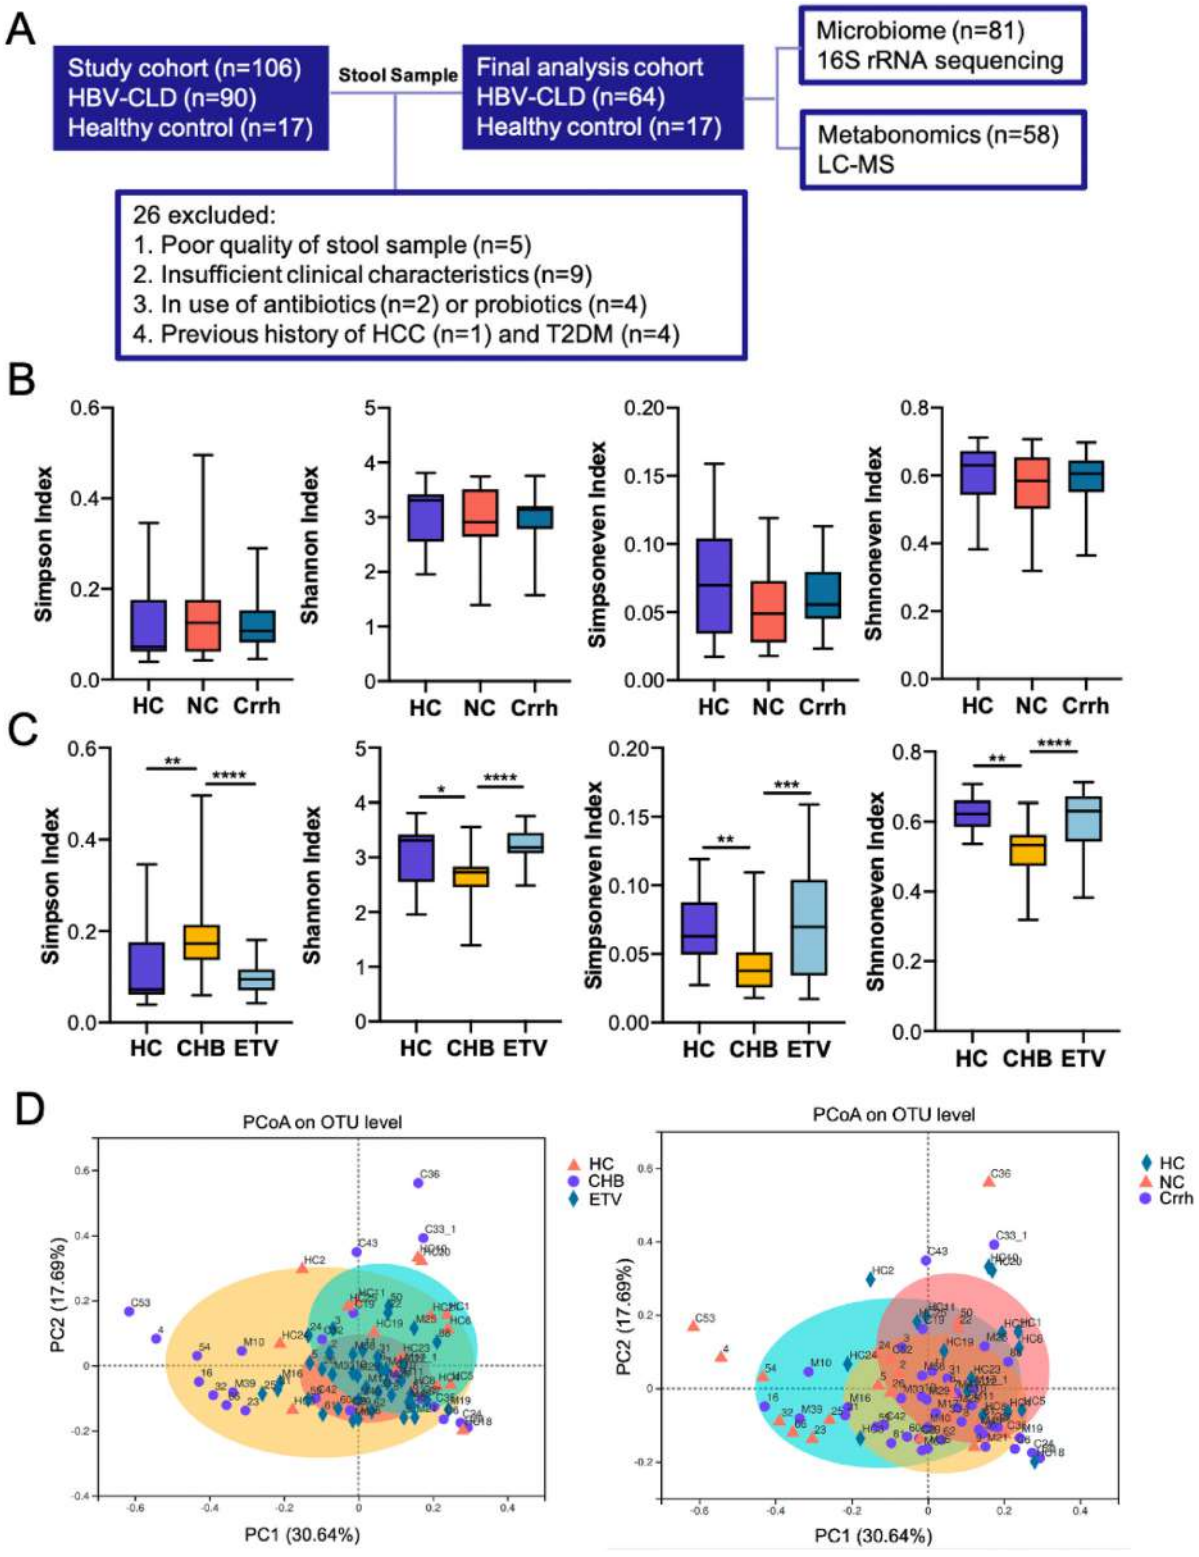

Figure 1: (abstract: THU151)

Collinsella and Lactococcus were found to decrease, accompanying with 206 metabolites statistically different in abundance. Importantly, distinct patterns of microbiota composition and metabolic activity were identified in subgroup analysis based on disease stages and the presence of antiviral treatment (Fig. 2 and 3). It was demonstrated that there was a potential association between microbial or metabolic signatures and clinical characteristics (Fig. 4). Notably, disease-enriched genera Streptococcus and metabolite 20-hydroxy-leukotriene E4 were negatively correlated with albumin (ALB) and positively with direct bilirubin (DB). Concordant depletion of Turicibacter and Adlercreutzia accompanying with 4-hydroxyretinoic acid tended to correlate with elevated AST and DB in CHB patients. Potential links between clinical parameters and restored genera or metabolites in CHB patients receiving antiviral treatment were detected. In particular, concordant increase of Ruminococcaceae_UCG-013 and sebacic acid was positively correlated with ALB, suggesting that novel host-microbial interplay was involved in the antiviral treatment of CHB patients.

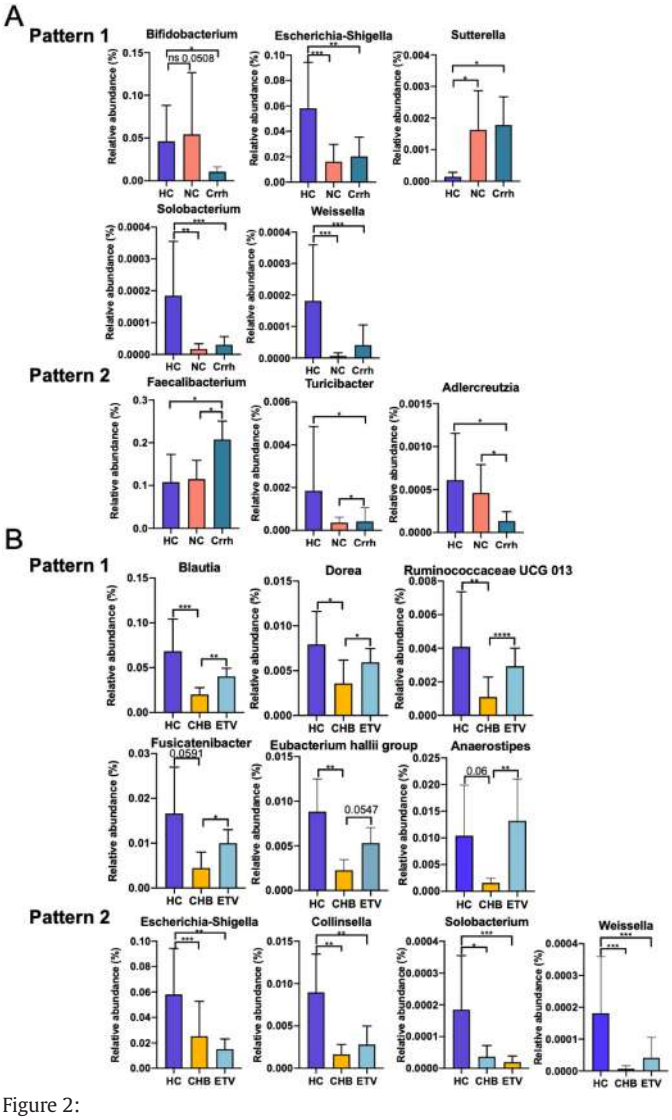

Figure 2:

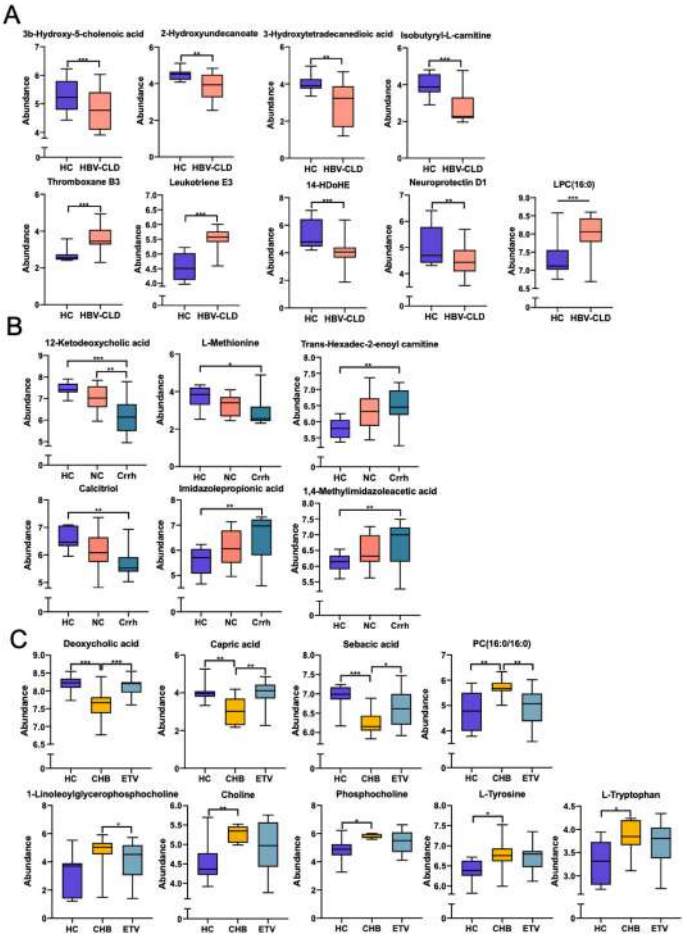

Figure 3:

Conclusion: Microbiome and metabolomics analysis was integrated to provide a comprehensive profile of gut dysbiosis characterized by microbial and metabolic alterations in CHB patients. CHB progression and antiviral treatment significantly contributed to the imbalance of gut microbial community and metabolomics profiles in this study.

The therapeutic effect of Lactobacillus plantarum on metabolic phenotypes in non-alcoholic fatty liver disease mice model

DongYun Kim[1,2], Jun Yong Park[3,4], Heon Yung Gee[2]. [1]*Yonsei University Graduate School of Medicine, Department of Medicine, Physician-Scientist Program;* [2]*Yonsei University College of Medicine, Department of Pharmacology, Graduate School of Medical Science, Brain Korea 21 Project;* [3]*Yonsei University College of Medicine, Department of Internal Medicine, Institute of Gastroenterology;* [4]*Yonsei University College of Medicine, Yonsei Liver Center*
Email: drpjy@yuhs.ac

Background and aims: *Lactobacillus* is considered a potential probiotic and has shown therapeutic potential for several liver diseases including non-alcoholic fatty liver disease (NAFLD). However, it is not known how dietary supplementation of *L. plantarum* has favoring effect on liver. Therefore, we investigated the therapeutic potential of *L. plantarum* supplementation on NAFLD in a mouse model and aimed to elucidate its mechanism.
Method: We used the choline-deficient high fat diet (CD-HFD)-induced murine model that recapitulates key features of human metabolic syndrome. To induce NASH status, C57BL/6N mice were fed a CD-HFD for 30 weeks. Then these mice were divided into three groups: vehicle, *L. plantarum* (10^9 CFU/day), and empagliflozin, selective SGLT2 inhibitor (10 mg/kg/day). After 12 weeks of treatment, mice were sacrificed and subjected to blood measurements, and liver tissue for RNA isolation, lipid measurements, histology, and stool for microbiome analysis.
Results: *L. plantarum* and empagliflozin treatment significantly improved several metabolic phenotypes such as insulin tolerance, and hepatic lipid contents compared to vehicle group, respectively. However, the histological NAFLD activity score (NAS) was more improved in the *L. plantarum* group (3.0, $p = 0.0286$) than in the empagliflozin group (4.0, $p = 0.0591$) compared to vehicle group (5.5). RNA-sequencing analysis revealed that administration of *L. plantarum* downregulated genes related to inflammation such as T cell differentiation and leukocyte activation in liver. In the microbial analysis of stool samples, the elevated Firmicutes-to-Bacteroidetes ratio in the vehicle group (21.97) was decreased in the *L. plantarum* group (0.86). Furthermore, disrupted intestinal epithelial barrier function was restored in *L. plantarum* group and elevated serum endotoxin level was significantly reduced in *L. plantarum* group compared to vehicle group.
Conclusion: Our data demonstrated that administration of *L. plantarum* can improve NAFLD associated phenotypes by altering gut microbiome composition and decreasing serum endotoxin levels.

Email: j.cox@researchinliver.org.uk

Background and aims: Cirrhosis is associated with changes in gut microbiota in both saliva and stool. However, the relative linkage patterns of stool vs saliva microbiota with systemic metabolomics are unclear. Moreover, these may differ across countries. We hypothesized that stool has a greater linkage with plasma metabolites than saliva, which is unique depending on country of origin. Aim: Correlation analyses of plasma metabolomics with stool and saliva microbiota in healthy and cirrhotic subjects from USA vs Mexico (MX).
Method: Age-balanced outpt cirrhotics, compensated (Comp) and decompensated (Decomp), and controls from USAandMX underwent plasma collection and dietary recall. Plasma metabolomics were analyzed using NMR spectroscopy. Microbiota in stool and saliva samples were analyzed using 16SrRNA community analyses. Correlation network differences between both saliva and stool gut microbiota and plasma metabolites were compared in controls, Comp and Decomp pts within/between countries.
Results: 313 age-balanced subjects; 135 USA (47 control, 48 Comp, 40 Decomp) and 178 MX (71 control, 56 Comp, 51 Decomp) were enrolled. MELD/cirrhosis severity including lactulose and rifaximin use was comparable (Fig A). Correlation networks demonstrated more microbiome-metabolite linkages in stool compared to saliva in both populations, while there were no salivary correlations with microbiota across MX and decomp USA (Fig B).
Lactobacillus correlations: Network differences of plasma lactate showed a positive correlation to stool *Lactobacillus* in MX Decomp. For USA Decomp, plasma lactate showed a positive correlation to stool *Bifidobacterium* but no correlation with stool *Lactobacillus*. Stool *Lactobacillus* in USA showed a negative correlation with *Faecalibacterium*. Stool *Lactobacillus* correlations with microbiota in stool (pink) vs saliva (blue) vs metabolites (orange) are shown for USA (Fig C) and MX (Fig D) Decomp.

Fig A Clinical Metadata *p<0.05 US vs MX, †p<0.05 within USA, ‡p<0.05 within MX						
	USA (n=133)			Mexico (n=142)		
	Control (n=40)	Comp (n=50)	Decomp (n=43)	Control (n=41)	Comp (n=49)	Decomp (n=52)
Age	57.8±10.1	61.2±6.9	60.4±6.6	57.9±7.1	59.0±9.2	58.1±9.7
Male*	35%	80%	80%	30%	50%	50%
MELD score‡†	-	8.8±3.1	14.5±5.5	-	9.2±2.5	16.0±7.9
NASH etiology	-	16%	7%	-	17%	12%
Alcohol etiology	-	22%	34%	-	2%	33%
Diabetes	-	26%	30%	-	15%	20%

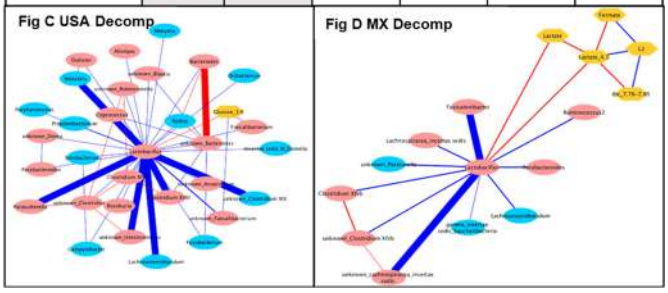
Ascites ‡†	-	-	67%	-	-	76%
Prior HE ‡†	-	-	81%	-	-	76%
S. albumin (g/dl) ‡†	-	3.75±0.49	3.01±0.98	-	3.80±0.53	2.89±0.73

Fig B Correlation between metabolites and sample type (r<-0.6 or>0.6 & p<0.05)						
Any significant correlations?	USA			Mexico		
	Control	Comp	Decomp	Control	Comp	Decomp
Stool	Yes	Yes	Yes	No	No	Yes
Saliva	Yes	Yes	No	No	No	No



Conclusion: Stool microbiota are more extensively linked with systemic metabolites than saliva microbiota, irrespective of cirrhosis severity and country. These changes are more prominent in Decomp and are centered around plasma lactate, which might be related to interaction of diet and lactulose therapy. Stool microbiota have a greater functional footprint associated with the systemic milieu compared to salivary microbiota.

THU154

The gut virome in non-alcoholic fatty liver disease: distinct changes in Phapecoctavirus composition in a human microbiota associated animal model

Hau-Tak Chau[1], Hein Tun[2], Saisai Zhang[1], Dengwei Zhang[2], Fung Yu Huang[1], Lung Yi Loey Mak[1,3], Man-Fung Yuen[1,3], Wai-Kay Seto[1,3]. *[1]The University of Hong Kong, Hong Kong, Department of Medicine, Hong Kong; [2]The University of Hong Kong, Hong Kong, School of Public Health, Hong Kong; [3]The University of Hong Kong, Hong Kong, State Key Laboratory of Liver Research, Hong Kong*
Email: wkseto@hku.hk

Background and aims: There is increasing knowledge on the role of the gut microbiome in the development of non-alcoholic fatty liver disease (NAFLD), but the role of the gut viral community in disease development remains poorly understood. We aimed to discover gut virome related to NAFLD development via a human-microbiota-associated (HMA) rodent model of NAFLD.
Method: Human fecal donors were recruited and classified into obese NAFLD, non-obese NAFLD and non-obese healthy controls. Liver steatosis was assessed by vibration-controlled transient elastography (Fibroscan, Echosens, Paris). The HMA-NAFLD rodent model was established by high-fat diet and transplantation of human fecal microbiota (FMT) for 12 weeks. The profile of the gut virome of both human donors and rodents was assessed by shotgun metagenomic sequencing (Illumina NovaSeq 6000, US).
Results: Human donors with NAFLD had a significantly higher controlled attenuation parameter measurement when compared to healthy controls (median 324 [IQR 305.5–355.75] vs. 182.5 [179.25–199.25] dB/m, p <0.001). Based on Bray-Curtis distance and PERMANOVA testing, human NAFLD donors had a distinct gut DNA virome compared with healthy controls (p = 0.04). Analysis via linear discriminate analysis (LDA) effect size method identified the Phapecoctavirus genus as a potential biomarker (LDA score 3.80), indicating a lower median relative abundance of Phapecoctavirus in NAFLD donors when compared to healthy donors (3.54% [IQR 2.93%-3.98%] vs. 4.15% [3.94%-4.94%], p = 0.038). As a putative host for Phapecoctavirus, the abundance of Escherichia coli was negatively associated with Phapecoctavirus (rho = – 0.51, p = 0.012). In the animal model, mice receiving FMT from obese NAFLD (FMT-ON) displayed a more severe NAFLD phenotype than those receiving FMT from healthy control (FMT-HC) (liver triglyceride: median 65.35 [IQR 62.32–73.33] vs. 48.7 [38.61–54.44] mg/g liver tissue, p = 0.015; blood triglyceride: 207.89 [187.87–216.94] vs. 110.05 [102.16–120.76] mg/dL, p <0.001). Phapecoctavirus genus was similarly identified as a potential fecal biomarker when comparing FMT-ON vs. FMT-HC (LDA score 3.19). It was the only viral genus that distinguished NAFLD from control in both human donors and mouse recipients. FMT-ON mice with more severe NAFLD had a significantly lower level of fecal Phapecoctavirus than FMT-HC mice (median 2.47% [IQR 2.39%-2.75%] vs. 2.82% [2.6%-3.14%], p = 0.038).
Conclusion: We reported the association of reduced fecal Phapecoctavirus with NAFLD in both human donors and HMA-mice recipients. Further interventional studies in animal and human are warranted to determine its potential causality and function in NAFLD.

THU155

Mitochondrial hyperactivation determines a transferable protective gut microbiota profile in metabolic-associated fatty liver disease development

María Juárez-Fernández[1], Naroa Goikoetxea[2], David Porras[1], María-Victoria García-Mediavilla[1,3], Héctor Rodríguez[4], Esther Nistal[1,3], Susana Martínez-Flórez[1], Mercedes Rincón[5], Marta Varela-Rey[2], Javier González-Gállego[1,3], Leticia Abecia[4,5], Juan Anguita[4,6], María Luz Martínez-Chantar[2,3], Sonia Sánchez-Campos[1,3]. *[1]Institute of Biomedicine (IBIOMED) University of León, Spain; [2]Liver Disease laboratory, CIC bioGUNE, Centro de Investigación Biomédica en Red de Enfermedades Hepáticas y Digestivas (CIBERehd), Spain; [3]Centro de Investigación Biomédica en Red de Enfermedades Hepáticas y Digestivas (CIBERehd), ISCIII, Spain; [4]Inflammation and Macrophage Plasticity laboratory, CIC bioGUNE, Spain; [5]University of Vermont, Department of Medicine and Immunobiology, College of Medicine, Burlington, United States; [6]Ikerbasque, Spain*
Email: ssanc@unileon.es

Background and aims: Mitochondrial dysfunction plays a key role in metabolic-associated fatty liver disease (MAFLD). Methylation-controlled J protein (MCJ) is a negative regulator of mitochondrial complex I. Its deletion increases mitochondrial activity and reduces diet or hepatotoxic drug-induced lipid accumulation and hepatic damage. The study aims to determine the microbiome signature associated to MCJ deficiency and its capacity to transfer its hepatoprotective phenotype to germ-free (GF) mice through caecal microbiota transplantation.
Method: Wild type (WT) and MCJ-KO C57BL/6J mice were fed with a control or a choline-deficient high fat diet (CDA-HFD) for 6 weeks. Then, a donor mouse from each experimental group was selected based on MAFLD development parameters. GFm were colonized with caecal microbiota from donors and subjected to dietary intervention (C or CDA-HFD) for 3 weeks. After that, samples were collected and processed for assessment of liver disease and gut microbiota composition.
Results: CDA-HFD during 6 weeks induced an inflammatory and fibrotic state compatible with steatohepatitis development. MCJ-KO mice showed a lower liver expression of inflammatory and fibrotic markers. This effect was reproduced in GFm colonized with microbiota from MCJ-KO donors and fed with CDA-HFD. Metagenomic analysis revealed a profound reshaping of gut microbiota due to the diet, but also changes in specific bacterial

taxa attributed to MCJ-KO genotype. *Dorea* and *Oscillospira* genera were increased, while *AF12, Allobaculum* and *Ruminococcus* were decreased. This microbiota profile was also observed in GFm following microbiota transplantation, highlighting an increase in the abundance of the genus *Dorea* in all groups colonized with microbiota of MCJ-KO mice. Finally, MCJ-KO mice fed with CDA-HFD showed a higher hepatic and intestinal production of nicotinamide-adenine dinucleotide (NAD), likewise a higher expression of its synthesis enzymes. These results were reproduced in GFm transplanted with MCJ-KO microbiota.

Conclusion: The protective effect of MCJ deficiency on MAFLD progression implies a mitochondrial hyperactivation mechanism associated to a higher NAD production capacity, that determines a gut microbiota profile, which is transferred by transplantation to GFm.

THU156

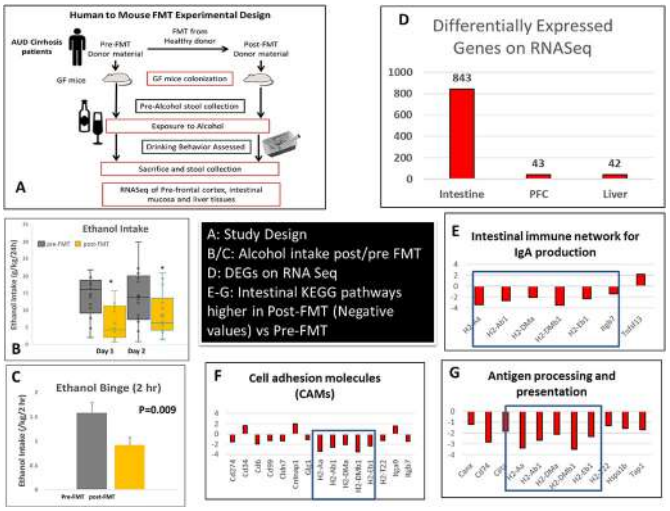
Fecal transplant-related reductions in Alcohol intake from human to mice are associated with alterations in the intestinal but not liver or prefrontal cortex transcriptome

Jennifer Wolstenholme[1], Maren Smith[1], Ryan Balfour Sartor[2], Javier Maeso-Gonzalez[1], Derrick Zhao[1], Huiping Zhou[1], Jason Kang[1], Phillip Hylemon[1], Jasmohan S Bajaj[1]. [1]*Virginia Commonwealth University and Richmond VA Medical Center;* [2]*UNC Chapel Hill*
Email: jasmohan.bajaj@vcuhealth.org

Background and aims: In a recent randomized placebo-controlled trial in men with cirrhosis, we found that fecal microbiota transplant (FMT) reduced alcohol craving and consumption compared to placebo. We found that transmitting stool post-FMT but not pre-FMT to germ-free mice (GF) reduces alcohol drinking but the metabolic pathways associated with this reduction are unclear. Aim: determine the genes activated along the gut-liver-brain axis after stool transfer into mice.

Method: To test whether FMT can act as a therapy to reduce craving, mice were gavaged with fecal microbiota material from the same patients described above (Fig A). 30 GF male C57BL/6 mice received combined stool from pts prior to FMT (pre-FMT) or stools from the same pts after FMT (post-FMT). Initial ethanol acceptance, intake and preference were measured using a 2-bottle choice ethanol drinking assay. A bottle of ethanol (20% v/v) and water were placed on each mouse's cage and readings were taken at 2 (binge), 24 and 48 hours. Intestinal mucosa, liver and prefrontal cortex (PFC) were harvested 18 hours post-alcohol. RNASeq was run on 6 mice that drank the most in the pre-FMT and the least in the post-FMT group for all 3 sites. Differentially expressed genes (DEG) were further analyzed using GO and KEGG pathway analyses with DAVID and Revigo. Finally, Ingenuity Pathway Analysis was also performed.

Results: Alcohol preference/intake: Exposure to post-FMT stool significantly reduced initial ethanol acceptance, and 24-hour ethanol intake and preference compared to those who got pre-FMT material (Fig B/C). RNASeq Results: The overwhelming majority of DEGs were in the intestine (Fig D) with only 1/20th of genes differentially expressed in the liver and PFC pre- vs. post-FMT. Overrepresented KEGG pathways were focused on IgA production, antigen processing and presentation, and cell adhesion molecules most of which were significantly higher in post-FMT vs. pre-FMT mice (Fig E-G). Specifically, these were related to immune regulators such as transforming growth factor beta 1 (*Tgfb1*), interleukin receptor 10 alpha and 1 beta (*Il10ra, Il1b*), interferon γ (*Infg*), and tumor necrosis factor (*Tnf*). Sphingosine synthesis was lowered post-FMT.



Conclusion: FMT from humans, through a successful trial, leads to lower alcohol intake in GF mice colonized with post-FMT stools through significant changes in intestinal genes rather than liver or prefrontal cortex. Changes in gut immune-inflammatory response after FMT could strengthen the gut barrier and reduce gut-liver-brain signaling and underlines the role of the gut in the modulation of behavior that is transmissible from humans.

Email: m.j.hole@studmed.uio.no

Background and aims: The fecal microbiota in primary sclerosing cholangitis (PSC) is characterized by low diversity and increased relative abundance of *Veillonella*, while data on the mucosal microbiota are inconsistent. No particular microbiota features have been linked to the presence of PSC-IBD, and little is known about the impact of recurrent PSC (rPSC-LT) after liver transplantation (LT). We aimed to investigate the mucosal microbiota in PSC and utilize rPSC to define consistent microbiota features associated with PSC irrespective of transplantation.

Method: We included 84 PSC and 51 PSC-LT patients (of which 25/51 [49%] had or developed rPSC median 5.0 years after LT) with biopsies available from at least two ileocolonic segments. 19 healthy controls (HC) were included for comparison. Biopsy DNA was subjected to 16S rRNA sequencing (V3-V4) and analyzed using QIIME2.

Results: Mucosal gut expansion of Proteobacteria was more pronounced in PSC-LT (up to 19%) than in in PSC (up to 11%), compared to only ~5% in HCs (Q_{FDR} <0.05). A limited set of genera was significantly associated with PSC both before (PSC compared with HCs) and after LT (rPSC-LT compared with PSC-LT). This set consisted of *Bilophila*, *Eubacterium hallii* and two different *Lachnospiraceae*, which had reduced relative abundance in PSC, and *Enterococcus*, *Streptococcus*, *Eisenbergiella* and *Hungatella,* which had increased abundance in PSC.

Alpha diversity was reduced (p <0.05) and *Veillonella* was significantly increased in PSC and PSC-LT compared to HCs, but did not separate rPSC-LT from PSC-LT. Concomitant IBD was associated with significantly reduced relative abundance of *Akkermansia*, irrespective of LT, ranging from 0.8–1.0% to 4.5–5.6% mean relative abundance. The potential pathobiont *Klebsiella* was detected in the mucosa in at least one segment in 18% of the patients before and 41% after LT (p <0.05) and associated with significantly reduced transplantation- and recurrence-free survival.

Conclusion: Liver transplantation does not normalize potentially disease-related microbiota features. Multiple bacterial genera associated with both PSC and rPSC-LT, and *Akkermansia* associated with PSC-IBD irrespective of transplantation status. Furthermore, *Klebsiella* associated with poor outcome both before and after liver transplantation.

THU158

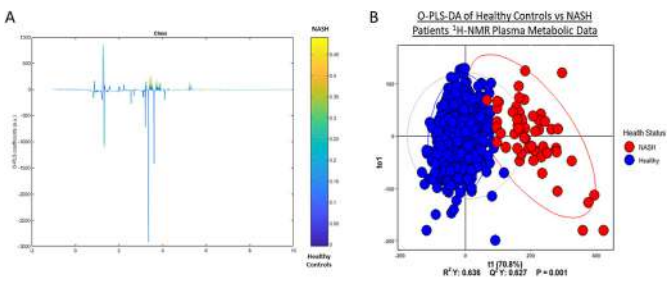
Designing a polymetabolic risk score for non-alcoholic steatohepatitis patients by differentiating their metabolic profiles from healthy controls

Nadeen Habboub[1,1], Pinelopi Manousou[1], Roberta Forlano[1], Benjamin H. Mullish[1], Gary Frost[1], Benjamin Challis[2], Mark Thursz[1], Marc-Emmanuel Dumas[1,3]. *[1]Imperial College London, Metabolism, Digestion and Reproduction, London, United Kingdom; [2]AstraZeneca, Biopharmaceuticals Research and Early Development, Translational Science and Experimental Medicine, Cambridge, United Kingdom; [3]Imperial College London, Heart and Lung Institute, London, United Kingdom*
Email: nh819@ic.ac.uk

Background and aims: The gut microbiome plays a role in the pathogenesis of non-alcoholic fatty liver disease (NAFLD) and its progression to non-alcoholic steatohepatitis (NASH). Studies have shown that changes in gut microbiota result in increased intestinal permeability, facilitating the translocation of bacteria and gut microbiome-modulated metabolites to the liver, inciting NASH. Our aim is to investigate the differences in metabolic profiles of NASH patients in comparison to healthy controls. We designed a metabolic profile scoring model based on plasma ^{1}H-NMR metabolic data which could distinguish NASH/NAFLD patients from healthy individuals.

Method: Biopsy-proven NASH patients (n = 55) were recruited from St Mary's Hospital and were compared to controls (n = 677), selected from the AIRWAVE population study by excluding the clinical characteristics of metabolic syndrome. Metabolic profiling of non-fasted plasma and urine samples were carried out by ^{1}H-NMR spectroscopy and UPLC-MS using HILIC and C18 reverse-phase columns. Untargeted and targeted ^{1}H-NMR metabolic profiles of plasma samples from both cohorts were examined by multivariate analysis for signature variation and scoring.

Results: We have demonstrated distinct differences in the plasma ^{1}H-NMR metabolic profiles of NASH patients and healthy controls. Multivariate models of the ^{1}H-NMR data showed a significant separation between the controls and NASH patients' clusters (R^2 >0.6, Q^2 >0.6, pR^2Y <0.001, pQ^2 <0.001). The polymetabolic based risk score was computed using the O-PLS-DA model of the untargeted ^{1}H-NMR metabolic profiles of the controls and NASH patients.



Conclusion: We have shown that the ^{1}H-NMR plasma metabolic profiles of NASH patients and healthy controls are significantly distinctive, which allowed for the construction of a polymetabolic risk-score to separate and distinguish these groups, demonstrating potential for interventions based on the metabolome.

THU159

Intestinal hyperpermeability in cirrhosis is predictive for survival and associated with distinct microbiome changes

Rosa Haller[1], Benard Aliwa[1,2], Angela Horvath[1], Vanessa Stadlbauer[1,3]. *[1]Medical University of Graz, Department of Gastroenterology and Hepatology, Graz, Austria; [2]University of Nairobi, Department of Food Science, Nutrition and Technology, Nairobi, Kenya; [3]CBmed Center of Biomarker Research in Medicine, Area Microbiome Research, Graz, Austria*
Email: vanessa.stadlbauer@medunigraz.at

Background and aims: Liver cirrhosis, the 10th most common cause of death in the western world is associated with increased intestinal permeability and alterations of gut microbiome composition. It is however not fully understood how intestinal permeability and the microbiome are interrelated in cirrhosis. We aim to investigate the potential of gut permeability biomarkers to predict mortality and their relation to microbiome composition.

Method: Stool, serum and urine samples from 78 cirrhotic patients (56 ± 9 years, 22 female) were obtained at baseline and after six months; survival was assessed after 24 months. Intestinal permeability was assessed by zonulin in stool and diamine oxidase (DAO) in serum. Kaplan-Mayer survival analysis, group comparisons and correlation analysis (Spearman) were performed. Gut microbiome 16 s rRNA sequencing data were analyzed by diversity metrics, ANCOM and LEfSe.

Results: Neither DAO nor zonulin at baseline were able to predict mortality, but when assessing the dynamics over 6 months, patients whose zonulin levels worsened or did not change (ZWOR, n = 45) had a higher mortality than those whose zonulin levels improved (ZIMP, n = 33) (log rank Mantel-Cox p = 0.048). ZWOR patients did not differ in etiology from ZIMP patients but had significantly worse international normalized ratio (p = 0.021) levels, and MELD score at baseline (p = 0.032). Microbiome composition (alpha- and beta diversity) did not differ between ZWOR and ZIMP patients. The genus *Phascolarctobacterium* was more abundant in ZIMP patients with both ANCOM and LEfSe. The relative abundance of *Phascolarctobacterium* correlated negatively with calprotectin in stool and sCD14 in serum as biomarker for intestinal inflammation and bacterial translocation.

Conclusion: Worsening of zonulin levels in over 6 months predicted mortality in patients with liver cirrhosis, indicating that serial assessments of this biomarker improve predictive power in cirrhosis. The genus *Phascolarctobacterium* was more abundant in ZIMP patients and correlated negatively with markers for intestinal inflammation and bacterial translocation. *Phascolarctobacterium* can produce short-chain fatty acids and upregulate the mRNA expression of claudin-1, a tight junction protein, indicating a possible link between the microbiome and intestinal hyperpermeability.

THU160

Novel multi-technology meta-analysis identifies gut microbiome strains associated with clinical fibrosis in NAFLD patients

Nicole Narayan[1], Erica Rutherford[1], Karim Dabbagh[1], Arun Sanyal[2], Todd Z. DeSantis[1]. *[1]Second Genome, Brisbane, United States; [2]Virginia Commonwealth University, Richmond, United States*
Email: nicole@secondgenome.com

Background and aims: While NAFLD consists of two subtypes (NAFL and NASH), patients within both subtypes lie on spectrums of multiple axes of disease severity including fibrosis. NASH diagnosis typically relies on liver biopsy. However, liver biopsies are not only invasive but carry substantial risk of complications rendering them

impractical for tracking disease progression in patients. Therefore, there is a substantial need for non-invasive diagnostic tools to identify patients with advancing stages of NASH, including clinical fibrosis (fibrosis scores 2–4). While many studies have associated members of the gut microbiota with NAFLD and NASH, these studies either do not discriminate by fibrosis score or they focus on advanced disease (fibrosis score 4). Here we integrated samples from multiple datasets to find strains specifically associated with clinical fibrosis compared to controls and low fibrotic score NAFLD patients using multi-technology meta-analysis (MTMA). We hypothesized that patients with clinical fibrosis would display a different microbial signature and this could constitute the basis of a diagnostic method to non-invasively diagnose clinical fibrosis.

Method: We incorporated data from 189 patients across three studies (two public datasets and one collaboration between Arun Sanyal and Second Genome). Across this meta-cohort, 42 patients had clinical fibrosis (fibrosis score 2–4) and 147 patients were either controls or NAFL with low fibrosis (fibrosis score 0–1). All studies were processed using Second Genome's sg-4sight platform to harmonize 16S amplicon and shotgun metagenomic sequencing, mapping all data against our proprietary StrainSelect reference database. We developed a novel multi-technology meta-analysis (MTMA) procedure to identify the strains which are consistently associated with clinical fibrosis in NAFL patients.

Results: A total of 996 strains were found common across at least two of the three datasets used for analysis. After adjusting for false discovery, MTMA found seven strains from families Lachnospiraceae, Erysipelatoclostridiaceae, and Ruminococcaceae were associated with clinical fibrosis, with four reduced and three enriched in clinical fibrosis. Two of these strains are within provisionally-named taxa not identified with existing open access tools, and therefore would not have been found without leveraging Second Genome's StrainSelect database. This demonstrates the utility of using reference databases which organize both well-documented and emerging taxa.

Conclusion: Second Genome's proprietary technology (including sg-4sight, StranSelect, and MTMA) was able to leverage multiple datasets and find a robust signature of strains associated with clinical fibrosis.

THU161

A nine-strain bacterial consortium improves portal hypertension and insulin signaling and delays non-alcoholic fatty liver disease progression in vivo

Iris Pinheiro[1], Aurora Barbera[2], Imma Raurell[2,3], Federico Estrella[2], Marcel de Leeuw[1], Selin Bolca[1], Davide Gottardi[1], Nigel Horscroft[1], Sam Possemiers[1], Maria Teresa Salcedo[4], Joan Genesca[2,3], María Martell[2,3], Salvador Augustin[2,3]. *[1]MRM Health NV, Ghent, Belgium; [2]Hospital Universitari Vall d'Hebron, Institut de Recerca Vall d'Hebron, Universitat Autònoma de Barcelona, Liver Unit, Department of Internal Medicine, Barcelona, Spain; [3]Centro de Investigación Biomédica en Red de Enfermedades Hepáticas y Digestivas (CIBERehd), Madrid, Spain; [4]Pathology Department, Hospital Universitari Vall d´Hebron, Universitat Autònoma de Barcelona, Barcelona, Spain*
Email: salva.augustin@gmail.com

Background and aims: The current lack of approved therapies encourages to search for new treatments that allow reversing the progression of non-alcoholic steatohepatitis (NASH). Stool transplantation has been shown to improve NASH features and portal hypertension. However, more patient-friendly treatments are required. Here, we aimed testing the effect of a defined bacterial consortium of nine gut commensal strains on two *in vivo* rodent models of NASH (a rat dietary model of NASH and portal hypertension (PHT), and the STAM™ mouse model).

Method: The bacterial consortium was administered orally *qd* after disease induction in 2 NASH models. In the NASH PHT rats, the consortium was administered for 2 weeks and compared to stool transplant, and effects on PHT and endothelial dysfunction were evaluated. Liver transcriptomics and predictive functional metagenomic studies were then carried out. In the STAM™ study administration was performed for 4 weeks, and effects on NASH activity and fibrosis were compared to vehicle or Telmisartan at the stage of early fibrosis. A second group of animals was followed for another 3 weeks to assess later-stage fibrosis.

Results: In the NASH rats, the bacterial consortium showed a protective effect on body weight, a trend to improve fasting blood insulin levels and HOMA-IR, and a marked protective effect on PHT, namely a significant reduction in portal pressure (10.32 vs. 9.58 mmHg, p <0.05) and intrahepatic vascular resistance (7.58 vs. 4.20 mmHg/ml*min*100 g, p <0.05). An improvement in all features of endothelial function (p-eNOS, p-Akt and Klf2) and fibrotic markers (*alpha-Sma* and *Col1a1*) was also observed. Gut microbial compositional changes revealed that the consortium achieved a more defined and richer replacement of the gut microbiome than stool transplantation. Moreover, liver transcriptomics suggested a beneficial modulation of pro-fibrogenic pathways. An improvement in histological liver fibrosis was then confirmed in the STAM™ study, significantly reducing collagen- and fibronectin-positive areas in liver sections at 12 weeks. The consortium also improved the NASH activity score, consistent with a decrease in steatosis and ballooning. In addition, consortium-treated animals displayed reduced inflammation (as measured through macrophage F4/80 positive area) and apoptosis (reduction in serum cytokeratin 18 levels), suggesting an overall beneficial effect on all key aspects of NASH biology.

Conclusion: Administration of a specific bacterial consortium of defined composition can ameliorate NASH, PHT and fibrosis and delay disease progression.

Duodenal permeability is associated with mucosal microbiota in compensated cirrhosis

Patricia Bloom[1], Krishna Rao[1], Shi-Yi Zhou[1], Christine Bassis[1], Borko Nojkov[1], Chung Owyang[1], Vincent B. Young[1], Anna Lok[1].
[1]University of Michigan, Ann Arbor, United States
Email: ppbloom@med.umich.edu

Background and aims: Several complications of cirrhosis result from the translocation of bacteria or their products across the intestinal epithelium. However, little is known regarding the precise relationship between mucosal bacteria and epithelial permeability in cirrhosis. We aimed to assess epithelial permeability and associations with mucosal bacteria in patients with compensated cirrhosis.

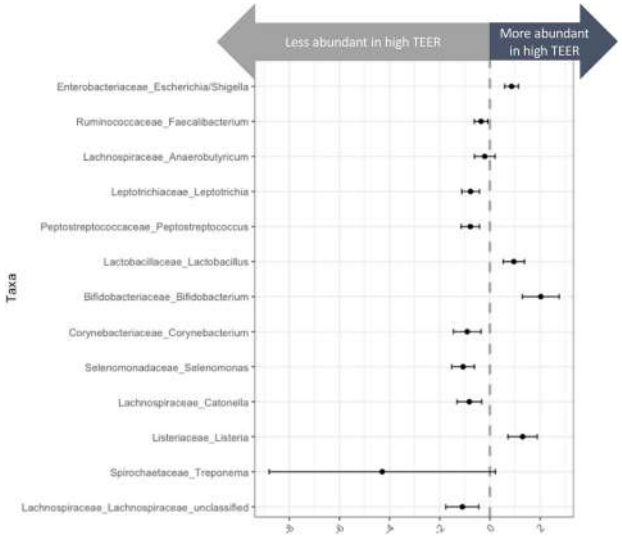
Method: We obtained duodenal tissue biopsies from patients with compensated cirrhosis and controls without liver disease. Patients were excluded if they used antibiotics or immunosuppression. The composition of the mucosal microbiota was determined via 16S rRNA gene sequencing and epithelial permeability assessed by measuring transepithelial electrical resistance (TEER) and tight junction protein expression. Associations between microbiota relative abundance and markers of epithelial permeability were assessed in a beta binomial model.

Results: We studied 24 patients with compensated cirrhosis and 20 controls. Patients with cirrhosis were older than controls (61 vs. 51 years, $p = 0.02$), but had a similar number of extra-hepatic comorbidities (Charlson Comorbidity Index without points for liver disease: 2.2 vs. 1.4, $p = 0.13$). Patients with compensated cirrhosis had median MELD 7 (IQR 7, 10); 62% were male.

Patients with compensated cirrhosis had lower duodenal TEER (i.e. increased epithelial permeability; 13.3 $\Omega/cm^2 \pm 3.4$ vs. 18.9 $\Omega/cm^2 \pm 7.1$; $p = 0.004$) and trended towards diminished expression of tight junction proteins: claudin-1 ($p = 0.18$), occludin ($p = 0.19$), and zonulin-1 ($p = 0.09$).

Patients with compensated cirrhosis had lower microbial burden in the duodenal mucosa (median: 34, 962 copies vs. 20, 982 copies,

$p = 0.08$), as well as lower alpha diversity (median Inverse Simpson: 13.1 vs. 4.6, $p = 0.14$). Furthermore, patients with compensated cirrhosis had a distinct mucosal microbiota community structure relative to controls based on analysis of molecular variance of the Yue and Clayton dissimilarity index ($p = 0.09$).
The beta binomial model found that 13 microbes associated with TEER, when using a false discovery rate of 0.05 (Figure). Relative abundance of a *Lactobacillus* and a *Bifidobacterium* bacteria positively associated with TEER, indicating that these two microbes are associated with a less permeable epithelial layer.



Conclusion: Compensated cirrhosis is characterized by increased duodenal epithelial permeability, with a distinct mucosal microbial community. Intriguingly, bacteria previously associated with health, *Lactobacillus* and *Bifidobacterium*, were protective of duodenal permeability. Future research will be required to extend and validate these findings in larger cohorts, to investigate if these microbes have a mechanistic role in epithelial barrier function, and to assess whether these trends persist or progress in decompensated cirrhosis.

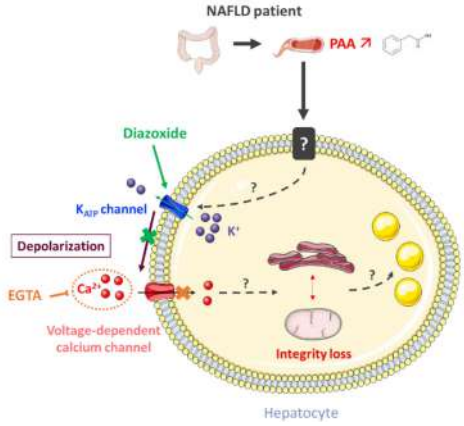
THU163

Impact of phenylacetic acid, a microbiota derived-metabolite, on hepatic endoplasmic reticulum-mitochondria interactions and steatosis

Rémy Lefebvre[1], Cyrielle Caussy[1,2], Jennifer Rieusset[1]. [1]*CarMeN Laboratory, UMR INSERM U1060/INRA U1393, 69495 Pierre-Bénite, France;* [2]*Hospices civils de Lyon, département endocrinologie, diabète et nutrition, 69495 Pierre-Bénite, France*
Email: remy.lefebvre@univ-lyon1.fr

Background and aims: The gut-liver axis has emerged as an important factor in the development of non-alcoholic fatty liver diseases (NAFLD). Microbiota-derived metabolites such as phenylacetic acid (PAA) have been shown to trigger hepatic steatosis in human primary hepatocytes but the molecular mechanism involved is not elucidated. Moreover, mitochondrial dysfunction is also a key component of NAFLD and oxidative capacities of mitochondria are regulated by the communication of this organelle with endoplasmic reticulum at contact points named mitochondria-associated membranes (MAMs). Hence, MAMs are nutrient sensitive controlling mitochondrial oxidative metabolism and ER-mitochondria miscommunication was associated with hepatic insulin resistance and steatosis. We hypothesized that PAA may induce hepatic steatosis through a disruption of MAMs integrity (Figure 1).
Method: We investigated the impact of PAA (500 µM) on MAMs integrity and steatosis in Huh7 cell line and primary mouse hepatocytes (PMH) incubated for 16 hours in normal (BSA) and lipotoxic (palmitate 200 µM) conditions. Co-treatments with diazoxide (100 µM) or EGTA (10 mM) allowed to investigate the involvement of electrogenic effects of PAA in Huh7 cells. ER-mitochondria interactions were measured by *in situ* proximity ligation assay (PLA) targeting VDAC1 (mitochondrial protein) and IP3R1 (reticular protein) proximity and BODIPY labelling was used to evaluate hepatocyte lipid accumulation. Fixed cells were analyzed by fluorescent microscopy and images analyses were performed using either blobfinder (PLA) or ImageJ (BODIPY) to quantify mitochondria-endoplasmic reticulum contacts and lipid droplets size respectively. All experiments were performed in a single time triplicate.
Results: Treatment with PAA reduced MAMs in Huh7 (n = 30 photos, fold change = – 72 ± 0.025%, p = 0.0001) and PMH (n = 30 photos, fold change = – 23 ± 0.064%, p <0.0001), it also induced lipid accumulation in Huh7 (n = 30 photos, fold change = +20 ± 0.035%, p = 0.0001) and PMH (n = 20 photos, fold change = +35 ± 0.047%, p = 0.0001). The effect of PAA on MAM integrity is observed as soon as one hour of treatment (n = 30 photos, fold change = – 39% ± 0.029, p <0.0001) in Huh7. This effect is fully prevented by diazoxide which inhibits membrane depolarization (n = 30 photos, fold change = +9% ± 0.066% with diazoxide versus – 30 ± 0.042% without it, p <0.0001) and partially by EGTA treatment, a Ca^{2+} chelation agent, (n = 30 photos, fold change = – 29 ± 0.044% with EGTA versus – 50 ± 0, 022% without it, p <0.0007). Altogether, these results suggest an electrogenic mechanism of PAA action on MAMs.

Figure 1: Potential electrogenic effect of PAA leading to MAMs disruption and hepatic steatosis



Conclusion: PAA, a gut-microbiome derived metabolite, induces MAM disruption and hepatocyte lipid accumulation. The effect of PAA on MAMs is mediated through an electrogenic mechanism. Whether preventing the electrogenic effect of PAA impacts hepatic steatosis is under investigation.

Dynamics of the gut-liver axis in rats with varying fibrosis severity

Hongyan Xiang[1], Zongyi Liu[1], Huanyu Xiang[1], Dejuan Xiang[1], Shuang Xiao[1], Jing Xiao[1], Wei Shen[1], Peng Hu[1], Hong Ren[1], Ming-Li Peng[1]. [1]*The Second Affiliated Hospital, Chongqing Medical University, Key Laboratory of Molecular Biology for Infectious Diseases (Ministry of Education), Institute for Viral Hepatitis, Department of Infectious Diseases, Chongqing, China*
Email: peng_mingli@hospital.cqmu.edu.cn

Background and aims: The classic carbon tetrachloride (CCl_4) -induced liver injury model is widely used to study the pathogenesis of fibrosis and evaluate anti-fibrotic drugs. However, the alterations of gut-liver axis in this model itself remain unclear. Here, this study aimed to explore the dynamic changes of gut microbiota, bile acid and gut barrier over fibrosis severity in CCl_4-induced rats.
Method: Hepatic fibrosis was induced by intraperitoneal injection of CCl_4 with 50%CCl_4 1 ml/kg body weight, twice weekly for 12 weeks.

Fecal samples lengthways collected at 1, 4, 8 and 12 weeks after modeling were used for gut microbiota 16S rDNA sequencing. Bile acid profiles in feces and serum were measured by ultra-performance liquid chromatography-tandem mass spectrometry (UPLC-MS/MS). Intestinal barrier integrity was assessed by measuring ileal permeability to FITC-dextran 4 kDa and Lipopolysaccharide.

Results: Different fibrosis stages from inflammation, mild, moderate to advanced fibrosis were successfully induced by CCl_4 administration for 1, 4, 8, 12 weeks respectively. 16S rDNA sequencing revealed that gut dysbiosis mainly occurred in the early and advanced stages of fibrosis, while the composition of the gut microbiota was close to normal in the moderate stage of fibrosis. Only the relative abundances of Lactobacillus at different phylogenetic levels were underrepresented in the four fibrosis stages. As fibrosis progressed, total bile acids in feces gradually decreased, mainly manifested as a decrease in unconjugated bile acids such as lithocholic acid (LCA) and Deoxycholic acid (DCA). Conversely, serum total bile acids increased, with marked increase in conjugated bile acids such as glycocholic acid hydrate (GCA) and tauro-alpha-murocholic acid (T-alpha-MCA). The hepatic FXR-SHP and intestinal FXR-FGF15 pathways, the master regulators of BA biosynthesis in the enterohepatic circulation, were significantly inhibited with increasing fibrosis. Interestingly, in our experimental settings, ileal pathology and permeability tests showed that the intestinal barrier remained relatively intact even in the cirrhotic stage.

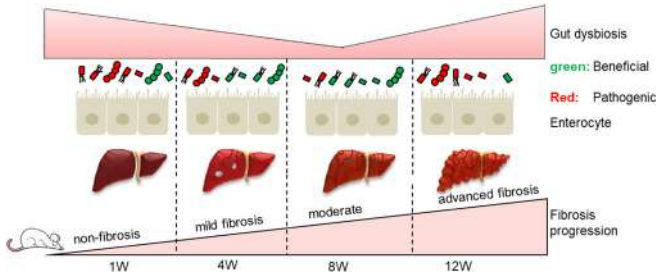

Figure 1: Dynamics of the gut microbiota in rats with varying fibrosis severity

Conclusion: The advances in knowledge of the gut-liver axis of this model provide useful supplements for us to apply it for research and drug evaluation.

Email: qixiaolong@vip.163.com

Background and aims: Gut microbial dysbiosis is associated with the progression of cirrhosis, but the relationship to the risk of variceal bleeding (EVB) remain unknow. Our study aims to evaluate the diagnostic value of gut microbiome for EVB in compensated cirrhosis.

Method: A total of 270 compensated cirrhotic patients from 13 centers in China were prospectively recruited between July 2019 and April 2021. Stool samples and results of endoscopy was collected following a standard detailed protocol. The total bacterial DNA in each stool sample was extracted and profiled by sequencing the 16S rRNA gene V4 region. Then the role of gut microbiome in EVB was explored and compared with endoscopy, which was considered as the gold standard for evaluating the risk of EVB.

Results: In this prospective multicenter study (NCT03990753, CHESS1901), the median age was 53 years (range 20–75 years), and 69.6% (n = 188) were male. 95 patients were assessed as high risk of EVB, and 175 patients were estimated at low risk. Firstly, patients from Lanzhou (LZ, n = 30), Tianjin (TJ, n = 131), Xingtai (XT, n = 74) and Chengdu (CD, n = 20) cities were picked out to explored whether regional variation could affect the composition of gut microbiota. Although alpha diversity was similar in four regions (Fig. A), the relative abundances at the phylum and genus levels of all samples were quite different (Fig. B, C). At the phylum level, the relative abundance of Firmicutes was higher in XT than in other cities; conversely, Bacteroidetes were relatively less abundant in XT. Furthermore, the genus level further reflected the relative differences in the abundance of microbial composition. Principal coordinate analysis (PCoA) based on unweighted UniFrac distance showed that the spatial distributions of patients for four regions were significantly different from each other overall ($p = 0.001$, Fig. D). However, we did not observe significant differences between high risk and low risk of EVB groups for alpha diversity, beta diversity or the relative abundances of the predominant bacterial taxa (Fig. E-H). In addition, no significant difference was obtained between the groups of high and low risk of EVB for the single center in TJ and XT, respectively (Fig. J, K).

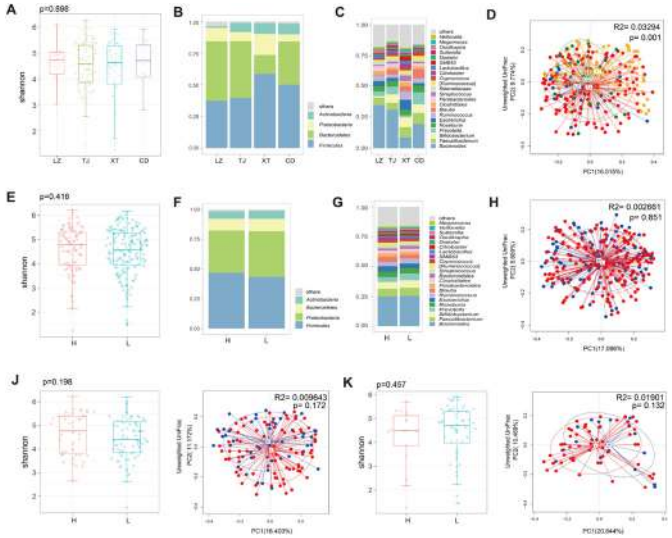

Figure: Gut microbiota composition for four major cities and groups of EVB risk. Composition of Alpha diversity (A, E). Average relative abundances of the predominant bacterial taxa at the phylum (B, F) and genus (C, G) levels. Scatter plots of PCoA based on Unweighted UniFrac for gut microbiota composition to show beta diversity (D, H). Alpha diversity and PCoA plots for the single center in TJ (J) and XT (K).

Conclusion: The multicenter study suggested that gut microbiome varies from region to region, but both alpha and beta diversity weren't associated to risk of EVB in compensated cirrhosis. Further studies exploring specific differential bacteria correlated with the risk of EVB are needed.

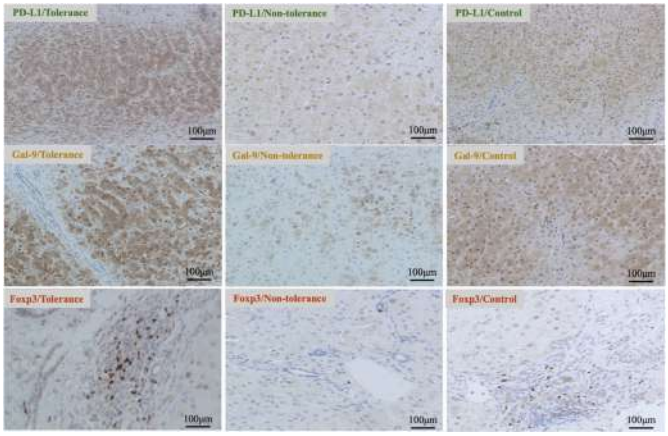
Email: ktaura@kuhp.kyoto-u.ac.jp

Background and aims: Programmed cell death protein 1 (PD-1)/its ligand PD-L1, concomitant with T cell immunoglobulin and mucin domain-containing protein 3 (TIM-3)/its ligand galectin 9 (Gal-9) and the forkhead box protein P3 (Foxp3) might be involved in tolerance after liver transplantation (LT).
Method: Liver biopsies from 38 tolerant, 19 nontolerant (including 16 samples that triggered reintroduction of immunosuppression (IS) and 19 samples after IS reintroduction) and 38 control LT patients were studied. The expressions of PD-1, PD-L1, Gal-9, and Foxp3 were determined by immunohistochemical and immunofluorescence (IF) staining. The success period of IS withdrawal was calculated using Kaplan-Meier analysis.
Results: Tolerant and control patients exhibited higher PD-L1, higher Gal-9, and higher Foxp3 levels than nontolerant patients at the moment of triggering IS reintroduction. High expression of PD-L1 and Gal-9 was associated with prolonged success of tolerance (83.3% vs. 36.7%, p <0.01; 73.1% vs. 42.9%, p = 0.03). A strong correlation between PD-L1 and Gal-9 expression levels was detected (Spearman r = 0.73, p <0.0001) and IF demonstrated colocalization of PD-L1 and Gal-9 in the cytoplasm of hepatocytes.



Conclusion: The present study demonstrated that an increased expression of PD-L1 and Gal-9 was associated with sustained tolerance after IS withdrawal in pediatric liver transplantation.

THU168

Acidic microenvironment aggravates the severity of hepatic ischemia/reperfusion injury by modulating PPAR-γ signal

Wei Ding[1], Yunfei Duan[1], Zhen Qu[1], Donglin Sun[1], Yunjie Lu[1]. *[1]The Third Affiliated Hospital of Soochow University, Hepatopancreatobiliary Surgery Department, Changzhou, China*
Email: sdldoctor@163.com

Background and aims: Hepatic injury induced by ischemia and reperfusion (HIRI) is a major clinical problem after liver resection or transplantation. The polarization of macrophages plays an important role in regulating the severity of hepatic ischemia/reperfusion injury. Recent evidence had indicated that the ischemia induces an acidic microenvironment by causing increased anaerobic glycolysis and accumulation of lactic acid.
Method: We hypothesize that the acidic microenvironment might cause the imbalance of intrahepatic immunity which aggravated HIRI. The hepatic ischemia/reperfusion injury model was established to investigate the effect of the acidic microenvironment to liver injury. Liposomes were used to deplete macrophages in vivo. Macrophages were cultured under low pH conditions to analyze the polarization of macrophages in vitro. Activation of the PPAR-γ signal was determined by Western Blot. PPAR-γ agonist GW1929 was administrated to functionally test the role of PPAR-γ in regulating macrophage-mediated effects in the acidic microenvironment during HIRI.
Results: We demonstrate that acidic microenvironment aggravated HIRI while $NaHCO_3$ reduced liver injury through neutralizing the acid, besides, liposome abolished the protective ability of $NaHCO_3$ through depleting the macrophages. In vivo and vitro experiment showed that acidic microenvironment markedly promoted M1 polarization but inhibited M2 polarization of macrophage. Furthermore, the

mechanistic study proved that the PPAR-γ signal was suppressed during the polarization of macrophages under pH = 6.5 culture media. The addition of PPAR-γ agonist GW1929 inhibited M1 polarization under acidic environment and reduced HIRI.
Conclusion: Our results indicate that acidic microenvironment is a key regulator in HIRI which promoted M1 polarization of macrophages through regulating PPAR-γ. Conversely, PPAR-γ activation reduced liver injury, which provides a novel therapeutic concept to prevent HIRI.

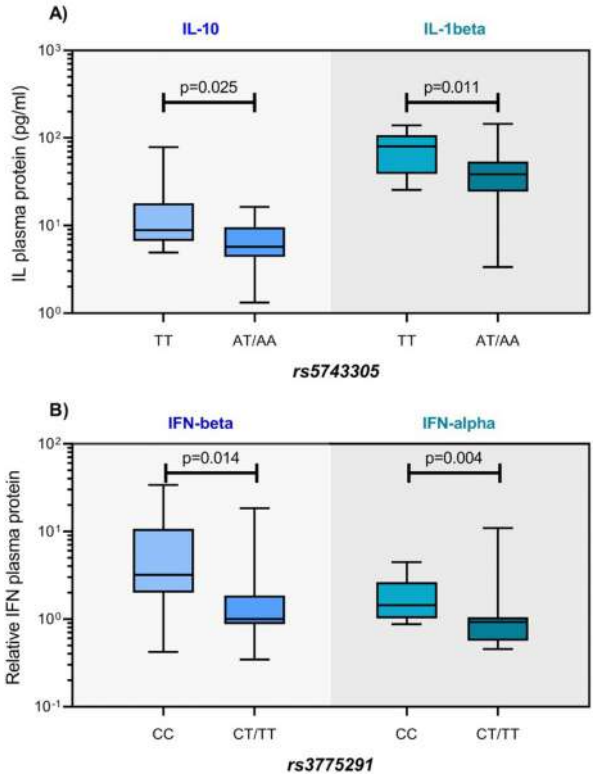
Toll-like receptor 3 polymorphisms rs5743305 and rs3775291 affect innate immune responses in whole blood analyses

Sophia Barkow[1], Madlen Matz-Soja[1], Thomas Berg[1], Janett Fischer[1].
[1]*Division of Hepatology, Department of Medicine II, Leipzig University Medical Center, Laboratory for Clinical and Experimental Hepatology, Leipzig, Germany*
Email: janett.fischer@medizin.uni-leipzig.de

Background and aims: As a part of the innate immunity, the Toll-like receptors (TLR) 3 signaling has been linked to the outcome of hepatitis B virus (HBV) infection. Polymorphisms (SNPs) in the *TLR3* gene were associated with an increased risk of developing chronic hepatitis B. This research aimed to assess the impact of the two *TLR3* SNPs *rs5743305* and *rs3775291* on the immune responses in a whole blood assay.
Method: The study included 30 healthy volunteers matched according to the two functionally relevant *TLR3* SNPs (10 TT/10 TA/10 AA for *rs5743305* and 11 CC/12 CT/7 TT for *rs3775291*), and in age and gender. Heparinized whole blood was treated with 5 µg/ml polyinosinic-polycytidylic acid (PolyI:C) for 3 and 6 hours. The relative gene expression (rGE) of TLR3, IL1β, IL6, IL10, IL12, IFNβ, IFNα and TNFα was analyzed by quantitative real-time polymerase chain reaction. Normalization ($2^{\Delta\Delta Ct}$) was performed in relation to the housekeeping gene TBP and untreated blood. The plasma protein levels (PPL) of all cytokines were measured after 6 h of stimulation by performing a bead-based sandwich-immunoassay.



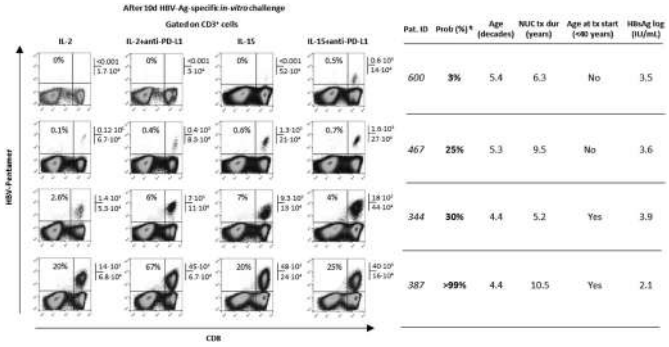
Results: The *rs5743305* minor allele A showed significantly lower rGE of IL10 (A: 8.97, TT: 14.82, p = 0.022) and absolute PPL (A: 6.99 pg/ml, TT: 15.6 pg/ml, p = 0.025) after 6 h compared to the wild type (WT) TT. Additionally, IL1β PPLs were reduced for the minor allele A compared to the WT (A: 43.5 pg/ml, TT: 75.95 pg/ml, p = 0.011) as depicted in figure A. The *rs3775291* risk allele T showed increased rGE of IFNβ after 6 h (T: 4.32, CC: 2.08, p = 0.017). Interestingly, the relative PPL of IFNβ was significantly lower for the T allele than for the WT CC (T: 2.6, CC: 8.52, p = 0.014). Furthermore, the risk allele significantly reduced the relative PPL of IFNa (T: 1.4, CC: 1.9, p = 0.004) (figure B).
Conclusion: This study showed significant effects of the two *TLR3* SNPs on cytokine expression in the complex whole blood system. The minor allele A of *rs5743305* decreased pro- and anti-inflammatory cytokine expression. As expected, the *rs3775291* risk allele T reduced the synthesis of inflammatory type 1 interferons. This may lead to a dysbalanced immune system and therefore to a less functional defense against virus infections. Further research in lager cohorts and in cell culture systems are required to enlighten the impact of the SNPs on immune responses, especially during HBV infection.

THU170

IL-15 boots HBV-specific CD8+ cell response by activated progenitor pool mitochondrial remodelling in on treatment e-Ag negative chronic hepatitis B

Julia Peña Asensio[1,2], Henar Calvo[1], Joaquin Miquel[1], Eduardo Sanz de Villalobos[1], Alejandro González Praetorius[1], Miguel Torralba[1,3], Juan Ramón Larrubia[1,3]. [1]*Guadalajara University Hospital, Translational Hepatology Unit, Guadalajara, Spain;* [2]*University of Alcala, Department of Biology of Systems, Alcala de Henares, Spain;* [3]*University of Alcala, Department of Medicine and clinical specialities, Alcala de Henares, Spain*
Email: hlnd.julia@gmail.com

Background and aims: In the HBV-specific-CD8$^+$ progenitor pool (PP), mitochondrial remodelling could re-establish the functionality of the effector proliferative progeny (EPP) in nucleos (t)ide analogue (NUC) treated eAg (-) chronic hepatitis B (CHBe (-)). We analysed the role of IL-15 in the metabolic profile of the HBV-specific CD8$^+$ PP after Ag encounter in CHBe (-) with low probability of T cell restoration during NUC treatment.
Method: According to clinical variables, level of HBV-specific-CD8$^+$ cell exhaustion was estimated in NUC treated CHBe (-). HBV-specific-CD8$^+$ cells were visualized by pentameric technology. After Ag-specific stimulation, activated PP (APP) was detected by TCF1 staining and FSC level. Metabolic profile, memory-like phenotype and mTORC1 activation in PP were analysed by Glut1, PGC1a, CPT1, PD-1, CD127 and prS6-P expression. The effector abilities in the effector proliferative progeny (EPP) were tested by proliferation ability, interferon- (IFN)gamma, Tumour necrosis factor (TNF)alpha and CD107a expression. The role of IL-15 ± anti-PD-L1 in remodelling metabolic profile and improving effector function was assessed.
Results: During CHBe (-), quiescent PP expresses a memory-like phenotype (PD-1+/CD127+). After Ag-encounter, APP gives rise to the EPP. In comparison with IL2, IL-15 decreases the initial boost of mTORC1 in APP, but maintains its activation longer, which translates into an inflation of EPP, and improvement in metabolic profile (Glut-1^{low}, PGC1a^{high}, CPT1^{high}). IL-15 induced metabolic changes correlate with an enhancement in EPP effector abilities (IFN gamma ^{high}, TNF alpha ^{high}, CD107a^{high}). In those cases with low probability of HBV-specific-CD8$^+$ cell restoration during NUC treatment, IL-15 plus anti-PD-L1 restored the proliferation ability of these cells after Ag-specific in-vitro challenge.



Conclusion: IL-15 induces an intermediate but sustained mTORC1 activation in HBV-specific CD8$^+$ APP that translates into a catabolic mitochondrial profile and enhancement in EPP of effector abilities. In those CHBe (-) cases with low probability of achieving a functional response during NUC treatment, IL-15+anti-PD-L1 in-vitro treatment restores their reactivity.

Mucosal-associated invariant T cells are rendered functionally exhausted within the tumour microenvironment in HCC in a cell-contact dependent manner

Junika Pohl[1], Alexandra Georgieva[1], Anna-Marie Pedde[2], Anna Hirschberger[2], Sebastian Deschler[1], Melanie Laschinger[3], Daniel Hartmann[3], Jan Boettcher[2], Norbert Hüser[3], Roland M. Schmid[1], Percy A. Knolle[2], Katrin Böttcher[1]. Email: katrin.boettcher@mri.tum.de

Background and aims: Hepatocellular carcinoma (HCC) is still one of the major causes of cancer death worldwide. Immunotherapy has recently become the first-line treatment for advanced HCC, although response rates remain low. MAIT cells, innate-like T cells particularly enriched in the liver, express pro-inflammatory cytokines as well as cytolytic molecules and have therefore been attributed anti-tumour properties. In this study, we aim to decipher direct interactions between MAIT cells and HCC cells in order to unravel mechanisms of immune cell exhaustion within the tumour microenvironment in HCC.
Method: MAIT cells were isolated from tumour tissue, adjacent liver tissue and peripheral blood of human patients with HCC or other liver tumours and healthy controls. Primary MAIT cells were co-cultured with various HCC cell lines *in vitro* and MAIT cell phenotype and function was analysed by multi-colour flow cytometry.
Results: We show that MAIT cells frequency is significantly reduced in peripheral blood of HCC patients compared to healthy controls, as well as in HCC tumour tissue compared to the adjacent liver tissue. Such MAIT cell loss was specific, since frequency of conventional T cell subsets was unaffected in HCC and MAIT cell frequency was unchanged in other liver tumours. Whereas MAIT cells from peripheral blood of HCC patients remained functional, tumour-educated liver-derived MAIT cells showed increased exhaustion marker expression and significantly impaired effector function, suggesting MAIT cell exhaustion within the tumour microenvironment in HCC. Interestingly, such MAIT cell dysfunction could be induced by co-culture of MAIT cells with different HCC cell lines, while the hepatocyte-like cell line HepG2 was unable to induce MAIT cell exhaustion. Mechanistically, induction of MAIT cell exhaustion by HCC cells was dependent on direct cell-cell contact.
Conclusion: Taken together, we show that MAIT cells, innate-like T cells with anti-cancer potential, are rendered dysfunctional within the HCC microenvironment, suggesting MAIT cells as a potential target for anti-cancer therapy in HCC. Understanding mechanisms of local MAIT cell exhaustion in HCC may facilitate the development of novel immunotherapeutic strategies against HCC.

Preclinical model for the study of immune responses specific for a hepatic-self-antigen

Anaïs Cardon[1,2], Jean-Paul Judor[1,2], Arnaud Nicot[1,3], Sophie Conchon[1,3], Amédée Renand[1,3]. [1]*INSERM UMR 1064 Centre de Recherche en Transplantation et Immunologie, Nantes, France;* [2]*Université de Nantes, Nantes, France;* [3]*INSERM, France*
Email: anais.cardon@univ-nantes.fr

Background and aims: Despite a bias toward immune tolerance in the liver, autoimmune liver diseases such as autoimmune hepatitis (AIH) can occur. The etiology of this disease is still not well characterised, and little is known about the emergence process and dynamics of self-antigen-specific immune responses. Thus, to better understand AIH initiation mechanisms, we developed preclinical murine models allowing the study of specific immune responses (CD4+ and CD8+ T cells and antibody) against a liver antigen.
Method: The expression of the antigen hemagglutinin (HA) was induced with a CRE/LoxP system (cross-breeding of ROSA HA floxed mice with TTR-CREind mice). An adenovirus encoding for the CRE recombinase (AdCRE) was injected intramuscularly (i.m.) to induce a peripheral immunization or intravenously (i.v.) to induce hepatic HA expression and inflammation. Feeding mice with tamoxifen dry food induced HA expression only in the liver. In the different settings, HA-specific CD4+ and CD8+ T cells in the spleen and the liver were detected and characterized using tetramers, and antibody class switch was assessed by ELISA tests.
Results: Peripheral HA immunization (AdCRE i.m.) leads to a strong HA immune response, marked by the emergence of anti-HA responses (CD4+ T cells and antibodies) and linked to HA expression in the muscle (but not in the liver). When HA expression is specifically induced in the liver (tamoxifen), no HA-specific adaptive response is detected, confirming the tolerogenic environment of the liver. However, after a peripheral immunization (AdCRE i.m.), tamoxifen-induced liver-specific HA expression leads to a massive recruitment of HA-specific PD-1+ CD25- CD4+ T cells in the liver. Finally, AdCRE i.v. causes concomitant hepatic HA expression and inflammation leading to the generation of HA-specific PD-1+ CD25- CD4+ T cells in the spleen and liver for over 12 weeks, and anti-HA IgG1 antibodies reflecting a chronic reaction against HA.
Conclusion: Our study shows that the conditions of expression of the antigen in the liver (e.g. inflammatory environment, peripheral immunisation) modulate hepatic self-antigen-specific responses. Taken together, this could depict a key element in the initiation of autoreactive responses toward a hepatic antigen. A long-term analysis of antigen-specific responses (CD4+ T cells and antibody) in our models will provide a better understanding of responses dynamics during AIH development.

THU173

Proximity labelling reveals potential cis interactions of CD52 glycoprotein counter-receptors on circulating CD4+HLA-G+ regulatory T cells in acute decompensation of cirrhosis

Tong Liu[1], Gang Wu[2], Cathrin Gudd[1], Thomas Barbera[1], Rooshi Nathwani[1], Francesca Trovato[3], Yan Liu[1], Mark J W McPhail[3], Mark Thursz[1], Wafa Khamri[1]. [1]*Imperial College London, Department of Metabolism, Digestion and Reproduction, London, United Kingdom;* [2]*Imperial College London, Department of Life Sciences, London, United Kingdom;* [3]*King's College London, Institute of Liver Studies, London, United Kingdom*
Email: tong.liu15@imperial.ac.uk

Background and aims: We have recently described the expansion of a non-classical regulatory CD4$^+$HLA-G$^+$ T cell population and its

potential contribution to defective peripheral immune responses in patients with acute decompensation (AD) of cirrhosis. Gene profiling of this cell subset revealed an up-regulation of gene encoding for CD52: a sialylated glycosylphosphatidylinositol-anchored glycoprotein known to be involved in lymphocyte functions by ligating its released soluble form and the sialic acid-binding immunoglobulin-like lectin 10 (Siglec-10) receptor. However, the impact of cell surface CD52 is not fully understood. In this study, we aim to investigate the role of membrane-bound CD52 in $CD4^+HLA\text{-}G^+$ T cells.

Method: First, we examined the cell surface protein expression of CD52 and Siglec-10 in $CD4^+HLA\text{-}G^+$ versus $CD4^+HLA\text{-}G^-$ T cells of AD patients (n = 17) using flow cytometry. Endogenous CD52 N-glycan was digested with sialidase and binding affinity of CD52 to Siglec-10 was measured by flow cytometry using fluorochrome-labelled recombinant Siglec-10. Proximity labelling was used to identify potential membrane counter-receptors of CD52 on $CD4^+HLA\text{-}G^+$ T cells. Cells were probed with horseradish peroxidase (HRP) conjugated anti-CD52 antibody, biotinyl tyramide was used to biotinylate membrane proteins within 100 nm radius of the HRP complex. Biotinylated proteins in proximity of CD52 were then enriched by streptavidin beads and identified via mass spectrometry.

Results: CD52 cell surface expression was significantly increased in $CD4^+HLA\text{-}G^+$ compared to $HLA\text{-}G^-$ cells (mean fluorescence intensity (MFI) median 25052 IQR [22989–26755] vs. 11529 [9459–14081], p <0.0001). Siglec-10 expression was also significantly increased in the same subset (MFI 26987 [23892–28533] vs. 16765 [14534–17983], p <0.0001). The membrane CD52 on $CD4^+$ T cells showed high binding affinity towards Siglec-10, and this affinity could be reversed by digestion of the sialylated N-glycan of CD52. Proximity labelling revealed the T cell receptor (TCR) complex namely CD3 epsilon, CD3 gamma, and TCR beta were in the immediate vicinity of CD52 on $CD4^+HLA\text{-}G^+$ T cells from patients with AD. Moreover, the results imply that Siglec-10 interacting with CD52 could depend on TCR stimulation.

Conclusion: CD52 and its counter-receptor Siglec-10 are co-expressed on the $CD4^+HLA\text{-}G^+$ T cells of AD patients. Proximity labelling identified potential *cis*-ligands recruited to the proximity of the membrane-bound CD52 likely to have implications on $CD4^+HLA\text{-}G^+$ T cells responsiveness to TCR stimulation.

Email: samer.al-dury@wlab.gu.se

Background and aims: Patients with chronic liver disease are at a higher risk of morbidity and mortality in COVID-19 and professional societies have recommended the vaccination despite the scarce data from registration trials regarding their efficacy and safety in this vulnerable population.

Method: In a prospective study, we compared the rate of humoral (antibody response to spike protein) and cellular (interferon-γ production) immunity before, after the 1st and 2nd dose of mRNA vaccines in patients with chronic liver disease (CLD) with and without liver cirrhosis and healthy volunteers. We also investigated whether the degree of immune response correlates with liver fibrosis stage using transient elastography.

Results: 64 patients with CLD and 39 healthy volunteers were included. Both serological and T-cell responses were significantly lower in patients with CLD compared to healthy volunteers after the 1st and 2nd vaccine dose. 79% and 15% of CLD patients had inadequate antibody response after the 1st and 2nd vaccine dose respectively. Additionally, 79% and 38% of CLD patients had inadequate interferon-γ production after the 1st and 2nd vaccine dose, respectively. The potency of immune response did not correlate to liver fibrosis grade. Nevertheless, patients with higher Child-Pugh (CP) scores had a worse response to the vaccine. There were no differences in the occurrence of side effects to the vaccine between the groups.

Conclusion: Patients with CLD have a poorer response to vaccination against SARS-CoV-2 compared to healthy volunteers regardless of their fibrosis stage and many continue to be inadequately protected despite full vaccination.

THU175

Efficacy of branched-chain amino acid granules to restore innate immunity in cirrhosis-associated immune dysfunction: a randomized controlled trial

Natthapat Rujeerapaiboon[1,2], Teerha Piratvisuth[1], Naichaya Chamroonkul[1], Pimsiri Sripongpun[1], Apichat Kaewdech[1].
[1]*Songklanagarind Hospital, Internal Medicine, Tambon Kho Hong, Thailand;* [2]*Ramathibodi Hospital, Internal Medicine, Thailand*
Email: teerha.p@psu.ac.th

Background and aims: Cirrhosis-associated immune dysfunction (CAID) has been proposed as one of the significant complications in cirrhotic patients, demonstrated by an impairment of innate immunity. Previous studies showed that reduction of phagocytic activity, as a part of innate immunity, might predict infection occurrence and 90-day survival in cirrhosis. However, there are still limited data on immunotherapeutic approaches to modulate the dysfunctional immune response. Our study aims to determine the effect of branched-chain amino acid (BCAA) granules on phagocytic activity in cirrhotic patients.

Method: A double-blinded, randomized-controlled trial was conducted at a single-centre tertiary care hospital. Thirty-seven cirrhotic patients were randomly assigned in a 1:1 ratio stratified by Child-Pugh status to receive either BCAA granules at a dose of 4.15 grams thrice daily or placebo. All patients received a multidisciplinary approach from hepatology and nutrition specialists. They were also assigned to record the adherence to study drug, seven-day food recall, and side effects, if occurred, in an interventional diary. At baseline, the 3rd and 6th months of the study, the phagocytic activity was assessed by a biochemist using pHrodo Red *E. coli* BioParticles Phagocytosis Kit and Image Stream II Imaging Flow Cytometer. The primary end point was the restoration of innate immunity at the sixth month, define by phagocytic activity ≥ 75%. Key secondary end points were the accretion of phagocytic activity and number of hospitalizations due to infection.

Results: Of all 37 eligible patients, the patients in Child-Pugh A/B/C were 26/8/3, respectively. Eighteen patients were in placebo, and nineteen were in BCAA group, the baseline characteristics and phagocytic activity were comparable between groups. At 6th month, a significantly higher phagocytic activity restoration was demonstrated in the BCAA group compared with placebo (68.4% vs 5.6%, p <0.001). The mean phagocytic activity in the BCAA and placebo group were 75.4% and 63.4%, respectively (p <0.001). The progressive accretion of phagocytic activity was observed during the 3rd and 6th months, as shown in Figure. There were no differences in serum albumin and other inflammatory markers. Despite a higher phagocytic restoration rate in the BCAA group, there was no difference in hospitalization due to infectious events in comparison to the placebo group (2 VS 3 events, p = 0.487).

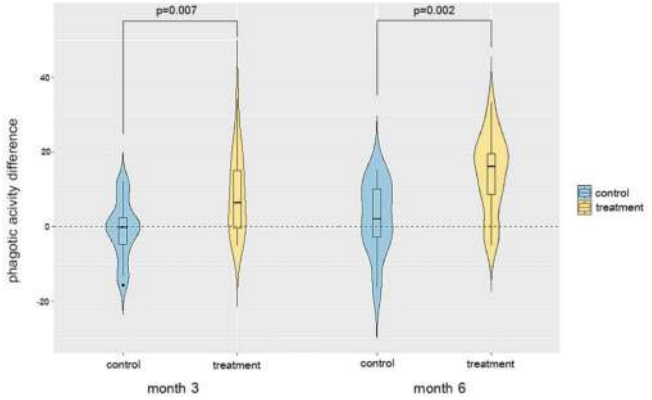

Figure: Phagocytic activity change from baseline at the 3rd month and 6th month of the study.

Conclusion: BCAA can significantly improve phagocytic activity in cirrhotic patients across all Child-Pugh stages. This may be an option for immunotherapeutic intervention of CAID. However, whether the improvement in phagocytic activity would correlate with a better outcome especially infectious complications may need longer follow-up studies.

THU176

The close correlation between sarcopenia and the phagocytic dysfunction in respond to bacterial pathogen Ecoli in cirrhotic patients

Naichaya Chamroonkul[1], Natthapat Rujeerapaiboon[1,2], Pimsiri Sripongpun[1], Apichat Kaewdech[1], Teerha Piratvisuth[1].
[1]Songklanagarind Hospital, Tambon Kho Hong, Thailand; [2]Ramathibodi Hospital, Thailand
Email: naichaya@gmail.com

Background and aims: Sarcopenia and phagocytic dysfunction were demonstrated to be associated with poorer clinical outcomes in cirrhotic patients. Branched-chain amino acid (BCAA) is a pivotal factor that activates the mammalian target of rapamycin (mTOR) complex, a central node that controls immunity and muscle synthesis. In cirrhosis with sarcopenia, the BCAA is depleted, which may associate with phagocytic dysfunction. However, there is a paucity of studies that established the effect of sarcopenia on phagocytic activity. Therefore, our study aims to determine the correlation between sarcopenia and the phagocytic activity in cirrhotic patients.

Method: We conducted a randomized controlled trial (RCT) evaluating the role of BCAA on phagocytic activity. In this study, we used the baseline data in patients enrolled in the RCT to study the correlation and factor affecting phagocytic activity. Thirty-seven cirrhotic patients with sarcopenia were included in this study (defined with skeletal muscle index [SMI] according to the JSH criteria). The SMI was measured at L3 vertebra by a cross-sectional CT scan and calculated by DICOM software. The phagocytic activity assessment was performed by a biochemist, using the pHrodo Red *E. coli* BioParticles Phagocytosis Kit for flow cytometry and Image Stream Mk II Imaging Flow Cytometer. The correlations between SMI and phagocytic activity was analysed using spearman test and adjusted with other covariates by multivariable linear regression

Results: Thirty-seven patients were included, the patients in Child-Turcotte-Pugh (CTP) A/B/C were 26/8/3, respectively. The baseline characteristics were difference as cirrhotic stage progressed from CTP-A to C. Our study demonstrated a trend towards lower phagocytic activity in the more severity of cirrhosis, but not statistically significant, as 62.3%, 60.5%, and 54.3% in CTP A, B, C, respectively ($p = 0.12$). In a multivariable linear regression analysis, CTP-C and SMI (cm^2/m^2) are independent factors associated with the prediction of phagocytic activity, with adjusted beta-coefficients of – 14.4% ($p = 0.001$), and +0.75% ($p < 0.001$), respectively. The strong correlation between SMI and phagocytic activity was demonstrated in the CTP-A cirrhosis, $r = 0.84$ ($p < 0.001$) whereas there was no significant correlation in CTP-B/C cirrhosis, $r = – 0.068$ ($p = 0.84$) as shown in the figure.

Conclusion: In cirrhosis with sarcopenia, our study demonstrated that both CTP-C and lower SMI were associated with phagocytic dysfunction. Emerging data had shown a strong correlation between sarcopenic status and phagocytic dysfunction, especially in CTP-A. Therefore, sarcopenic assessment is essential for all stages of cirrhosis despite compensated CTP-A status, to initiate the treatment and prevent further decompensation.

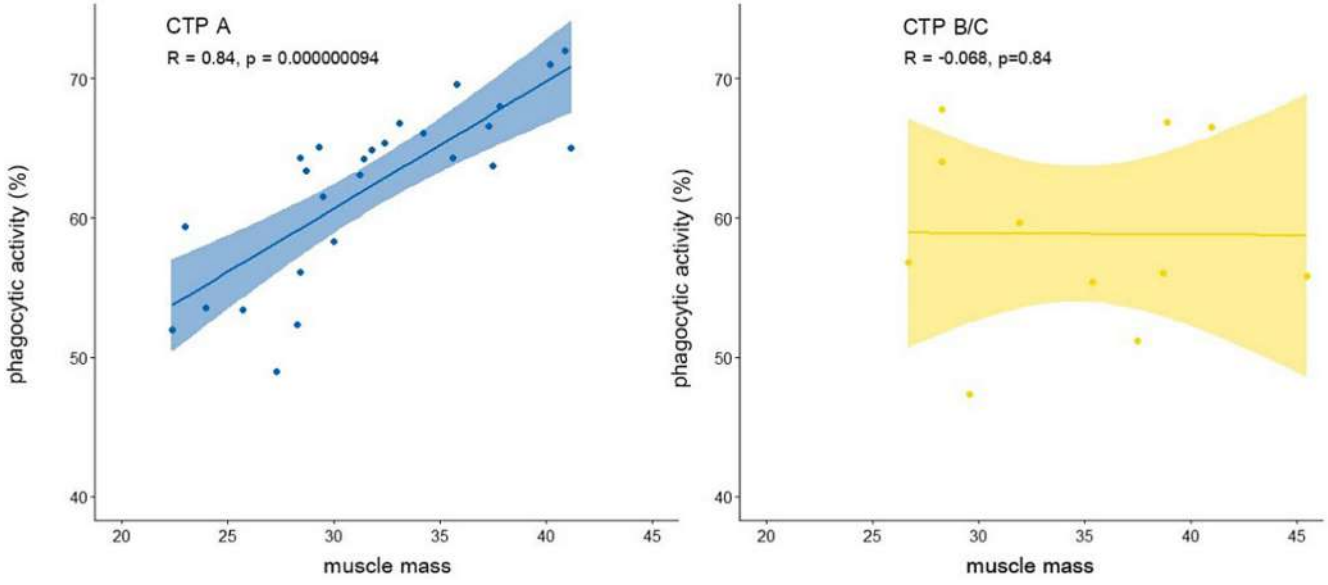

Figure: (abstract: THU176): The correlation between phagocytic activity and muscle mass in various stages of cirrhosis.

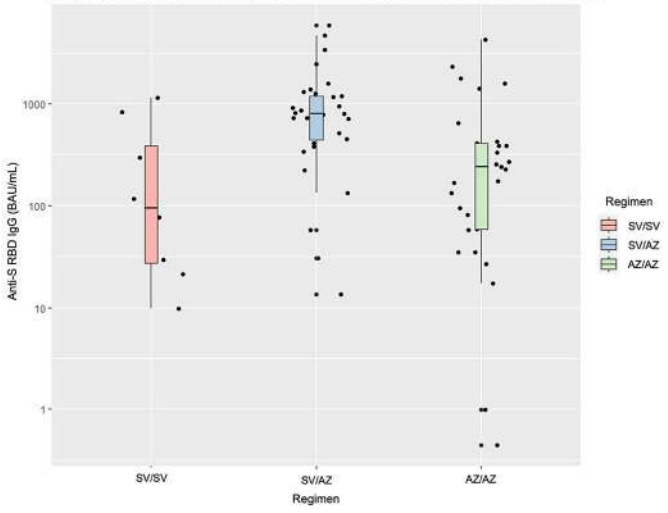
Email: pim072@hotmail.com

Background and aims: To control the COVID-19 pandemic, vaccination is the principal for general population globally. In patients suffered from SARS-Cov-2 infection, having cirrhosis has been associated with a higher risk of poor outcomes, and those with cirrhosis were strongly advised affirmatively by international hepatology societies to receive the SARS-Cov-2 vaccine. However, cirrhosis-associated immune dysfunction might contribute to hyporesponsive to the vaccine. Moreover, data of immune responses in those who received the different types of vaccines, especially heterologous vaccines are lacking. We studied whether different regimens of COVID-19 vaccines affect the humoral immune response in patients with cirrhosis.
Method: We conducted a prospective observational study, collecting blood samples from patients with cirrhosis who were regularly followed up at our centre, a tertiary care hospital in Thailand, and received 2 doses of SARS-Cov-2 vaccine. This is a preliminary report of patients enrolled between June and October 2021. Those who were on immunosuppressive agent were excluded. The SARS-Cov-2 vaccination in Thailand is provided by the government; there were 3 major vaccination regimens: inactivated vaccine (CoronaVac; SV/SV), viral vector vaccine (ChAdOx1 nCoV-19 vaccine; AZ/AZ), and heterologous vaccine (SV/AZ), and neither patients nor investigators had involved in the decision of the regimens given. The antibody (Ab) levels were measured at two-time points, before and at 4-week after receiving the 2nd dose vaccination. The anti-spike receptor-binding domain protein (RBD) IgG was measured using the Abbott SARS-CoV-2 IgG II Quant assay to determine Ab response. The Ab level of <50 AU/ml (7.15 BAU/ml) is considered to be inadequate immune response.

Figure: Serological response after the second dose of SARS-C0V-2 vaccination in cirrhotic patients
(Group 1: CoronaVac/CoronaVac, Group 2: CoronaVac/AstraZeneca, Group 3: AstraZeneca/AstraZeneca)



Results: A total of 61 patients completed their 2nd dose vaccine and had Ab level data available, 61% were male, the major cause of cirrhosis was chronic hepatitis B (42%), and 51/9/1 patients were in child A/B/C, respectively. Of those, 8 (13.1%) received SV/SV, 28 (45.9%) got heterologous SV/AZ, and 25 (40.9%) received AZ/AZ. The mean age was 53, 62, and 69 years in SV/SV, SV/AZ, and AZ/AZ, respectively ($p < 0.001$). Two patients in AZ/AZ had inadequate immune response while all patients in SV/SV and SV/AZ had Ab level >7.15 BAU/ml. Among 3 different vaccine regimens, the heterologous SV/AZ had the highest anti-spike RBD IgG level at the median level of 801.8 (IQR: 615.1, 1195.6) BAU/ml, significantly higher than SV/SV (median 95.8 (IQR: 27.3, 427.6) BAU/ml, $p = 0.01$) and AZ/AZ (median 238.3 (IQR: 57.7, 387.2) BAU/ml).
Conclusion: Heterologous COVID-19 vaccine with the inactivated vaccine followed by viral vector vaccine had a significant humoral immune response among patients with cirrhosis. This result highlighted the prime-boost effect of the vaccine to alleviate the shortage of vaccines in the situation of COVID-19 pandemic.

Email: s.phillips@researchinliver.org.uk

Background and aims: Discontinuation of long-term nucleos(t)ides analogue (NA) treatment can lead to clinical relapse and increased risk of hepatic decompensation in patients with HBeAg negative chronic hepatitis B. In others, NA cessation can result in functional cure. It is widely believed that restoration of antiviral immunity underpins this favourable outcome.
Method: Patients virally suppressed for >3 years were randomised to either stop-NA or discontinue NA for 4 weeks followed by 16 weeks of PEG-IFN-alpha before stopping both treatments (NA/IFN) (see Figure). Patients with exaggerated flares (ALT>20xULN) were retreated with NAs (RTx). Longitudinal peripheral blood mononuclear cells (PBMCs) (n = 459) were collected from 23 Stop-NA and 18 NA/IFN patients during a 3-year follow-up. Additional samples were collected during moderate (ALT>2xULN) and exaggerated flares. PBMCs were stimulated with 15 overlapping genotype-specific peptide pools (OPP), HBV core, surface (HBcAg/HBsAg) and recall antigens. Ex-vivo frequency of HBV-specific IFN-gamma (IFN-g) producing T-cells was assessed by ELISpot assays, validated and standardised at GCLP. Virological and clinical parameters were correlated with immunological assessments.
Results: At week 130, 74% Stop-NA and 94% NA/IFN patients remained off treatment while 26% and 6% needed RTx respectively. A lower frequency of IFN-g-specific T-cells at BL, which persisted during follow-up, was associated with RTx ($p = 0.04$). Conversely, one HBcAg OPP-specific T-cell subset was associated with RTx and detected at higher frequency at BL ($p = 0.019$). PEG-IFN treatment was associated with a broad loss of T-cell response and epitope recognition contraction. Whilst this T-cell response recovered after PEG-IFN cessation, a high proportion of patients experienced viral rebound (>2000 IU/ml) (63% vs 18%). In the Stop-NA group, NA withdrawal was associated with moderate flares (52%), accompanied by a peak in T-cell response in sharp contrast to NA/IFN group with flares (62%) occurring when T-cell response was diminished. Finally, the frequency of 3 OPP-specific T-cells subsets at BL was associated with flares in both groups ($p = 0.007$; $p = 0.005$; $p = 0.035$).

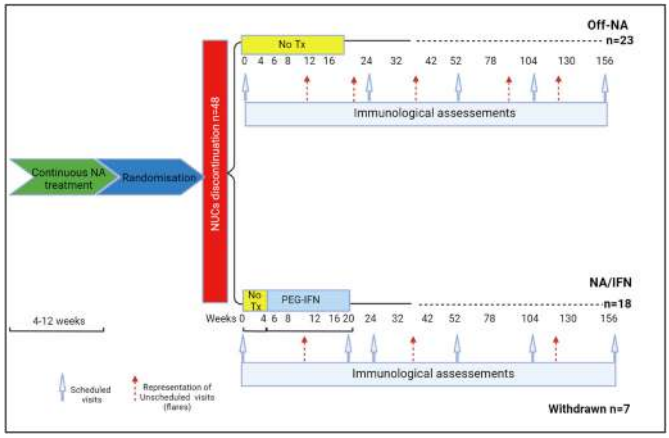

Figure: Created with BioRender.com

Conclusion: This is the first study to systematically characterise the HBV-specific T-cell responses during NA withdrawal and assess the impact of IFN therapy post-NA cessation on antiviral immunity. The findings reveal that epitope-specific T-cells may effectively predict CHB patients that can safely discontinue NA treatment.

THU179

MAIT-cells in blood are associated with a higher risk of infection in patients with cirrhosis

Bonnie Bengtsson[1,2], Christopher Maucourant[3], Ying Shang[1], Johan K. Sandberg[3], Niklas Björkström[3], Hannes Hagström[1,2,4].
[1]*Karolinska Institute, Huddinge Hospital, Unit of Gastroenterology and Rheumatology, Department of Medicin, Stockholm, Sweden;* [2]*Karolinska University Hospital, Huddinge, Division of Hepatology, Department of Upper GI diseases, Stockholm;* [3]*Karolinska Institute, Huddinge Hospital, Center for Infectious Medicine, Department of Medicine, Stockholm;* [4]*Karolinska Institutet, Solna, Clinical Epidemiology Unit, Department of Medicine, Stockholm*
Email: bonnie.bengtsson@ki.se

Background and aims: Bacterial infection is a common and serious complication in patients with liver cirrhosis. Previous research has found that mucosa-associated invariant T cells (MAIT cells), anti-bacterial T cells, are reduced in numbers in patients with cirrhosis, both in liver and in peripheral blood. Little is known if MAIT cell levels might predict incident clinically relevant outcomes including infections. The aim of this study was to evaluate if MAIT cell levels in peripheral blood can serve as a novel biomarker to cirrhotic patients with a higher risk for adverse outcomes.
Method: Patients with liver cirrhosis attending the Hepatology department at the Karolinska University Hospital between 2016 and 2019 were included. Levels of peripheral MAIT cells in blood were determined using flow cytometry. Baseline characteristics and incident outcomes (bacterial infections, hepatic decompensation and death) were ascertained by manual chart review during a mean follow-up of 2.6 years. A competing risk regression was performed to assess the risk of bacterial infection and hepatic decompensation, with death and liver transplant as competing events. Cox regression was performed to evaluate mortality rates. Both models were adjusted for age, sex and severity of liver disease.
Results: We included 106 patients with cirrhosis, median age was 63 years and 64% were men. Median MAIT-cell percentage was 0.8% MAIT cells out if T cells. We found an association of higher MAIT cell percentages with the risk of bacterial infections (adjusted sub-distribution hazard ratio (aSHR) 1.20 (95%CI = 1.05–1.38)). Higher MAIT cell percentages were also associated with a higher risk of hepatic decompensation (aSHR 1.24 (95%CI = 1.08–1.42)) but not with a higher risk of death (adjusted hazard ratio 1.08 (95%CI = 0.96–1.23)).
Conclusion: In contrast to our hypothesis, higher MAIT cell percentage were associated with a higher risk of bacterial infections and decompensation. These findings need to be further validated but identify MAIT cells as an interesting biomarker for adverse outcomes in patients with cirrhosis.

Fatty acids directly limit mucosal-associated invariant T cell effector function in non-alcoholic fatty liver disease

Sebastian Deschler[1], Percy A. Knolle[2], Katrin Böttcher[1], Ulrike Bauer[1], Marc Ringelhan[1], Jan Boettcher[2], Lukas Ramsauer[2], Alexandra Georgieva[1], Fabian Geisler[1], Roland M. Schmid[1], Junika Pohl[1]. [1]*University Hospital rechts der Isar, School of Medicine, Technical University of Munich (TUM), Department of Internal Medicine II, München, Germany;* [2]*University Hospital Rechts der Isar, School of Medicine, Technical University of Munich, Institute of Molecular Immunology and Experimental Oncology, München, Germany*
Email: katrin.boettcher@mri.tum.de

Background and aims: Non-alcoholic fatty liver disease (NAFLD) driven by lipotoxicity and inflammation is becoming the most common chronic liver disease worldwide. Besides promoting pathogenesis, the unique liver microenvironment allows for the development of hepatocellular carcinoma in NAFLD. Here, we aim to decipher novel mechanisms of hepatic immune regulation in NAFLD that could be exploited for therapy. To this end, we analysed how metabolic changes in NAFLD affect the phenotype and effector function of mucosal-associated invariant T (MAIT) cells, innate-like T cells with antimicrobial and anti-cancer potential enriched in the liver.
Method: MAIT cells were isolated from peripheral blood of NAFLD patients or healthy controls and re-stimulated *in vitro* in presence of free fatty acids. MAIT cell phenotype and function was analysed by multi-colour flow cytometry. MAIT cell metabolism was investigated by metabolic flux analysis.
Results: We show that MAIT cell frequency is significantly decreased in peripheral blood of NAFLD patients and that NAFLD MAIT cells express significantly higher levels of activation markers and effector cytokines *ex vivo*, suggesting MAIT cell activation in NAFLD *in vivo*. However, upon *in vitro* restimulation, these activated MAIT cells are dysfunctional and fail to produce effector cytokines, such as IFN gamma, Granzyme B and TNF alpha. Metabolically, MAIT cell effector function was dependent on glycolysis and oxidative phosphorylation, which was unaffected in NAFLD MAIT cells. Culture with distinct fatty acid species characteristic of the NAFLD microenvironment, however, impaired expression of effector cytokines by MAIT cells and induced MAIT cell death. Mechanistically, these effects were mediated by corrupted mitochondrial function and aberrant lipid metabolism.
Conclusion: These results show that MAIT cells are highly activated but dysfunctional in NAFLD and suggest that impairment of MAIT cell effector function is mediated by metabolic signals in the NAFLD microenvironment. Our data unravel a connection between lipotoxicity and immune cell dysfunction in NAFLD which may facilitate the development of therapeutic strategies.

Multimodal single cell analysis reveals the basis for butyrate induction of TNFα-secreting regulatory T cells

Mo Atif[1,2,3], Mustapha Cherai[1], Clara Cretet[1], Melissa Saichi[4], Lynda Aoudjehane[5], Baptiste Fouquet[1], Robert Balderas[6], Filomena Conti[1,2], Olivier Scatton[1,2], Ye Htun Oo[3,7], Guy Gorochov[1,2], Makoto Miyara[1,2]. Email: muhammadatif2@gmail.com

Background and aims: Short-chain fatty acids (SCFAs) such as butyrate are increasingly implicated in modulating T cells in the gut and liver. This is particularly relevant for regulatory T (Treg) cells as

they play an important role in maintaining homeostasis. However, Treg cells are phenotypically and functionally heterogeneous. In this study, we used multimodal single-cell profiling to delineate the mechanistic basis for the effects of butyrate on Treg cell heterogeneity.

Method: We studied the whole transcriptome and several surface protein markers of approximately 6000 Treg cells. This was combined with experimental studies for biological validation.

Results: We found that butyrate polarised naïve Treg cells into heterogeneous subpopulations with both immunosuppressive and pro-inflammatory subsets. Upon reconstructing the gene regulatory networks, we found an upregulation of the hypoxia, NFκB, JAK-STAT, TNFα, and MAPK signalling pathways. We also identified the individual regulons driving them. These findings were subsequently validated experimentally. Strikingly, butyrate increased the secretion of TNFα, IL-2, and IL-17A from the activated Treg cells whilst maintaining their immunosuppressive capacity. We also uncovered the novel capacity of butyrate to acutely inhibit STAT5 and p38.

Conclusion: Collectively, our work demonstrates the basis by which butyrate promotes diverse regulatory and effector cell subpopulations. These mechanisms could be therapeutically targeted to modulate the effects of SCFAs on Treg cells in the gut and liver.

THU182

COVID-19 vaccination in liver cirrhosis: safety and immune and clinical responses

Maria Ines Canha[1], Mario Jorge Silva[1], Maria Azevedo Silva[2], Mara Costa[3], Rita Catarina Saraiva[1], André Ruge[2], Mariana Machado[4], Catarina Félix[5], Bárbara Morão[6], Pedro Narra Figueiredo[3], Milena Mendes[1], Carina Leal[2], Filipe Calinas[1]. *[1]Centro Hospitalar Universitário de Lisboa Central, Gastroenterology; [2]Centro Hospitalar de Leiria, Gastroenterology; [3]Centro Hospitalar Universitário de Coimbra, Gastroenterology; [4]Hospital de Vila Franca de Xira, Gastroenterology; [5]Centro Hospitalar de Lisboa Ocidental, Gastroenterology; [6]Hospital Beatriz Ângelo, Gastroenterology*
Email: m.inescanha@gmail.com

Background and aims: Available data regarding safety and efficacy of COVID-19 vaccination in liver cirrhosis patients is lacking. Their dysregulated immune system makes them susceptible to serious disease and to an attenuated response to certain vaccines. Our goal was to study safety, immunological and clinical responses of cirrhotic patients to COVID-19 vaccination and assess their relation to demographic, clinical and vaccine-related factors.

Method: Interim analysis of an ongoing multicentric prospective study in patients with liver cirrhosis eligible for COVID-19 vaccination without prior infection. Demographic data, liver disease severity, comorbidities, medication and adverse events were registered. Patients were requested to assess IgG antibody titers (AbT) for SARS-CoV-2 at 2 weeks (W2), 3 months (M3) and 6 months after completing vaccination. During follow-up, post-vaccination infection and severity were registered. We analyzed the patients who completed the M3 assessment, using Stata® 15 and a $p < 0.05$.

Results: We included 121 patients, 82% males, mean aged 61 years. Alcohol is the most common (61%) cause of cirrhosis. Twenty percent have a Child Pugh score (CPS) of B/C; 42% had at least one decompensation and 68% have portal hypertension (PHT) signs. Seventeen percent of the patients reported adverse reactions after vaccination, none of them serious. Median [Q1; Q3] AbT were 1115 [291; 2080] BAU/ml at W2 and 293 [88; 1190] BAU/ml at M3. Group differences in AbT (using 33.8 and 200 BAU/ml as cut-offs) were assessed in a multivariable logistic regression considering the patients' age, gender, cause of cirrhosis, immunosuppressant drugs, severity of cirrhosis (Table 1), type of vaccine and adverse reactions. Only older age and type of vaccine proved to be associated with lower AbT at W2 and M3. None of the patients was diagnosed with COVID-19 infection during a mean follow-up of 137 days.

	AbT at W2			AbT at M3		
Clinical features	Median (BAU/ml)	<33.8 BAU/ml* (%)	<200 BAU/ml (%)	Median (BAU/ml)	<33.8 BAU/ml* (%)	<200 BAU/ml (%)
CPS A	1090	7.7	23.1	265	16.7	40.0
CPS B/C	1600	5.9	17.6	675	7.7	30.7
No PHT	1115	6.7	23.3	279	16.7	43.3
PHT	1135	7.7	21.2	304	14.0	34.8
Compensated disease	1585	8.0	24.0	304	12.7	38.3
Previous decompensation	1085	6.3	18.8	265	19.2	38.5

*Reference laboratory value for negative result.

Conclusion: COVID-19 vaccines in cirrhotics were safe and their clinical and humoral response seem not different from the observed in the general population assessed in clinical trials.

THU183

Building a case for pancreas and liver targeted intereukin-22 therapy in fatty liver disease

Haressh Sajiir[1], Kuan Yau Wong[1], Alexandra Mueller[1], Sahar Keshvari[2], Ran Wang[1], Percival Wiid[1], Grant Ramm[3], Graeme Macdonald[4], John Prins[5], Michael McGuckin[5], Sumaira Hasnain[1,6]. *[1]Mater Research Institute-The University of Queensland, Immunopathology group, Brisbane, Australia; [2]Mater Research Institute-The University of Queensland, Brisbane, Australia; [3]QMIR Berghofer Medical Research Institute, Brisbane, Australia; [4]Princess Alexandra Hospital, Brisbane, Australia; [5]The University of Melbourne, Melbourne, Australia; [6]Australian Infectious Diseases Research Centre, Brisbane, Australia*
Email: sumaira.hasnain@mater.uq.edu.au

Background and aims: We discovered that the cytokine interleukin-22 (IL-22) is an efficient natural inhibitor of cellular stress and improved insulin quality in pancreatic beta-cells in preclinical models of Type 2 diabetes. Importantly, IL-22 completely restored glucose tolerance, suppressed fasting hyperinsulinaemia/hyperproinsulinaemia, and restored insulin sensitivity in obese animals. Treatment of obese animals with IL-22 also showed significant improvements in circulating triglycerides, liver function (AST:ALT ratio) and a reduction in hepatic lipid accumulation. IL-22 has also been shown to be protective in other models of liver disease including alcoholic hepatitis, acute-on-chronic liver failure, hepatic fibrosis and paracetamol induced liver injury, and there are 3 versions of IL-22 based therapeutics in clinical trials for such pathologies. Interestingly, the IL-22 receptor, IL-22Ra1 is highly expressed in the pancreas and liver. Our study aimed to define the role of endogenous IL-22 in the liver and pancreas to provide additional support for IL-22-therapy in non-alcoholic fatty liver disease (NAFLD).

Method: To study the role of endogenous IL-22 in the pancreas and liver, we generated tissue specific IL-22Ra1 knockout mice lacking the receptor in pancreatic beta-cells ($IL\text{-}22Ra1^{b\text{-}cell\ -/-}$) and hepatocytes ($IL\text{-}22Ra1^{Hep\ -/-}$). We then challenged them with a high fat diet, and measured their glycaemic control, hepatic lipid accumulation, and hepatic markers of cellular stress, lipid, and glucose metabolism.

Results: We found that $IL\text{-}22Ra1^{Hep\ -/-}$ animals had increased hepatic markers of inflammation and cellular stress. Interestingly, we also observed this phenomenon in $IL\text{-}22Ra1^{b-cell\ -/-}$ mice. Additionally, $IL\text{-}22Ra1^{b\text{-}cell\ -/-}$animals also had defective glycaemic control and insulin secretion compared to littermate control animals, which worsened on a high-fat diet. We also found that whilst female animals did not gain as much weight as male animals on a high-fat diet, female $IL\text{-}22Ra1^{b\text{-}cell\ -/-}$ mice had a worsened phenotype compared to males.

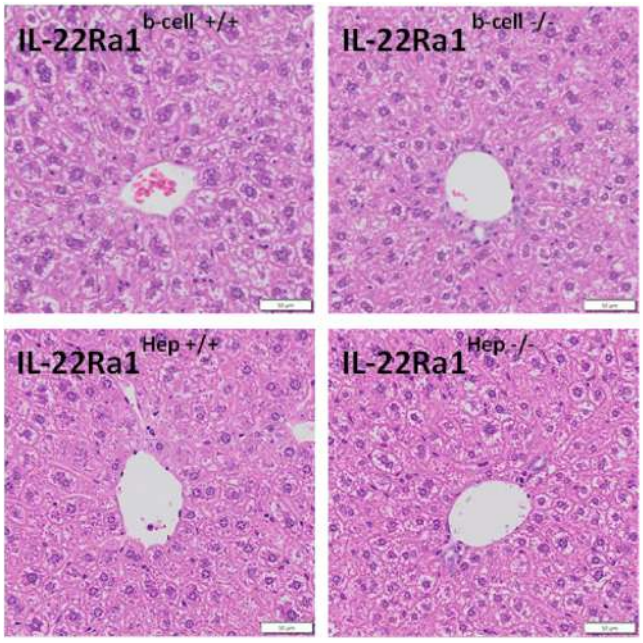

Figure: HandE sections of animal livers at 20 weeks of age

Conclusion: We confirmed the role of endogenous IL-22 in maintaining insulin quality control and healthy hepatic function. We also discovered a novel role for endogenous IL-22 in the pancreatic-beta cell-liver axis and demonstrated the importance of targeting IL-22 to both pancreatic beta-cells and hepatocytes to treat NAFLD.

Patients with decompensated cirrhosis and liver transplant recipients demonstrate poor humoral and cellular immune response against COVID-19 vaccine

Anand Kulkarni[1], Sasikala Mitnala[1], Sowmya Iyengar[1], Shashidhar Jaggaiahgari[1], Baqar Gora[1], Hardik Rugwani[1], Mithun Sharma[1], Nagaraja Rao Padaki[1], Nageshwar Reddy[1]. [1]*AIG Hospitals, Hyderabad, India*
Email: anandvk90@gmail.com

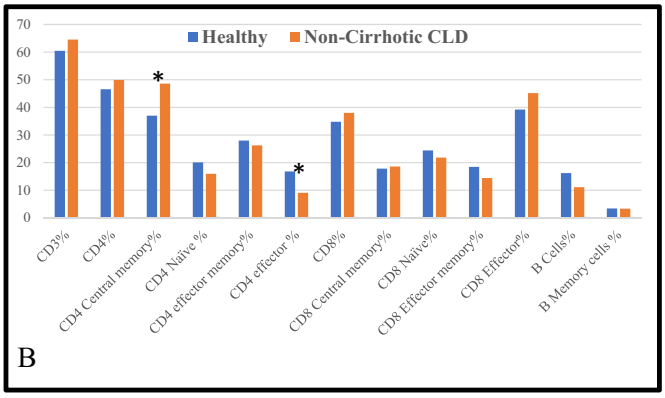
Background and aims: Coronavirus disease-2019 (COVID-19) vaccination is recommended for all patients with chronic liver disease (CLD) and liver transplant recipients (LTR). However, the immunogenicity of COVID-19 vaccines such as ChAdOx1 (vector-based) and BBV152 (inactivated virus) in these immunocompromised patients is unknown. Therefore, we aimed to compare the humoral and cellular immune responses of CLD patients, LTR, and healthy individuals against the available COVID-19 vaccines.

Method: Completely vaccinated (either with ChAdOx1 or BBV152) non-cirrhotic CLD patients (NCCLD), cirrhotic patients, and LTR were compared against age-matched healthy controls (HC) for anti-spike antibody response (by chemiluminescence immunoassay [CLIA] method) and immune profiling of the T and B cells (by flow cytometry). Also, we assessed the number of patients developing breakthrough infections post-vaccination. We excluded patients with renal failure, active sepsis, patients <2 weeks from the last vaccination dose. An individual with antibody levels <15 AU/ml was considered as a non-responder.

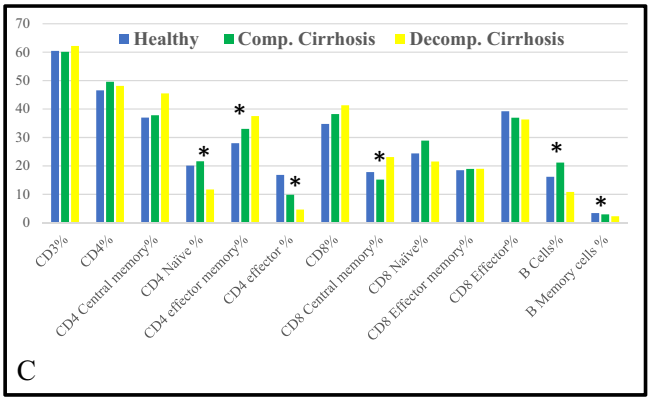
Results: Fifty NCCLD patients, 63 compensated cirrhosis (CC), 50 decompensated cirrhosis (DC) patients, 60 HC, and 17 LTR consented for the study (Fig. A). A similar proportion of patients in NCCLD (16%) and HC (8.3%) were non-responders (p = 0.21). CD4 central memory

Groups	Responders
Healthy controls (n = 60)	91.7%
Non-cirrhotic CLD (n = 50)	84%
Compensated cirrhosis (n = 63)	82.5%
Decompensated Cirrhosis (n = 50)	66%
LT recipients (n = 17)	41.2%

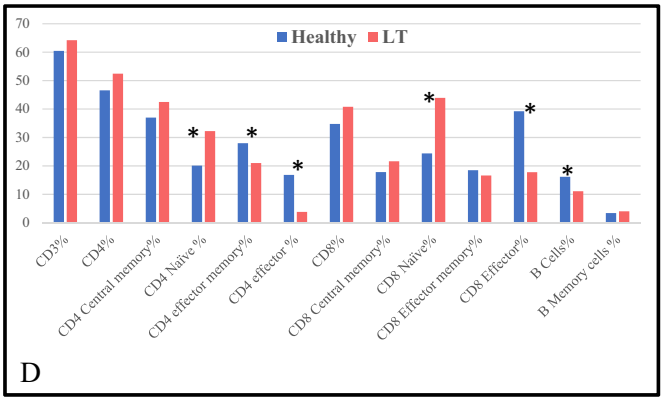
A



B



C



D

* P < 0.05

Figure: (abstract: THU184)

cells and CD4 effector cells were lower in the NCCLD patients, while the other immune cells were similar in both groups (Fig. B). Non-response was similar between CC (17.5%) and healthy individuals (8.3%; p = 0.18). Only CD4 effector cells were lower in CC patients than healthy individuals, while the other immune cells were similar in both groups. A higher proportion of patients in DC group (34%) were non-responders than CC (17.5%; p = 0.04) and HC group (8.3%; p = 0.001). CD4 naïve cells, CD4 effector cells, B cells, and B memory cells were lower in the DC group. Though the central memory cells were higher in the DC group, they could not differentiate into effector cells (Fig. C). Fifty-nine percent in LT group were non-responders compared to 8.3% in HC group (p <0.001). On immune profiling, CD4 and CD8 naïve cells were higher in the marrow in the LT group, while the CD4 effector memory cells and CD4 and CD8 effector cells were lower in the LT group. Furthermore, B cells were lower in the LT group, suggesting poor antibody response (Fig. D). Breakthrough infections were slightly higher in CC and DC group but non-significant (healthy-3.3%; NCCLD-2%; CC-8%; DC-8%; LTR-5.88%). Except for two patients in the DC group, all breakthrough infections were mild.

Conclusion: Patients with decompensated cirrhosis and liver transplant recipients demonstrate poor humoral and cellular immune response against COVID-19 vaccines. Therefore, decompensated cirrhosis patients and liver transplant recipients require a booster dose of COVID-19 vaccination.

THU185

Presence of cirrhosis in chronic liver disease patients associates with a lower immune response to COVID-19 vaccines-a multicenter european study

Background and aims: Vaccines in the European Union (EU) to prevent COVID-19 have been shown to be safe and effective in immunocompetent subjects. Nonetheless, studies in patients with chronic liver disease (CLD) are lacking. Our aim was to assess the humoral immune response of two-dose COVID-19 vaccines among CLD patients of different etiologies and identify predictors of "low" versus "high" humoral response.

Method: Patients were recruited from clinical centers in 6 EU countries, as part of a large consortium study. Serum levels of IgG, IgM (nM) and neutralizing antibodies (NA, %) against the SARS-CoV-2 spike S1 protein were determined in samples collected prior to vaccination (T0) and at least 14 days after the second vaccination dose (T2). Patients (n = 195) were divided into "low" (51.4%) or "high" (48.6%) responders according to their IgG antibodies at T2, using 419 nM (median) as the cut-off value. Logistic regression analysis was used to explore features associated with the vaccine-induced IgG levels.

Results: All patients were fully vaccinated with either BNT162b2 (68%), mRNA-1273 (21.5%) or ChAdOx1 (10.5%). Their median age was 58 (range 21–85); 57.4% were male. Underlying liver disease etiology included alcohol (28.7%), NAFLD (21%), HCV (29.2%) and HBV (16.9%), among others. 61.5% presented with cirrhosis. At T0, spike S1 IgG, IgM and NA levels were 0.76 (95% confidence interval (CI), 0.42–1.10), 0.37 (95% CI, 0.30–0.45) and 22.99 (95% CI, 21.39–24.58), respectively, increasing to 446.07 (95% CI, 400.60–491.53), 3.91 (95% CI, 2.20–5.62) and 78.88 (95% CI, 74.91–82.85) at T2 (p <0.0001 for all). In addition, IgG and NA levels showed a high positive correlation. Age [odds ratio (OR) 1.06 (1.03–1.10)], alcohol [OR 2.25 (1.15–4.41)], metabolic drugs [OR 2.30 (1.20–4.43)], hepatocellular carcinoma [OR 5.41 (1.15–25.52)] and evidence of cirrhosis [OR 3.85 (1.95–7.61)], as well as type of vaccine, predicted "low" response. In multivariable analysis, cirrhosis and type of vaccine (ChAdOx1 >BNT162b2 >mRNA-1273) remained the only independent predictors of "low" response.

Conclusion: CLD patients with cirrhosis exhibit lower immune responses to COVID-19 vaccination, irrespective of disease etiology. Further, the type of administered vaccine appears to predict levels of humoral response, although this needs validation in larger cohorts with a more balanced representation of all vaccines.

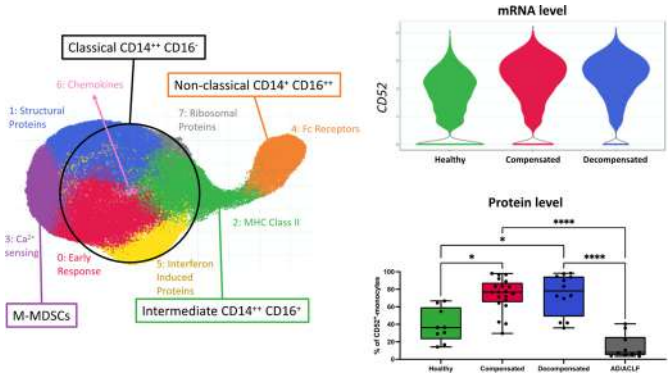
THU186

Heterogeneity of peripheral blood monocytes in patients with cirrhosis

Anne Geng[1], Robert G Brenig[1,2], Mechthild Lütge[3], Julien Roux[4], Hung-Wei Cheng[3], Patrizia Kuenzler[5], David Semela[2], Markus Heim[6,7], Burkhard Ludewig[3], Christine Bernsmeier[1,7]. *[1]University Hospital of Basel, Department of Biomedicine, Translational Hepatology, Basel, Switzerland; [2]Division of Gastroenterology and Hepatology, Cantonal Hospital St. Gallen, Liver Biology Laboratory, St. Gallen, Switzerland; [3]Cantonal Hospital St. Gallen, Institute of Immunobiology, St. Gallen, Switzerland; [4]University Hospital Basel, Department of Biomedicine, Bioinformatics Core Facility, Basel, Switzerland; [5]Cantonal Hospital St. Gallen, Division Gastroenterology and Hepatology, St. Gallen, Switzerland; [6]University Hospital of Basel, Department of Biomedicine, Hepatology, Basel, Switzerland; [7]Clarunis, University Center for Gastrointestinal and Liver Disease, Basel, Switzerland*
Email: anne.geng@unibas.ch

Background and aims: In patients with cirrhosis, we recently discovered dysfunctional monocytes (M-MDSC, $CD14^+HLA\text{-}DR^+AXL^+$, $CD14^+MERTK^+$) prevailing over regular monocytes, which were associated with reduced capacity to repel microbial challenge and infection susceptibility. Transcriptome wide single cell RNA sequencing (scRNA-seq) is expected to further enhance the understanding of the plasticity of immune cell differentiation processes in disease conditions. We aimed to systematically dissect the stage specific heterogeneity of circulating monocytes using scRNA-seq in cirrhosis with the intension to identify potential future immunotherapeutic targets.

Method: Monocytes (20.000 cells/sample) from compensated (CC, n = 5), decompensated (DC, n = 5) cirrhosis patients and healthy controls (HC, n = 5) were prepared for scRNA-seq (10x Genomics) and analysed (>4000 cells/sample) using R/Bioconductor. Flow cytometric analyses were used to confirm transcriptional findings on a translational level and to further evaluate the function of distinct monocytes.
Results: Our scRNA-seq data was grouped into eight monocyte clusters, based on the expression of specific genes, of which five clusters were annotated to classical ($CD14^{++}CD16^{-}$), one cluster to intermediate ($CD14^{++}CD16^{+}$) and one cluster to non-classical ($CD14^{+}CD16^{++}$) monocyte subsets. One cluster showed a M-MDSC-like gene expression. $CD14^{+}CD16^{++}$-like monocytes were reduced in CC and DC patients, while M-MDSC-like monocytes were increased and gene expression of MHC class II members was downregulated compared to healthy controls. Differentially expressed (DE) gene analysis revealed upregulation of *Cd52*, a T cell suppressor and inhibitor of TLR-signaling, in monocytes from CC/DC compared to HC. Upregulation of CD52 on monocytes was confirmed on translational level in CC/DC patients, but not detected on monocytes of patients with acute decompensation (AD) or acute-on-chronic liver failure (ACLF). CD52-expressing monocytes exhibited higher levels of CD16, HLA-DR, AXL and CD206, showed higher phagocytosis capacity and increased cytokine production (TNF-alpha, IL-6 and IL-10) upon microbial challenge (TLR4/TLR2 agonism). T cells co-cultured with monocytes with high proportion of CD52 expression (>60%) from cirrhosis patients showed reduced proliferation activity compared to T cells co-cultured with monocytes from healthy donors with lower CD52 expression (<40% of monocytes).



Conclusion: Using scRNA Seq we have identified eight circulating monocyte clusters with distinct prevalence between HC and CC/DC. DE gene analysis highlighted plasticity of CD52 expression on monocytes during disease evolution of cirrhosis.

THU187

JAM-A is a multifaceted regulator in hepatic fibrogenesis, supporting LSEC integrity and stellate cell quiescence

Jonathan Frederik Brozat[1], Elisa Brandt[1], Myriam Stark[1], Petra Fischer[1], Theresa Hildegard Wirtz[1], Alexander Flaßhove[1], Aaron Nikolai Rodenhausen[1], Tanja Vajen[2], Alexandra C.A. Heinzmann[3], Sophia M. Schmitz[4], Samira Abu Jhaisha[1], Anjali A. Röth[4], Rory R. Koenen[3], Hacer Sahin[1], Christian Trautwein[1], Marie-Luise Berres[1]. *[1]University Hospital RWTH Aachen, Department of Gastroenterology, Digestive Diseases and Medical Intensive Care, Internal Medicine III, Aachen, Germany; [2]Heinrich-Heine-University, Cardiovascular Research Laboratory, Division of Cardiology, Pulmonology and Vascular Medicine, Medical Faculty, Düsseldorf, Germany; [3]Maastricht University, Department of Biochemistry, Cardiovascular Research Institute Maastricht, Maastricht, Netherlands; [4]University Hospital RWTH Aachen, Department of General, Visceral and Transplantation Surgery, Aachen, Germany*
Email: jbrozat@ukaachen.de

Background and aims: Leukocyte extravasation is a hallmark of hepatic inflammation. Reduced shear stress within hepatic sinusoids and the specific phenotype of liver sinusoidal endothelial cells (LSEC) cumulate in differing adhesion characteristics during liver fibrosis. The Junctional Adhesion Molecule A (JAM-A) is a crucial regulator of leukocyte extravasation and upregulated in human viral fibrosis. The aim of this study was to define the functional role of cell-specific surface JAM-A during hepatic fibrogenesis, applying distinct knockout strategies in a murine model.
Method: Complete, conditional intestinal epithelial, conditional endothelial and bone marrow chimeric *Jam-a* knockout animals (C57Bl/6) were treated with carbon tetrachloride (CCl_4, 6 weeks). Livers were investigated by qRT-PCR, Western blotting, immunohistochemistry, immunofluorescent stainings and flow cytometry. The functional relevance of JAM-A was assessed using co-culture models and flow-based adhesion assays.
Results: Complete and bone-marrow derived *Jam-a* knockout animals showed aggravated fibrosis with increased non-sinusoidal, perivascular accumulation of $CD11b^{+}F4/80^{+}$ monocyte-derived macrophages in contrast to wild type mice. Despite being associated with disturbed epithelial barrier function, an intestinal epithelial *Jam-a* knockout did not affect fibrogenesis. In endothelial-specific *Jam-a* knockout animals, liver fibrosis was aggravated alongside CD31-sinusoid capillarization and hepatic stellate cell (HSC) activation. Here, leukocyte infiltration and adhesion to LSECs remained unaffected.
Conclusion: Our models decipher cell-specific JAM-A to exert crucial functions during hepatic fibrogenesis. JAM-A on bone marrow-derived cells regulates non-sinusoidal vascular immune cell adhesion and recruitment, while endothelial JAM-A controls liver sinusoid capillarization and LSEC-linked HSC quiescence.

THU188

Diminished function of cytotoxic T- and NK- cells in severe alcohol-associated hepatitis

Adam Kim[1], Christina Cajigas-Du Ross[1], David Streem[2], Nicole Welch[1], Jaividhya Dasarathy[3], Srinivasan Dasarathy[1], Laura Nagy[4]. *[1]Cleveland Clinic, Inflammation and Immunity, Cleveland, United States; [2]Cleveland Clinic, Lutheran Hospital, United States; [3]MetroHealth; [4]Cleveland Clinic, Inflammation and Immunity, Cleveland, United States*
Email: kima7@ccf.org

Background and aims: Severe Alcohol-associated Hepatitis (sAH) is characterized by inflammation and infiltration of immune cells into the liver. Peripheral monocytes are a major infiltrating cell type that can exacerbate inflammation and damage to the liver. sAH patients have a higher peripheral leukocyte count and an increased proportion of inflammatory monocytes. Even though there are more monocytes, sAH patients are often extremely susceptible to infections. Cytotoxic NK-cells and CD8 T-cells play an important immunological role in triggering apoptosis in infected cells, particularly monocytes. Cytotoxic cells secrete cytotoxic granules containing granzymes, perforin, and in humans, granulysin, to kill cells. We hypothesize that in sAH, cytotoxic cells are dysfunctional and unable to trigger cell death in target cells.
Method: We performed single-cell RNA-seq (scRNA-seq) in PBMCs collected from patients with sAH (n = 4) and healthy controls (HC, n = 4). Multi-panel intracellular flow cytometry was conducted to understand changes in cell proportion, correlated gene expression, and cytotoxic granule contents in NK-cells and CD8 T-cells in PBMCs from patients with sAH (n = 9) and HC (n = 7), as well as patients with moderate AH (mAH, n = 6), heavy drinkers (HD, n = 8), alcohol-associated cirrhosis (AC, n = 8), and non-alcohol-associated steatohepatitis (NASH, n = 8).
Results: scRNA-seq revealed receptors required for cytotoxic cell recognition of activated monocytes were downregulated in all

peripheral immune cells in patients with sAH. Additionally, granulysin was the most downregulated gene in both NK cells and effector CD8 T-cells. In cells from HC, expression of granulysin, perforin, and granzymes A and B was highly correlated, but in sAH these genes lost coordination, indicative of dysfunctional cytotoxic granule formation. Using flow cytometry, we observed a severe decrease in perforin and granzyme B expression in sAH patients. Interestingly, NK cells from patients with mAH, HD, AC, and NASH were not deficient in cytotoxic granules, but perforin and granzyme B were lower in CD8 T-cells from HD and AC.

Conclusion: Cytotoxic cells from sAH patients are deficient in cytotoxic granules, likely impairing their ability to kill target cells. While sAH patients had both dysfunctional NK-cells and CD8 T-cells, patients with HD and AC also had dysfunctional CD8 T-cells. Loss of cell-cell recognition receptors in both cytotoxic cells and monocytes is indicative of a loss of cell-cell communication and a possible mechanism for increased inflammatory monocytes in sAH. Together, these results indicate a loss of cytotoxic cell function in sAH, which might contribute to increased numbers of inflammatory monocytes and a decreased ability to kill infected cells.

Multi-omics analysis of human livers reveals variation in intrahepatic inflammation across chronic hepatitis B infection phases

Noé Axel Montanari[1], Ricardo Ramirez[2], Abhishek Aggarwal[2], Nicholas Van Buuren[2], Michael Doukas[1], Christina Moon[2], Scott Turner[2], Lauri Diehl[2], Li Li[2], Jose Debes[1], Becket Feierbach[2], Andre Boonstra[1]. *[1]Erasmus MC; [2]Gilead Sciences*
Email: boonstra.andre@gmail.com

Background and aims: Chronic HBV is clinically defined in 4 phases by a combination of serum HBV DNA levels, HBeAg status and ALT: immunotolerant (IT), immune-active (IA), inactive carrier (IC) and HBeAg-negative hepatitis (ENEG). Immune and virological differences between phases, as detected in blood, have proven useful but do not fully explain the interrelation between the clinical phenotype and the immunological mechanism in the liver. We aimed to study the intrahepatic immune profile across the clinical phases in order to better understand the immunological mechanism of HBV.

Method: Immunological composition and transcriptional profiles of FFPE core needle liver biopsies in chronic HBV phases vs healthy were evaluated by multiplex immunofluorescence and RNA-Seq (n = 37 and 78, respectively).

Results: Irrespective of the phase-specific serological profiles, increased intrahepatic immune-gene expression and frequency were observed in chronic HBV compared to healthy control livers. Greater transcriptomic de-regulation was seen in IA and ENEG (172 vs 243 DEGs) than in IT and IC (13 vs 35 DEGs) livers. ISG, immune-activation and exhaustion genes (ICOS, CTLA4, PDCD1) together with chemokine genes (CXCL10, CXCL9) were significantly induced in IA and ENEG livers. Moreover, distinct immune profiles associated with ALT elevation, and a more accentuated immune-exhaustion profile (CTLA4, TOX, SLAMF6, FOXP3) found in ENEG and set it apart from IA phase (LGALS9, PDCD1). Interestingly, all HBV phases showed downregulation of metabolic pathways vs healthy livers (fatty and bile acid metabolism). Finally, we found increased leukocyte infiltrate correlated with serum ALT, but not with HBV DNA or viral proteins.

Conclusion: Our comprehensive multi-omics analysis of human livers revealed distinct inflammatory profiles and pronounced differences in intrahepatic gene profiles across all chronic HBV phases in comparison to healthy liver.

THU190

Liver cirrhosis and cirrhosis etiology impacts the circulating immune mediators of early stage hepatocellular carcinoma

Boris Beudeker[1], Anthony Grooshuismink[1], Annemiek Van der Eijk[2], Jose Debes[1], Andre Boonstra[1]. *[1]Erasmus MC, Gastroenterology and hepatology, Rotterdam, Netherlands; [2]Erasmus MC, Viroscience, Rotterdam, Netherlands*
Email: borisbeudeker@live.nl

Background and aims: Novel blood biomarkers to predict and detect curable, early stage hepatocellular carcinoma (HCC) is the most effective strategy to improve survival of HCC patients. Others and we have recently published on the applicability of serum immune proteins as early HCC biomarkers, but these studies had limited reproducibility. We now study in detail the contribution of the cirrhotic stage and disease etiology on the circulating immune response, in order to increase the diagnostic robustness of an early HCC immune signature.

Method: A retrospective cohort of 1585 patients with pathology- or radiology-proven HCC was established of patients diagnosed at our large tertiary HCC referral center, among them were 522 (33%) with BCLC 0/A stage HCC. Immune profiles of a balanced cohort of 188 cirrhotic patients, and 195 early HCC patients with hepatitis B (HBV), hepatitis C (HCV), ALD alcoholic liver disease (ALD) or non-alcoholic liver disease (NAFLD) were determined through serum multiplex profiling.

Results: We show that liver cirrhosis had a profound effect on the levels of circulating immune proteins with significant dysregulation of 24 out of 59 serum immune mediators. Stratification of cirrhosis patients in groups with distinct etiologies identified 45 significant immune mediators and heat map revealed obviously distinct immune profiles in each etiology. HBV-cirrhosis was characterized by high levels of circulating TRAIL and IFN-gamma, HCV-cirrhosis by high levels of IP-10 and the immune profiles of ALD-cirrhosis; NAFLD-cirrhosis were more comparable with higher levels of IL-8, IL-6, CCL25 and LIF.

Eight immunological mediators were significant independent predictors of early stage HCC and displayed specificity for one of the four cirrhosis etiologies. These immune mediators improved existing tumors marker efficacy and when combined with AFP detected early stage HCC with an AUC of 0.80.

Conclusion: HCC develops in an inflammatory heterogenetic background. In our search for predictive HCC markers, we found that liver cirrhosis and cirrhosis etiology had a profound impact on the circulating immune response and associated with a wide repertoire of pro-inflammatory and HCC promoting immune mediators. Moreover, we identified Immunological markers that differentiated early stage HCC from cirrhosis. Strict stratification resulted in a set of immune mediators with good sensitivity for early stage HCC of different etiologies.

THU191

Ebola virus infection promotes reduced gene expression of antigen presentation molecules in hepatic CD68+ macrophages in cynomolgus macaques

Timothy Wanninger[1,2], Omar Saldarriaga[1], Daniel Millian[1], Jason Comer[2], Kamil Khanipov[3], George Golovko[3], Slobodan Paessler[1], Heather Stevenson[1]. *[1]University of texas medical branch, Pathology, United States; [2]University of texas medical branch, Microbiology and immunology, United States; [3]University of texas medical branch, Pharmacology and toxicology, United States*
Email: tiwannin@utmb.edu

Background and aims: Ebola virus (EBOV) is an emerging infectious disease found in West Africa, with the potential for case importation to other countries. Antigen presenting cells, including macrophages, are among the first cells infected following EBOV exposure. As a result, the liver, a macrophage-laden organ, is a key participant in EBOV infection. While the inflammatory contributions of

macrophages have been characterized *in vitro* or *ex vivo*, studying these cells within their tissue context is essential for understanding disease progression.
Method: We compared formalin-fixed, paraffin-embedded liver tissue from uninfected control and terminal EBOV-infected cynomolgus macaques. We characterized region-specific whole transcriptome expression in these tissues using GeoMx Digital Spatial Profiling (NanoString). Biological processes enriched or depleted in infection were identified using gene set analysis (Global Test) and Ingenuity Pathway Analysis (Qiagen). Macrophage (CD68+) accumulation in liver tissue was quantified by immunofluorescence image analysis using QuPath digital pathology software.
Results: Ebola virus infection was associated with increased CD68+ macrophage accumulation in the liver. Gene set analysis revealed altered immune, coagulation, metabolism, apoptosis, and tissue remodeling processes. Within the altered immune processes, key down-regulated genes included multiple MHC-II alleles (HLA-DPA1, HLA-DQB1, HLA-DRA, HLA-DRB1), CD74, and LGMN. In CD68+ macrophages, these down-regulations were associated with antigen presentation, monocyte/macrophage differentiation, as well as T cell differentiation, activation, and cytotoxicity gene sets.
Conclusion: Down-regulated MHC-II-related gene expression by hepatic CD68+ macrophages may reduce T cell activation in EBOV-infected cynomolgus macaques. Such impairment, identified by *in situ* regional transcriptomic analysis, may synergize with the known disruption of dendritic cell-mediated antigen presentation in this disease, further compromising the adaptive immune response to EBOV infection.

THU192
Plasmalemma vesicle-associated protein expression is driven by senescent cell-endothelial crosstalk and shapes the immune landscape in chronic liver disease

Alex Wilkinson[1], Daniel Patten[1], Sam Hulme[1], Matthew Hoare[2], Shishir Shetty[1]. [1]*University of Birmingham, Institute of Immunology and Immunotherapy, United Kingdom;* [2]*University of Cambridge, Department of Medicine, United Kingdom*
Email: axw717@student.bham.ac.uk

Background and aims: Chronic liver diseases (CLDs) are driven by leukocyte recruitment and persistent inflammation. Cellular senescence is a key feature of CLD, yet its contribution to liver inflammation is poorly understood. Senescent cells release a secretome (senescence-associated secretory phenotype or SASP) which facilitates their clearance through leukocyte recruitment. This process is mediated by hepatic sinusoidal endothelial cells (HSEC) which undergo phenotypic and functional changes in response to SASP treatment. Plasmalemma vesicle-associated protein (PLVAP) is highly expressed by foetal liver endothelium, playing an important developmental role, yet human single-cell studies have highlighted its re-emergence in liver cirrhosis and hepatocellular carcinoma (HCC). Whilst PLVAP has previously been proposed as a leukocyte trafficking molecule, its specific role in hepatic leukocyte recruitment is not known. We hypothesised that PLVAP expression is driven by the senescent tissue microenvironment in CLD and sought to investigate its potential role in SASP-mediated leukocyte recruitment.
Method: PLVAP expression was characterised, in human liver samples by qPCR and immunohistochemistry, and in primary human HSEC by immunocytochemistry. SASP was obtained using a model of oncogene-induced senescence (conditioned media from RAS-senescent IMR90 fibroblasts-RAS-CM), and the effects of SASP treatment on primary HSEC were determined by qPCR and confocal microscopy. To investigate the molecular mechanisms of SASP-mediated leukocyte recruitment, flow-adhesion assays were performed with SASP-stimulated HSEC (following siRNA or antibody treatment) and peripheral blood lymphocytes or monocytes.
Results: PLVAP was significantly upregulated in liver endothelium of CLD and HCC patients compared to healthy controls, correlating with increased expression of senescent markers, p21 and p16. Treatment of primary HSEC with RAS-CM significantly increased PLVAP expression and stimulated recruitment of both lymphocytes and monocytes under physiologically low shear stress. However, these processes were morphologically and molecularly distinct. Lymphocytes predominantly (~ 60%) transmigrate via the transcellular pathway which was selectively inhibited by ICAM-1 blockade. In contrast, >90% monocytes transmigrate paracellularly in a CD31-dependent manner. Furthermore, genetic or antibody-mediated inhibition of PLVAP selectively impaired SASP-mediated monocyte transmigration whilst having no effect on lymphocyte recruitment.
Conclusion: These data highlight a previously unreported link between PLVAP and senescence, in which PLVAP expression is driven in HSEC by the senescent secretome to facilitate monocyte recruitment. PLVAP could therefore be a novel target for perturbing aberrant monocyte recruitment in liver disease.

THU193
Dysfunctional liver-resident CXCR6+ CD8 T cells during persistent viral liver infection

Miriam Bosch[1], Nina Kallin[1], Donakonda Sainitin[1], Hannah Wintersteller[1], Ulrike Protzer[2,3], Dirk Wohlleber[1], Percy A. Knolle[1,4]. [1]*Institute of Molecular Immunology, Technical University of Munich, Munich, Germany;* [2]*Institute of Virology, Technical University of Munich;* [3]*Institute of Virology, Helmholtz Center for Environment and Health;* [4]*German Center for Infection Resarch, Munich*
Email: percy.knolle@tum.de

Background and aims: CD8 T cell-mediated immunity is key for the clearance of hepatitis B virus infection and other hepatotropic viral infections. Persistent viral liver infections, however, are characterized by a lack of a robust anti-viral CD8 T cell response. We aimed at determining the mechanism causing the lack of CD8 T cell functionality during persistent viral liver infection.
Method: We used Adenovirus-based models (coding for ovalbumin or the HBV genome) to investigate persistent or acute-resolved infection. For virus-specific T cell analysis, we transferred naïve ($CD44^{neg}CD62L^{hi}$) virus-specific CD8 T cells bearing a congenic marker before infection. T cells were analyzed at different time points for phenotypic and functional characterization and RNAseq.
Results: After acute-resolved viral infection, we identified two distinct virus-specific CD8 T cell populations in the liver, i.e. CX_3CR1^+ and $CXCR6^+CD69^+$ CD8 T cells. Contrastingly, virus-specific CD8 T cells during persistent infection were mainly $CXCR6^+CD69^+$ liver-resident CD8 T cells. Independent of infection outcome, liver $CXCR6^+CD69^+$ CD8 T cells expressed a tissue-residency gene signature. However, virus-specific $CXCR6^+CD69^+$ CD8 T cells during persistent infection did not produce cytokines, lacked cytotoxicity, and were hence termed dysfunctional liver-resident T cells. Transcriptome analysis enabled us to define a single pathway marking these dysfunctional $CXCR6^+CD69^+$ T cells in persistent infection when compared to cytotoxic liver-resident memory T cells after resolved infection.
Conclusion: The identification of a single transcription factor distinguishing effector liver-resident memory T cells from dysfunctional tolerized virus-specific liver-resident CD8 T cells in preclinical models of persistent expression of ovalbumin and HBV points towards a liver-specific mechanism mediating immune tolerance during persistent hepatocyte infection.

THU194

Fate of HDV-specific CD8+ T cells during bulevirtide monotherapy in patients with chronic hepatitis delta

Valerie Oberhardt[1], Elisabetta Degasperi[2], Marta Borghi[2], Kathrin Heim[1], Roberta Soffredini[2], Alessandro Loglio[2], Özlem Sogukpinar[1], Frances Winkler[1], Bertram Bengsch[1], Maike Hofmann[1], Robert Thimme[1], Pietro Lampertico[2,3], Christoph Neumann-Haefelin[1]. *[1]Medical Center-University of Freiburg, Department of Medicine II, Freiburg, Germany; [2]Foundation IRCCS Ca' Granda Ospedale Maggiore Policlinico, Milan, Italy; [3]CRC "A. M. and A. Migliavacca" Center for Liver Disease, Department of Pathophysiology and Transplantation, Milan, Italy*
Email: valerie.oberhardt@uniklinik-freiburg.de

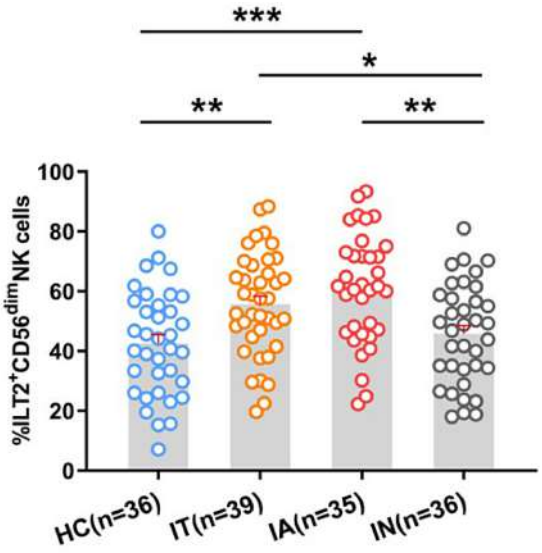
Background and aims: The viral entry-inhibitor bulevirtide (BLV) leads to a decline of HDV viremia in chronic HDV infection, however, treatment for several years is likely required to prevent relapse. Sustained treatment response may be fostered by therapy-induced restoration of HDV-specific CD8+ T cell responses that are exhausted due to high viremia and antigen loads during chronic HDV infection. We thus studied the effect of BLV monotherapy on HDV-specific CD8+ T cell repertoire, phenotype, and functionality.
Method: HDV-specific CD8+ T cell responses were studied in 35 HDV infected patients, of whom 14 cirrhotic patients started treatment with BLV. Samples were collected from baseline up to 40 weeks on-treatment. HDV-specific CD8+ T cells were analyzed either upon stimulation with overlapping peptides (olp), spanning the entire L-HDAg (51 olps, 15mers) or upon stimulation with optimal epitopes in HLA-matched patients, following 14 days of *in vitro* culture. *Ex vivo* high-dimensional flow cytometry analysis of peptide-loaded MHC class I-specific CD8+ T cells in selected patients throughout therapy is currently ongoing.
Results: In two-thirds of patients, an HDV-specific CD8+ T cell response was detectable at baseline. This was characterized by interferon (IFN) γ and tumor necrosis factor (TNF) co-secretion, without additional interleukin (IL)-2 production in response to optimal epitope stimulation in HLA matched patients. Targeted epitopes were restricted by HLA-B alleles only, predominantly by HLA-B*35 and HLA-B*18. Direct comparison of patient samples from an early time point during therapy (week 4) with a later time point during treatment (week 36–40) did not indicate a restoration or boosting of HDV-specific CD8+ T cell functionality coinciding with decreasing HDV viremia. Using the comprehensive olps approach, half of the patients displayed an HDV-specific CD8+ T cell response at the late time point during treatment (median of 2 olps recognized per patient), which is comparable with the response-rate in untreated patients.
Conclusion: During the first 40 weeks of BLV treatment, no obvious increase in HDV-specific CD8+ T cell response breadth and magnitude was observed. This might be due to the slow decline of HDV viremia, the fact that all patients treated with BLV had liver cirrhosis, and mostly unchanged HBsAg levels during BLV monotherapy that may continue to mediate HDV-specific CD8+ T cell exhaustion. In addition, some of the HDV-specific CD8+ T cell responses target epitopes affected by viral escape mutations and these responses are unlikely to benefit from reduction of viremia. Longer follow-up during continued BLV therapy, high-dimensional analysis of CD8+ T cell phenotype and function, as well as analysis of patients with BLV/pegIFN combination therapy will expand our understanding of HDV-specific CD8+ T cell restoration during BLV therapy.

THU195

Increased ILT2 expression contributes to dysfunction of CD56dimCD16+NK cells in chronic hepatitis B virus infection

Wenwei Yin[1], Yingzhi Zhang[1], Hong Ren[1]. *[1]Institute for Viral Hepatitis, Department of Infectious Diseases, Chongqing, China*
Email: yww@cqmu.edu.cn

Background and aims: Natural killer (NK) cells play a crucial role in the control of human viral infections but their activity is significantly impaired in patients infected with chronic hepatitis B (CHB). The mechanism that contributes to NK cell dysfunction in CHB needs further elucidation.
Method: In this study, we analyzed the expression and function of the novel inhibitory receptor immunoglobulin-like transcript-2 (ILT2) on NK cells from 110 CHB patients and 36 healthy controls.
Results: We observed ILT2 expression on circulating $CD56^{dim}CD16^{+}$NK cells was increased in immune-tolerant and active CHB patients compared with inactive carriers and controls. The frequency of $ILT2^{+}CD56^{dim}$NK cells was positively correlated with serum viral load in immune-tolerant patients. The percentage of $ILT2^{+}CD56^{dim}$NK cells decreased along with HBV load in active CHB patients that received antiviral therapy. Functional analysis showed that $ILT2^{+}CD56^{dim}$NK cells in CHB patients had significantly reduced degranulation and IFN-gamma production. Up-regulation of ILT2 was associated with high levels of apoptosis in $CD56^{dim}CD16^{+}$NK cells from CHB patients. ILT2 blockade was shown to increase CD107a expression and cytotoxicity of $CD56^{dim}$NK cells in CHB patients. Finally, ILT2 was found to be up-regulated by TGF-β1, which was increased in immune-tolerant and active CHB patients.



Conclusion: Our findings imply that high ILT2 expression would facilitate HBV viral persistence by tempering NK cells into silence and blockade of ILT2 can enhance NK cell function as an alternative approach to treat CHB.

THU196

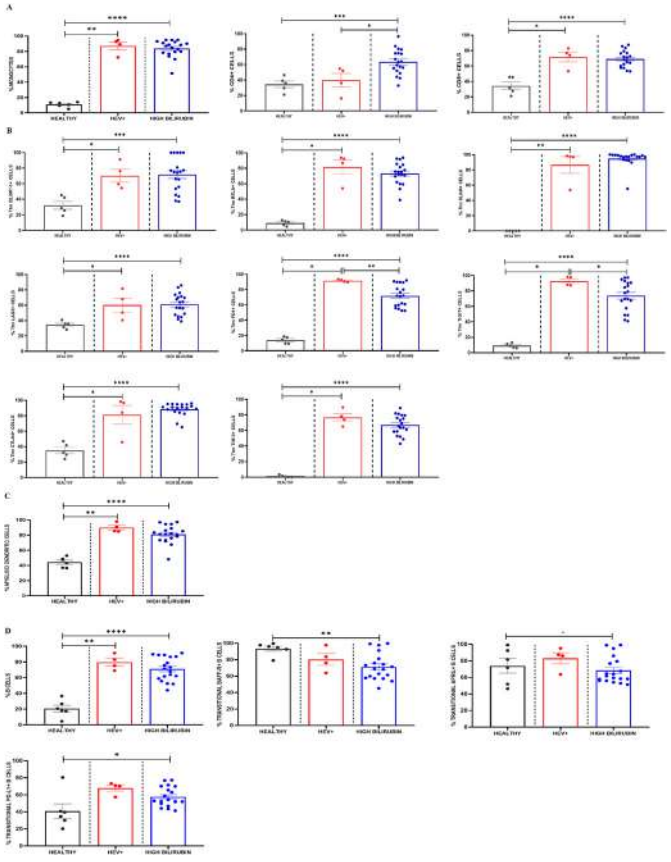
Elevated serum bilirubin levels and aminotransferases are associated with immuno-modulatory and suppressive subsets in pregnant females with intrahepatic cholestasis and hepatitis E virus infection

Anoushka Saxena[1], Minal Kashyap[2], Prabhjyoti Pahwa[1], Fatima Ali[1], Hamda Siddiqui[1], E. Preedia Babu[1], Y.M. Mala[2], Shakun Tyagi[2], Nirupma Trehanpati[1]. [1]*Institute of Liver and Biliary Sciences, New Delhi, India, Department of Molecular and Cellular Medicine, New Delhi, India;* [2]*Maulana Azad Medical College, New Delhi, India, Department of Obstetrics and Gynaecology, New Delhi, India*
Email: trehanpati@gmail.com

Background and aims: Elevated serum bilirubin levels and liver functions are well-recognized markers of hepatic damage and inflammation. Viral hepatitis, intrahepatic cholestasis of pregnancy, gallstones and pre-eclampsia are the most common causes of jaundice in pregnant women, inducing significant morbidity and mortality in both pregnant women and their infants. Therefore, we aimed to investigate the relationship between deranged liver function, high bilirubin and the immune dysfunction during pregnancy.

Method: An observational prospective study was carried out at a tertiary care hospital on antenatal patients with clinical and biochemical jaundice over a period of one year. Peripheral immune cell subsets were analyzed in pregnant women with serum bilirubin >2.0 mg/dl (Gr.1, n = 20, 25.8 ± 2), positive for IgM/IgG Hepatitis E virus (AVH-E) (Gr.2, n = 5, 24 ± 2) and healthy pregnant women (Gr.3, n = 7, 24.5 ± 2) by flow cytometry.

Results: Females with high bilirubin levels; 2–5 mg/dl (64%), 5–10 mg/dl (16%), >10 mg/dl (12%) had deranged LFT (28%), asymptomatic (12%), jaundice (31%), k/c/o liver disease (3%), k/c/o hepatitis-E (3%) and 6% presented with other complaints. Pregnant females with high bilirubin levels showed an overall increased percentage of Monocytes ($p = 0.0012$), CD4+ ($p = 0.0009$) and CD8+ T-cells ($p < 0.0001$), compared to healthy (Fig. A). However, an increased expression of inhibitory markers (Fig. B); PD-1 ($p < 0.0001$), CTLA-4 ($p < 0.0001$), BTLA ($p < 0.0001$), BLIMP-1 ($p = 0.0008$), SLAM-1 ($p < 0.0001$), LAG-3 ($p < 0.0001$), TIGIT ($p < 0.0001$), TIM-3 ($p < 0.0001$) on Transitional memory subset and PD-1 ($p < 0.0001$), CTLA-4 ($p < 0.0001$), BTLA ($p < 0.0001$), BLIMP-1 ($p = 0.0006$), SLAM-1 ($p < 0.0001$), LAG-3 ($p < 0.0001$), TIGIT ($p < 0.0001$), TIM-3 ($p < 0.0001$) on effector memory subset of T-cells was evident. Compared to healthy, myeloid dendritic cell population was significantly higher (Fig. C) in females with high bilirubin ($p < 0.0001$) and infected with HEV ($p = 0.0095$), as compared to healthy females, indicating immune suppression. An elevated frequency of B-cell subsets ($p < 0.0001$) was observed in all females with high bilirubin. Yet, a defect in activation and proliferation as suggested by diminished expression of BAFF-R ($p = 0.04$) and APRIL ($p = 0.02$) and rise in PDL1 ($p = 0.0025$) was determined (Fig. D).



Conclusion: Our results clearly indicate that pregnant females with high bilirubin, including those infected with HEV exhibit increased suppressive T and B cells with diminished BAFFR/APRIL expressing B cells.

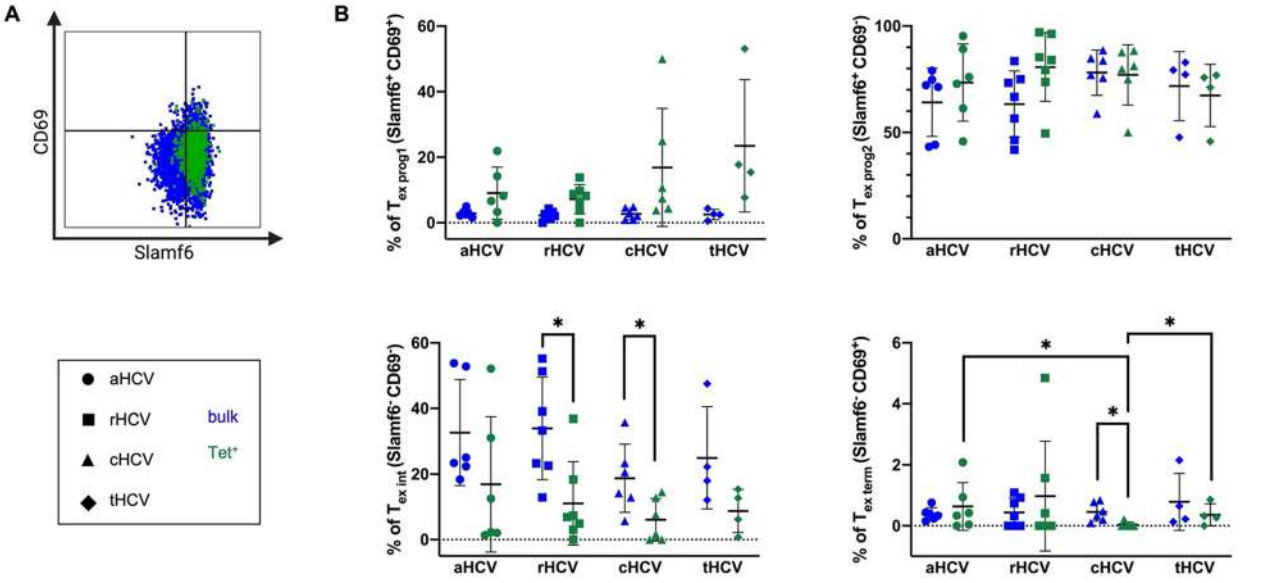
THU197

Classification of HCV-specific CD8+ T cells by the differential expression pattern of Slamf6 and CD69 predicts that the majority of cells are rather preterminally versus terminally exhausted regardless of disease stage

Maximilian Knapp[1], Christin Ackermann[1], Claudia Beisel[1], Vanessa Ditt[2], Melanie Wittner[1], Julian Schulze Zur Wiesch[1]. [1]*University Medical Center Hamburg-Eppendorf, I. Department of Medicine, Infectious Diseases Unit, Hamburg, Germany;* [2]*University Medical Center Hamburg-Eppendorf, Center for Diagnostics, Institute of Transfusion Medicine, Hamburg, Germany*
Email: julianszw@googlemail.com

Background and aims: Exhausted T effector cells, commonly described in chronic viral infections and cancer, are phenotypically and functionally heterogeneous cell populations whose development, maintenance, and response to immunotherapies are incompletely understood. Today, many differentiations into progenitors, intermediates and terminal stages of exhausted T cells are already known based on numerous markers. A better description regarding different subsets of exhausted T cells will allow a better understanding for future cancer therapy and viral cure approaches. Acute and chronic hepatitis C (HCV) infection are ideal models to examine the development of T-cell exhaustion and its potential reversibility at cellular and molecular levels. To assess the molecular fingerprint of potential populations, we aimed to investigate the interaction of different immunomodulatory targets.

Method: HCV-specific $CD8^+$ T cells from HLA-A*01:01, HLA-A*02:01 and HLA-A*24:02 positive patients were analyzed with a 21-color



Distribution of T_{ex} subsets and on total and HCV-specific CD8⁺ T cells.
HCV-specific CD8⁺ T cells from human PBMC of patients with acute (aHCV), resolved (rHCV), chronic (cHCV) and treated (tHCV) HCV infection were enriched and analysed due to MHC class I tetramers. The distribution of T_{ex} subsets as well as novel imunnomodulatory molecules were analysed using flow cytometry. (A) Representative overlay of bulk (blue) and Tet⁺ (green) CD8⁺ T cells gating Slamf6 vs. CD69 for differentiation between the T_{ex} subsets. (B) Frequencies of the different exhauted substes: progenitor 1 ($T_{ex\ prog1}$: Slamf6⁺ CD69⁺), progenitor 2 ($T_{ex\ prog2}$: Slamf6⁺ CD69⁻), intermediate ($T_{ex\ int}$: Slamf6⁻ CD69⁻) and terminally exhausted ($T_{ex\ term}$: Slamf6⁻ CD69⁺). For all tests, two-tailed p values were generated and results with a p-value ≤0.05 were considered statistically significant. Levels of significance are translated to asterisks as follows: * p≤0.05; ** p≤0.01; *** p≤0.001; **** p≤0.0001.

Figure: (abstract: THU197)

FACS-panel evaluating the surface expression of lineage markers (CD3, CD4, CD8), ectoenzymes (CD38, CD39, CD73), markers of differentiation (CD62L, CD127), and markers of exhaustion and activation (CD96, TIGIT, PD-1, CD69, Slamf6, CD28) and transcription factors (T-bet, TCF1, NR2F6, TOX, IRF4).
Results: Analyzing the TIGIT-CD96-axis, the majority of HCV-specific Tet⁺ CD8⁺ T cells of all patient groups was TIGIT⁺ and CD96⁺. The frequencies of CD96⁺ cells in the Tet⁺ T cells were significantly higher than in bulk CD8⁺ T cells for acute, resolved and chronic infection. Furthermore, HCV-specific CD8⁺ T cells were stratified into four novel subsets of exhausted T cells based on expression of the transmembrane protein Slamf6 and the early activation antigen CD69 as currently described by Beltra et. al. (2020, Immunity 52, 825–841) in the LCMV mouse model describing progenitor 1 ($T_{ex\ prog1}$: Slamf6⁺ CD69⁺), progenitor 2 ($T_{ex\ prog2}$: Slamf6⁺ CD69⁻), intermediate ($T_{ex\ int}$: Slamf6⁻ CD69⁻) and terminally exhausted ($T_{ex\ term}$: Slamf6⁻ CD69⁺) T cells. The majority of HCV-specific Tet⁺ cells in peripheral blood are in the $T_{ex\ prog2}$ state and less than 6% of the Tet⁺ T cells were at the $T_{ex\ term}$ state.

Conclusion: We identified four exhausted T cell subsets defined by Slamf6 and CD69 in patients with different clinical status of HCV infection. The frequencies detected in PBMC of our patients are similar to those described in the LCMV mouse model by Beltra et. al. They could also show that the majority of the $T_{ex\ term}$ subset is localized in the liver. To investigate the $T_{ex\ term}$ population in human, analyses from liver biopsies are required. In this context, it will be of interest whether the responsiveness of the $T_{ex\ int}$ subset to PD-1 blockade described in mice can also be confirmed in human. Co-inhibitory receptors like CD96 in the TIGIT-CD155 signaling pathway also shaped the HCV-specific T cells.

THU198
TAPBPR shapes the hepatitis B immunopeptidome presented on HLA class I molecules

Ricky Sinharay[*,1,2], Andreas Neerincx[1], Arwen Altenburg[1], Jens Bauer[3,4,5], Mark R. Wills[6], Juliane S. Walz[3,4,5,7], Will Gelson[8], Louise H. Boyle[1]. *[1]University of Cambridge, Department of Pathology, Cambridge, United Kingdom; [2]Cambridge University Hospitals NHS Foundation Trust, Cambridge Liver Unit, Addenbrooke's Hospital, Cambridge, United Kingdom; [3]University Hospital Tübingen, Clinical Collaboration Unit Translational Immunology, German Cancer Consortium (DKTK), Department of Internal Medicine, Tübingen, Germany; [4]University of Tübingen, Institute for Cell Biology, Department of Immunology, Tübingen, Germany; [5]University of Tübingen, Cluster of Excellence iFIT (EXC2180) "Image-Guided and Functionally Instructed Tumor Therapies", Tübingen, Germany; [6]University of Cambridge, Department of Medicine, Addenbrookes Hospital, Cambridge, United Kingdom; [7]Margarete Fischer-Bosch Institute of Clinical Pharmacology and Robert Bosch Center for Tumor Diseases (RBCT), Stuttgart, Germany; [8]Cambridge University Hospitals NHS Foundation Trust, Cambridge Liver Unit, Addenbrooke's Hospital, Cambridge, United Kingdom*
Email: rickysinharay@doctors.org.uk

Background and aims: The presentation of virus derived peptides on HLA class I molecules is crucial for mounting antiviral immune responses. TAPBPR is a recently identified peptide editor involved in optimizing antigen selection on MHC class I molecules. Here, we present novel data on the impact of TAPBPR on the hepatitis B (HBV) immunopeptidome presented on HLA class I by using a mass spectrometry approach.
Method: HeLa cells (HLA-A*68:02, -B*15:03 and -Cw12) and TAPBPR knock-out HeLa cells ($TAPBPR^{KO}$) overexpressing individual HBV proteins HBsAg, Pol, HBcAg and HBx were generated. These cells were expanded to 5×10^8 cells, lysed and peptides were eluted using a pan HLA class I antibody (W6/32). Analysis was performed by liquid

chromatography coupled to tandem mass spectrometry (LC-MS/MS). Mass spectra data were then searched against a database of possible peptides that could be derived from the host and/or pathogen proteomes, to identify HBV derived peptides presented on HLA class I. The HBV immunopeptidome in TAPBPR depleted cells was compared to HeLa cells expressing wild type TAPBPR and individual HBV proteins.

Results: A greater number of HBV peptides were presented in TAPBPR^{KO} cell lines compared to wild type cell lines, which was consistently observed between cells expressing different HBV proteins. This was despite the fact that no substantial change in the total cellular peptide count was observed between wild type and TAPBPR^{KO} cells. Amino acids positions 2 and 9 were clearly preferred for binding in both wild type and TAPBPR^{KO} cells, and a greater number of peptides were assigned to HLA-B*15:03 than HLA-A*68:02. Furthermore, semi quantitative analysis revealed that depletion of TAPBPR resulted in up-modulation of almost all HBV-derived peptides identified. In addition, changes in the hierarchy of the abundance of HBV peptides presented were observed in TAPBPR^{KO} cells. Of the up-modulated peptides, only four have been identified previously and are catalogued on IEDB. A total of 26 HBV-derived peptides were identified, 22 (84.62%) of which were novel. Of the novel peptides 7 were only identified in the TAPBPR^{KO} cell lines.

Conclusion: These findings strongly support a role of TAPBPR in HBV-derived peptide selection for presentation on HLA class I. However, it is still unclear whether this is advantageous for individuals with HBV expressing HLA alleles where TAPBPR mediates peptide exchange.

THU199

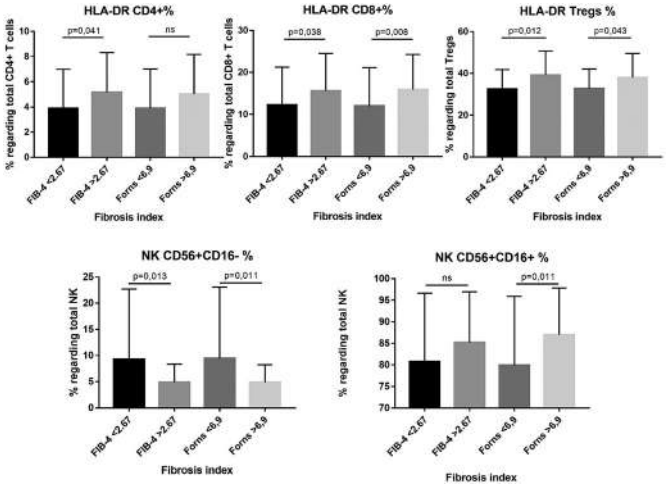
Phenotypes of NK cells and the activation profile of T cells in the early stages of alcohol liver diseases

Coral Zurera[1,2], Anna Hernandez[3], Aina Teniente[1], Daniel Fuster[3], Eva Martínez-Cáceres[1], Robert Muga[3], Paola Zuluaga[*,3]. [1]*investigation institute germans trias i pujol, immunology, badalona, Spain;* [2]*Universitat Autònoma de Barcelona, Bellaterra, Spain;* [3]*university hospital germans trias i pujol, internal medicine, badalona, Spain*
Email: ypzuluaga.germanstrias@gencat.cat

Background and aims: The role of cellular immunity in alcohol-related liver diseases (ARLD) is currently being characterized. While CD8 T cell activation is known to be detrimental, enhancing liver damage, the decrease of naïve T cells is associated with advanced liver fibrosis (ALF) in patients with alcohol use disorder (AUD). Natural Killer (NK) cells and NKT cells play an important role in the development of ARLD having subsets with opposing roles in the development of liver fibrosis. We aimed to evaluate the phenotype of NK and NKT cells and the activation profile of T cells in patients with AUD according to the presence of ALF.

Method: Patients were admitted to treatment of AUD between 2019 and 2021 in Germans Trias I Pujol Hospital, Spain. ALF was defined if the FIB-4 score was >2.67 (n = 19) or Forns score was >6.9 (n = 21). Patients with HCV infection, HIV infection and history of liver cirrhosis were excluded. Immunophenotyping of NK cells (CD3-CD56+CD16+, CD3-CD56+, CD3-CD16+), NKT cells (CD3+CD56+), and the activation status of CD4+, CD8+ and regulatory T cells (Tregs) was evaluated according to the presence of HLA-DR.

Results: 79 patients (51 years, 71% males) were included. Patients had a mean AUD duration of 18 ± 11 years with a daily alcohol consumption of 155 ± 77 gr/day. Regarding the immunophenotype in peripheral blood, the mean ± SD absolute values were: 2.1 ± 0.9 cells/L for total lymphocytes, 1054.5 ± 501.7 cells/µL for CD4+, 540 ± 335.7 cells/µL for CD8+, 49.3 ± 24.8 cells/µL for Tregs, 150.3 ± 97.5 cells/µL for NK cells and 69.8 ± 78.3 cells/µL for NKT cells. The percentage of CD3-CD56+ NK cells of patients with ALF was significantly lower (4.8 ± 3.3 and 4.9 ± 3.4) than in patients without ALF (7.8 ± 6.2 and 7.7 ± 6.2) according to Forns and FIB-4, respectively. The percentage of CD3-CD16+CD56+ NK cells was significantly higher in patients with ALF (87 ± 11) compared to patients without ALF (80 ± 16) according to Forns. No significant differences were observed in the percentage of CD3-CD16+ NK cells and NKT cells among groups. ALF patients also presented an increased percentage of HLA-DR+-expressing Tregs (38 ± 11.6 and 39.2 ± 11.5) and CD8+ (16 ± 8.3 and 15.6 ± 8.8) compared to Tregs (32.7 ± 9.4 and 32.5 ± 9.3) and CD8+ (12 ± 9.1 and 12.2 ± 9) in patients without ALF according to Forns and FIB-4, respectively. The percentage of HLA-DR+ CD4+ was higher in patients with ALF (5.1 ± 3.1) than in patients without ALF (3.9 ± 3) according to FIB-4. Figure 1 depicts the aforementioned significant differences (p <0.05).



Conclusion: Severe AUD patients with ALF presented an increased NK cytotoxic phenotype concomitant with a decreased immunoregulatory and cytokine-secreting phenotype, possibly as a compensating mechanism of liver fibrosis. Meanwhile, the increased activation pattern observed in T cell subsets of patients with ALF could be a mechanism that favors the development and maintenance of liver fibrosis.

THU200

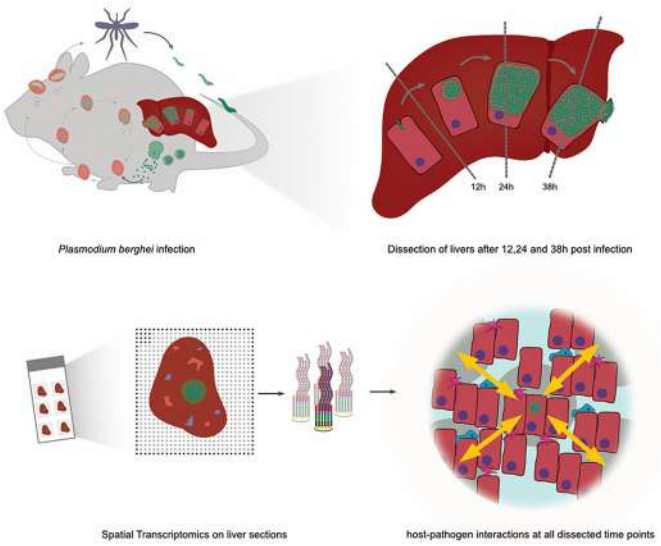
A spatio-temporal map of malaria infected mouse liver

Franziska Hildebrandt[1], Johan Ankarklev[1]. [1]*Stockholm University, Department of Molecular Biosciences, Stockholm, Sweden*
Email: franziska.hildebrandt@su.se

Background and aims: The liver is crucial for malaria parasite development in the vertebrate host. Once transmitted by a female mosquito, the malaria parasites start their development in the liver, before entering the symptomatic blood stage. Since the liver has high potential for an effective immune response towards invading parasites and other intruders, choosing the liver as a developmental niche is paradoxical. Thus, we aim to delineate host-pathogen interactions during the time course of an ongoing liver infection *in vivo*, with the main aim of studying the host's response in a spatial context.

Method: To this end we are using Spatial Transcriptomics to describe the spatial organization of transcriptomic response in the mouse liver to an ongoing infection, using mosquito salivary gland lysate as a control.

Results: Our preliminary data suggests a differential onset of inflammation between infected and control mice, due to the presence of parasites in the tissue. We further investigated gene expression as a function of the distance to the site of infection for multiple time points and cell type compositions in specific areas of infection but also in the larger tissue context.



Conclusion: Our data indicates patterns of differential expression due to the influence of malaria parasites both locally and across tissues in challenged mice. Our preliminary data further suggests that the.
immune response towards a *Plasmodium* infection shows spatio-temporal patterns on the transcriptional level, providing a promising outlook for more detailed studies on the influence of the parasite on the surrounding liver environment.

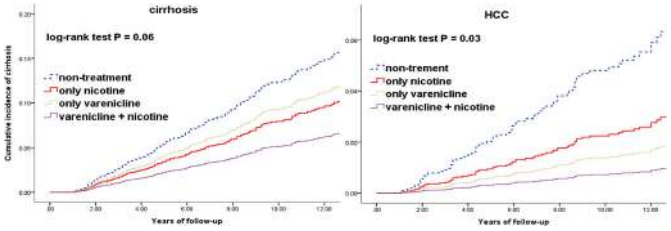
Reducing the risk of liver cirrhosis and hepatocellular carcinoma after treatment for smoking cessation in patients with chronic hepatitis B or C infection: a 12-year follow-up study

Ruey-Chang Lin[1], Chun Hsiang Wang[1,2], Kuo-Kuan Chang[1], Lien-Juei Mou[1], Yuan Tsung Tseng[3]. [1]*Tainan Municipal Hospital (Managed by Show Chwan Medical Care Corporation), Tainan, Taiwan, Department of Hepatogastroenterology;* [2]*Chung Hwa Medical University, Tainan, Taiwan, Department of Optometry;* [3]*Tainan Municipal Hospital (Managed by Show Chwan Medical Care Corporation), Tainan, Taiwan, Committee of Medical Research*
Email: b891040733@yahoo.com.tw

Background and aims: The possible hepatotoxic effect of cigarette smoking in patients with chronic hepatitis B virus (CHB) or chronic hepatitis C (CHC) virus infection has been proposed in numerous epidemiological and experimental studies. Varenicline and nicotine replacement therapy (NRT) are the current first-line treatment for smoking cessation. The present study compared the effects of different standard treatments for smoking cessation and of receiving no treatment for smoking cessation on the risk of liver cirrhosis and hepatocellular carcinoma (HCC) among patients with CHB or CHC infection.
Method: We identified patients with CHB or CHC infection who smoked regularly and whose data were input into Taiwan's National Health Insurance Research Database between January 1, 2007, and December 31, 2018. The patients' demographic data, medical history (including smoking habits), and paraclinical information were collected. The patients were classified into 4 groups—the no smoking cessation treatment, NRT only, varenicline only, and varenicline + NRT groups—according to the smoking cessation treatment they had received. Cox proportional hazards models were used to analyze the patients' risks of liver cirrhosis and HCC, with adjustment for age, sex, comorbidities, and Charlson Comorbidity Index.
Results: A total of 4210 patients with CHB or CHC infection were recruited; 2535, 568, 427, and 680 were assigned to the NRT only, varenicline only, varenicline + NRT, and comparison (no treatment) groups, respectively. The mean follow-up duration was 7.2 ± 4.8 years. The outcomes were significantly different among the four groups. The NRT only, varenicline only, and varenicline + NRT groups had a lower prevalence of liver cirrhosis (p = .06) and HCC (p = .03) than did the no-treatment group in the cumulative incidence analysis (liver cirrhosis: prevalence = 8.5%, 3.9%, and 2.1% vs 11.3%, respectively; HR = 0.74[95%CI: 0.33–1.63], 0.63[0.34–1.15], and 0.40[0.19–0.84], respectively; HCC: prevalence = 15.0%, 11.6%, and 11.5% vs 23.1%, respectively; HR = 0.62[0.31–1.25], 0.32[0.10–1.00], and 0.26[0.10–0.69], respectively).



Conclusion: This study evaluated the effect of one month of NRT, varenicline, both, or no treatment on the risk of liver cirrhosis and HCC in smokers with CBC or CHC infection undergoing a smoking cessation program. All 3 smoking cessation treatments appeared to be effective in minimizing the risk of liver cirrhosis and HCC; a low prevalence of both conditions was observed in each of the 3 treatment groups.
Cumulative incidence rates of liver cirrhosis and HCC over time among patients with CHB or CHC infection in the no smoking cessation treatment, NRT only, varenicline only, and varenicline + NRT groups.

THU218

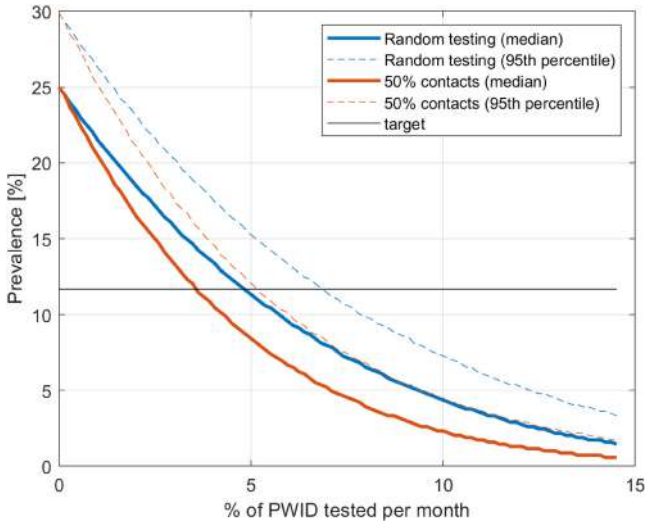
Testing coverage and strategy required to sustain Hepatitis C elimination in an injecting network of people who inject drugs: a network-based model

Chloe Siegele-Brown[1], Martin Siegele-Brown[2], Charlotte Cook[3], Mark Wright[1], Julie Parkes[3], Salim Khakoo[3], Ryan Buchanan[3]. [1]*University Hospital Southampton NHS Foundation Trust, United Kingdom;* [2]*University of Sussex, United Kingdom;* [3]*University of Southampton, United Kingdom*
Email: chloe.brown@doctors.org.uk

Background and aims: The World Health Organisation has set a target for the global elimination of Hepatitis B (HBV) and C (HCV) by 2030. To achieve the elimination target, a widespread scale-up of testing and treatment services is required. However, little is known about the level of testing required to sustain the low-prevalence state of elimination. In this study we model the testing coverage required to maintain HCV elimination in an injecting network of people who inject drugs (PWID). We also test the hypothesis that a 'bring your friends' testing strategy will be more efficient.
Method: We create a dynamic injecting network structure connecting 689 PWID based on empirical data. A burn-in period, where PWID are randomly treated according to empirical parameters until the elimination target is achieved, is followed by the 5-year simulation period. The primary outcome is the testing coverage required per month to maintain prevalence at the elimination threshold over 5 years. We compare two treatment scenarios: 1) random testing, and 2) 'bring your friends' testing, where 50% of tests are random and 50% of tests in injecting partners of randomly selected individuals.

Results: After 5 years, without any testing or treatment provision, the prevalence of HCV increased from the elimination threshold (11.68%) to a mean of 25.0% (SD 3.0%). To maintain elimination with random testing, on average 4.92% (SD 0.84%) of the injecting network needs to be tested per month. However, with a 'bring your friends' strategy, 3.69% (SD 0.63%) of the network needs to be tested per month ($p <$ 0.000001).

The superiority of the 'bring your friends' approach was maintained in a sensitivity analysis that adjusted for changes in needle and syringe provision and the rate of engagement with treatment following a positive test.



Conclusion: If HCV testing and treatment does not continue after elimination targets are met, the prevalence of HCV in an actively injecting network of PWID will increase. A 'bring your friends' approach to treatment is a more efficient approach to maintaining elimination.

Line graph showing change in prevalence at 5 years (y axis) with increasing testing coverage in two testing scenarios. The elimination threshold (prevalence <11.68%) is indicated. Results are from 100 simulations in 100 generated networks.

THU219

Hepatocellular carcinoma screening trends in individuals with cirrhosis in North Carolina

Christine Hsu[1], Jennifer Lund[1], Andrew Moon[2], Louise Henderson[2].
[1]*University of North Carolina at Chapel Hill, Chapel Hill, United States;*
[2]*UNC School of Medicine, Chapel Hill, United States*
Email: cdhsu@live.unc.edu

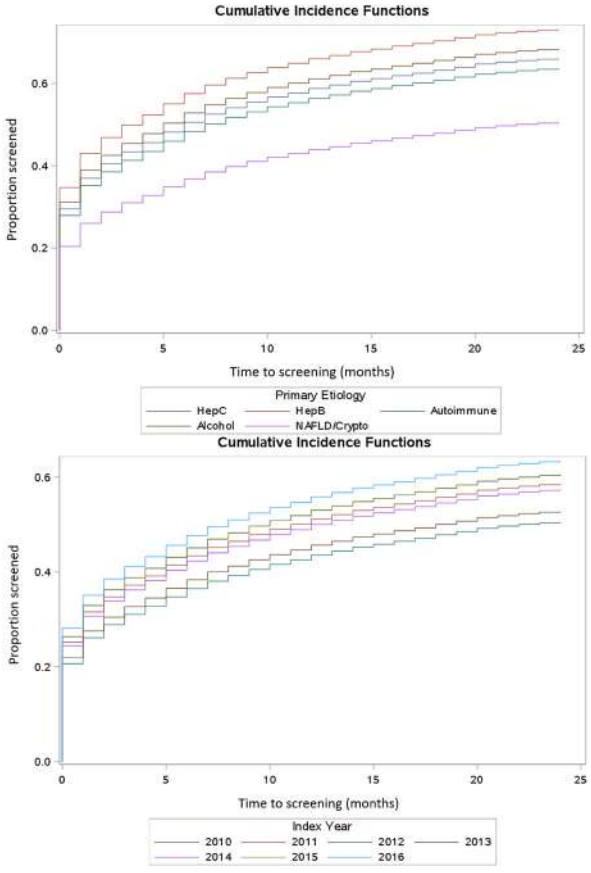
Background and aims: The epidemiology of cirrhosis has shifted but little is known about how these shifts impact hepatocellular carcinoma (HCC) screening. We characterized patterns of HCC screening over time and by cirrhosis aetiology among a privately insured population in North Carolina.

Method: We conducted a retrospective cohort study of individuals with a diagnosis of cirrhosis using insurance claims data from a large private insurer in North Carolina that covers 3.5 million people annually, or 35% of the state's population. We included individuals ≥18 years with an ICD-9/10 code for cirrhosis between 1 January 2010 and 30 June 2018 with continuous enrolment one year before their cirrhosis diagnosis and no prior HCC or liver transplant. Cirrhosis aetiology was defined using a validated claims-based algorithm. The main outcome was HCC screening by abdominal ultrasound, CT, or MRI. We determined 1-year and 2-year cumulative incidences for HCC screening overall, by aetiology, and by calendar year of cirrhosis diagnosis.

Results: Among the 7,739 individuals in the cohort, 56.9% were male, 75.2% lived in an urban area, and the mean age was 53 years. Most individuals had NAFLD/cryptogenic aetiology (43.4%), followed by alcohol-related liver disease (25.1%), hepatitis C virus (21.4%), autoimmune hepatitis (8.5%), and hepatitis B virus (1.6%). Nearly half of individuals had decompensated cirrhosis (47%). Most individuals (68.9%) received care from a gastroenterologist/hepatologist during their follow-up time, while 22.4% received care from a general practitioner alone.

The 1-year and 2-year cumulative incidences were 43.5% and 49.8%, respectively, for receiving screening by abdominal ultrasound. The 1- and 2-year cumulative incidences were 53.0% and 60.0%, respectively, for receiving any HCC screening. Individuals with hepatitis B virus had the highest 2-year cumulative incidence (73.2%) while those with NAFLD/cryptogenic aetiology had the lowest 2-year cumulative incidence (50.6%).

The 2-year cumulative incidence was 66.1% for hepatitis C virus, 63.7% for autoimmune hepatitis, and 68.4% for alcohol-related liver disease aetiologies. The 2-year cumulative incidence of HCC screening by calendar year of cirrhosis diagnosis ranged from 52.5% in 2012 to 63.4% in 2016.



Conclusion: We observed that HCC screening was underutilized among privately insured individuals with cirrhosis in North Carolina, indicating a need for targeted interventions to increase HCC screening rates.

THU220

Cost- effectiveness evaluation of the hepatitis C elimination strategy in Cyprus in the era of affordable direct-acting antivirals

Ilias Gountas[1], Petros Katsioloudes[2], Ioanna Yiasemi[3], Evi Kyprianou[3], Christos Mina[3], Chrysanthos Georgiou[4], Antri Kouroufexi[5], Anna Demetriou[6], Eleni Xenofontos[7], Georgios Nikolopoulos[1].
[1]*University of Cyprus, Medical School;* [2]*Evangelistria Medical Centre;* [3]*Cyprus National Addictions Authority, Cyprus Monitoring Centre;* [4]*Nicosia General Hospital;* [5]*Pharmaceutical Services, Ministry of Health;* [6]*Health Monitoring Unit, Ministry of Health;* [7]*Limassol General Hospital, Department of Internal Medicine*
Email: eliagoun@gmail.com

Background and aims: In the Republic of Cyprus, the prevalence of chronic Hepatitis C virus (CHC) among the general population is estimated at 0.6%, while the CHC prevalence among people who inject drugs (PWID) is estimated at 43%. A previous mathematical modeling study highlighted that to achieve Hepatitis C virus (HCV) elimination, 3080 (95% Credible intervals (CrI): 3000, 3200) patients need to be diagnosed and treated by 2034 (2680 from the general population and 400 from PWID)[1]. For the optimal use of available resources, it is essential to evaluate the cost-effectiveness of any proposed strategy. This study aims to undertake a cost-effectiveness analysis of the proposed HCV elimination strategy in Cyprus.
Method: A previously published, dynamic, stochastic, individual-based model of HCV transmission, disease progression, and cascade of care was calibrated to data from Cyprus (1). The model stratifies the population into the infected general population and the PWID population. We assumed that the ongoing HCV transmission is limited to the PWID group. The incremental cost-effectiveness ratio (ICER) per disability-adjusted life year (DALY) averted for HCV elimination versus the status quo scenario was computed. Cost-effectiveness was determined using Cyprus' willingness-to-pay (WTP) threshold of €26623 per DALYs averted.
Results: Compared to the status quo, the elimination strategy would prevent 195 (95% CrI: 115, 220) and 2070 (95% CrI: 1600, 2640) new infections and DALYs by 2034, respectively. The additional required investment to meet the HCV elimination goals would be €20.4M (95% CrI: €19.4M, €21.4M)). The cost per averted DALY is estimated at €9915 (95% CrI: €7600, €13100) indicating that the elimination strategy is very cost-effective. In the probabilistic sensitivity analysis, 100% of simulations were below the WTP threshold (Figure).

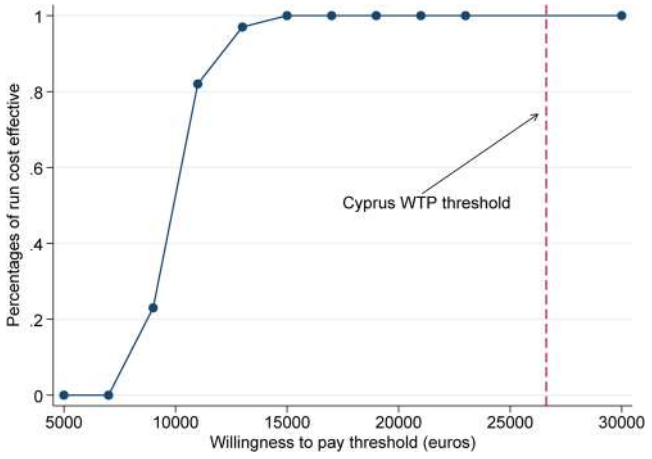


Figure: Cost-effectiveness acceptability curve

Conclusion: Scaling-up HCV testing and treatment in Cyprus to reach the elimination targets is estimated to generate significant health and economic benefits.

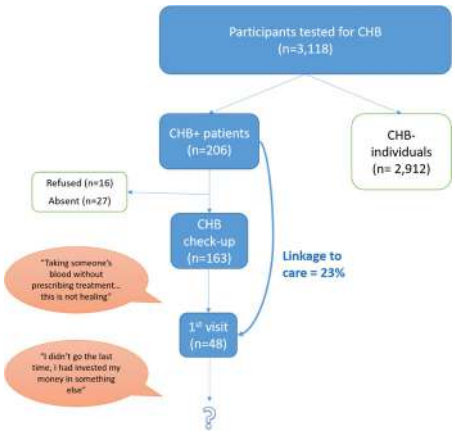
THU221

Rethinking the management of chronic hepatitis B in the context of rural sub-saharan Africa: results from a social justice mixed methods study in rural Senegal (the AmBASS-PeCSen study)

Marion Coste[1,2], Cilor Ndong[3], Aldiouma Diallo[4], Assane Diouf[4], Sylvie Boyer[2], Jennifer Prah[5]. [1]*Aix Marseille Univeristy, CNRS, AMSE, Aix-Marseille School of Economics, Marseille, France;* [2]*Aix Marseille Univ, INSERM, IRD, SESSTIM, Sciences Économiques and Sociales de la Santé and Traitement de l'Information Médicale, Marseille, France;* [3]*Cheikh Anta Diop University, Anthropology, Dakar, Senegal;* [4]*Campus International IRD-UCAD de l'IRD, UMR VITROME, IRD-Université Aix Marseille, AP-HM, SSA, IHU-Méditerranée Infection, Dakar, Senegal;* [5]*University of Pennsylvania, School of Social Policy and Practice and Perelman School of Medicine, Philadelphia, United States*
Email: marion.coste@univ-amu.fr

Background and aims: Worldwide, the burden of chronic hepatitis B (CHB) infection is estimated to reach 800, 000 deaths annually, with highest CHB prevalence found in Western Pacific and Africa. In Senegal, where up to 10% of the adult population lives with CHB, the government aims to treat 30, 000 patients by 2023. In this context, the Ministry of Health is piloting the decentralization of CHB care to rural populations in the Fatick region drawing from the 2017 EASL Clinical Practice Guidelines on the management of CHB. This study documents the CHB cascade of care in rural Senegal after community-based testing.
Method: All residents of households randomly selected in the rural area of Niakhar (Senegal) were offered at-home hepatitis B testing using dried blood sampling and administered socio-economic questionnaires (ANRS12356 AmBASS survey). Following a free CHB initial check-up, patients were referred to local healthcare facilities-or invited to join a cohort in Dakar if eligible-for CHB management as per the Senegalese national recommendations adapted from the 2017 EASL guidelines. A few months after referral, purposeful sampling of one-on-one qualitative interviews based on an adaptation of the health capability profile were conducted to document perceptions, obstacles and levers in CHB participants linked to care and those who were not (A*Midex PeCSen study).
Results: In 2018–2019, 3, 118 participants representative of the Niakhar area's population undertook hepatitis B testing. 206 participants tested positive, and among them, 163 patients (79%) performed the initial CHB check-up. By September 30 2021, 48 patients had gone to at least one visit for CHB management-a 23% linkage to care. Interviews (n = 34) revealed complex CHB-related health capability profiles, starring high health-related motivation, skills, and self-efficacy despite low CHB-related knowledge. Gendered social norms, shared decision-making, reluctance towards blood sampling in the absence of treatment prescription, and limited ability to pay are among the main obstacles to linkage to care, and retention in CHB follow-up.



Conclusion: As the first mixed-methods study of the cascade of CHB care in rural Sub-Saharan Africa, our results call for action in rethinking CHB management to make it acceptable, accessible, and affordable to rural populations.

THU222

Global survey of healthcare workers' attitudes to treatment of chronic hepatitis C infection in children and adolescents

Farihah Malik[1], Philippa Easterbrook[2], Giuseppe Indolfi[3], Claire Thorne[1]. [1]*UCL Great Ormond Street Institute of Child Health, London, United Kingdom;* [2]*World Health Organization, Genève, Switzerland;* [3]*University Hospital Meyer, Firenze, Italy*
Email: farihah.malik.18@ucl.ac.uk

Background and aims: Direct acting antivirals (DAAs) are now approved for treatment of adolescents and children >3 years living with chronic hepatitis C (HCV) however, there is limited understanding of the attitudes of health care workers (HCWs) on expanding treatment, especially to younger age groups. We undertook the first global survey of HCWs managing HCV infection regarding treatment of children and adolescents, and on key challenges to implementation, to inform updated World Health Organization (WHO) HCV guidelines.
Method: A cross-sectional online survey was conducted during September 2021, distributed to networks providing care to children and adolescents living with HCV infection, and other key stakeholders. Survey questions were developed to reflect two key questions: which age groups to treat and prioritise, and which DAA regimens to use.
Results: There were 142 survey respondents, of whom 94 (66%) had cared for children or adolescents with HCV over the past 3 years. Every WHO region was represented, with highest proportion of respondents from the Western Pacific (43%) and the Americas (19%). There was a trend towards higher preference for treating older age groups: 60% of respondents reported a strong preference for treating (i.e., stating they were very likely or likely to treat) children aged 3 to <6 years, increasing to 81% and 94% for those aged 6 to <12 years and 12 to <18 years respectively. The main reasons reported for preferring not treating younger age groups were the chance of spontaneous clearance, lack of drug approvals and registration for treatment of younger age groups, slow disease progression and asymptomatic nature of disease in early childhood, difficulties with administering medication to young children and lack of clinical trial data.
The most commonly preferred and used DAA regimens for treatment across all paediatric age groups were: sofosbuvir/velpatasvir, sofosbuvir/ledipasvir and glecaprevir/pibrentasvir. The most frequent reasons for these regimen preferences were safety, guideline recommendations, drug availability, suitability to treat prevalent HCV genotypes (including pangenotypic) and efficacy.
Conclusion: This survey demonstrates strong HCW support for treatment of children and adolescents with HCV infection, especially those 6 years or older. Future priorities include updating national policies to incorporate case-finding strategies and treatment for children and adolescents, and access to paediatric DAA formulations.

THU223

Impact of community-based campaign in United States to increase hepatitis B virus screening and linkage to care among Asian immigrants from high endemic countries

Sung Kwon[1,2], Aziza Win[3], Gregory Wu[4]. [1]*Holy Name Medical Center, Teaneck, United States;* [2]*Columbia University Irving Medical Center, New York, United States;* [3]*Ross University School of Medicine-Academic Campus, Bridgetown, Barbados;* [4]*Geisinger Commonwealth School of Medicine, Scranton, United States*
Email: steve-kwonmd@holyname.org

Background and aims: With the ongoing population movements of migrants from high (>8%) to low (<2%) endemic regions, the prevalence and incidence of chronic Hepatitis B virus surface antigen (HBsAg) carriers are changing in low endemic countries like the United States. To address this, in the efforts for hepatitis B virus (HBV) eradication, the American Association for the Study of Liver Disease has established guidelines pushing for HBV screening in immigrants from high endemic regions including many Asian countries. Yet, many Asian immigrants remain unscreened and those with chronic hepatitis B (CHB) are often not linked to care citing multiple barriers. We sought to determine the impact of community-based HBV campaigns on screening and linkage to care (LTC) efforts through a large-scale community screening initiative.
Method: Asian immigrants from the New Jersey and New York metropolitan areas were screened for HBV using surveys and serological testing from 2009 to 2019. Those participants found to be positive were followed up by telephone, mail or email. We started to collect LTC data starting in 2015. In 2017, because of low LTC rates, nurse navigators whose role was to help participants navigate through individual barriers to care were hired to aid in the LTC process. Those excluded from the LTC data included those who were already linked to care, those who declined to be linked to care and those who had moved or passed away.
Results: 13, 566 participants were screened from 2009 to 2019, of which, the results for 13, 466 were available. Of these, 372 (2.7%) were found to have positive HBV status. Approximately 49.3% were female and 50.1% were male, and the rest were of unknown gender. A total of 1, 191 (10.0%) participants were found to be HBV negative but required vaccination. When we started to track LTC, we found 195 participants that were eligible for LTC between 2015 through 2017 after the exclusion criteria were applied. It was found that only 33.8% were successfully linked to care in that time period. After hiring nurse navigators, we saw LTC rates increase to 85.7% in 2018 and to 89.7% in 2019.

	Number of HBV Infected	Percentage (%)
Successful LTC		
Up to 2017	56 (out of 195)	33.8%
2018	12 (out of 14)	85.7%
2019	26 (out of 29)	89.7%

Figure: Successful linkage to care rates 2009 to 2019. A nurse navigator was hired in 2017 to focus on linkage to care.

Conclusion: HBV community screening initiatives are imperative to increase screening rates in the Asian immigrant population. We were also able to demonstrate that nurse navigators can successfully help increase LTC rates. Our HBV community screening model can address issues with barriers to care including lack of access in comparable populations.

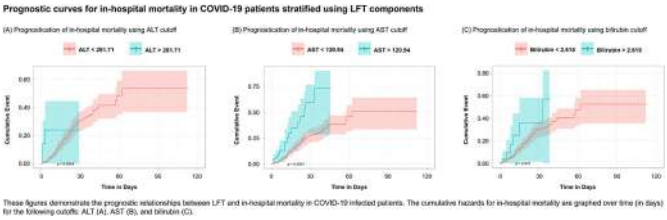
THU224

The prognostic implications of liver function test abnormalities in patients admitted to hospital with COVID-19

Jason Cohen[1], David Uihwan Lee[2], Gregory Fan[1], David Hastie[1], Akaash Mittal[1], Khanh Le[1], Yeeun Jang[1], Sarav Daid[1], Raffi Karagozian[1], Raza Malik[1]. [1]*Tufts Medical Center, Gastroenterology/Hepatology, Boston, United States;* [2]*University of Maryland Medical Center, Gastroenterology/Hepatology, Baltimore, United States*
Email: jcohen1353@gmail.com

Background and aims: Prior studies have indicated the presence of hepatic inflammation (as signified by elevated liver function test (LFT) values), as conferring an escalated risk toward adverse outcomes in patients admitted with COVID-19. In line with this hypothesis, we study the various thresholds of LFTs and its associated prognostic risks toward COVID-19 related hospital deaths.
Method: This was a single-center retrospective study involving patients admitted with COVID-19. Univariate Cox regression analysis identified the LFT variables significantly associated with our primary end point, in-hospital death. Subsequently, 500 iterations of thresholds were generated for each biomarker to estimate the prognostic

relationship between biomarker and end point. Multivariate Cox regression and event-analyses were performed for each threshold to identify the minimal cutoffs at which the prognostic relationship was significant. Event curves were drawn for each significant relationship.
Results: A total of 858 patients with COVID-19 were included with a median follow-up time of 5 days from admission. From the total, 90 patients passed away during admission (10.5%). Upon univariate Cox analysis, the following LFT parameters were associated with in-hospital death: Bilirubin ($p < 0.001$), AST ($p < 0.001$), ALT ($p < 0.001$). However, alkaline phosphatase ($p = 0.449$) was not associated with the primary end point. The iterations of event regression analyses using 500 sequences of LFT thresholds showed the following cutoffs to be significantly associated with in-hospital death (minimally significant values): ALT (281.71 IU/L), AST (120.94 IU/L), bilirubin (2.615 mg/dL). On the multivariate analysis, while controlling for demographics and cardiopulmonary/medical comorbidities, the following adjusted hazard ratios were derived for each cutoff: ALT (aHR: 6.43 95%CI 1.85–22.40), AST (aHR: 3.35 95%CI 1.84–6.11), and bilirubin (aHR: 2.77 95%CI 1.15–6.65).



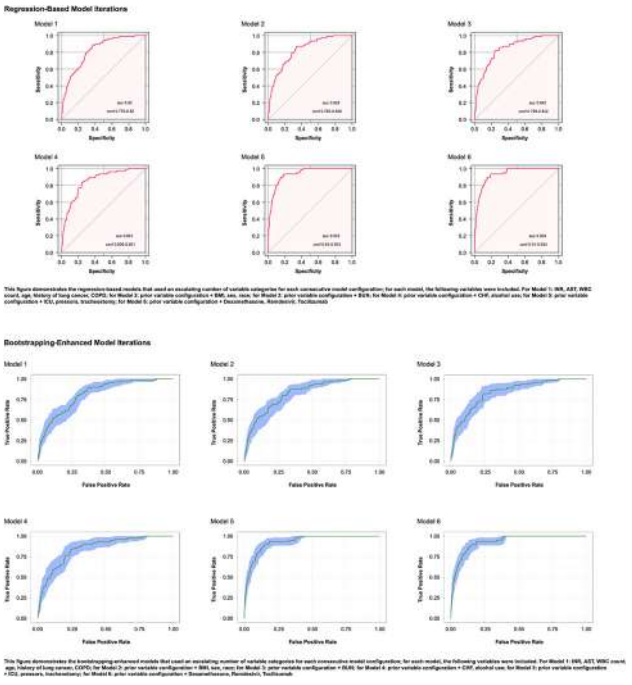
These figures demonstrate the prognostic relationships between LFT and in-hospital mortality in COVID-19 infected patients. The cumulative hazards for in-hospital mortality are graphed over time (in days) for the following cutoffs: ALT (A), AST (B), and bilirubin (C).

Conclusion: The delineated cutoffs for AST, ALT, and bilirubin levels can serve as clinical benchmarks to help determine when a COVID-19 infection poses significant risk. Given this finding, the cutoffs can be used as part of a risk assessment for patients to support early preventative therapies and medical management.

THU225
A novel prognostic model including liver function parameters accurately predicts 30-day mortality in patients admitted with COVID-19

David Uihwan Lee[1], Jason Cohen[2], Gregory Fan[2], David Hastie[2], Akaash Mittal[2], Khanh Le[2], Yeeun Jang[2], Sarav Daid[2], Raffi Karagozian[2], Raza Malik[2]. *[1]University of Maryland Medical Center, Gastroenterology/Hepatology, Baltimore, United States; [2]Tufts Medical Center, Gastroenterology/Hepatology, Boston, United States*
Email: jcohen1353@gmail.com

Background and aims: While the relationship between elevated liver enzymes and COVID-19 related adverse events is well-established, a liver-dependent prognostic model that predicts the risk of death is helpful to accurately stratify admitted patients. In this study, we use a bootstrapping-enhanced method of regression modeling to predict COVID-19 related deaths in admitted patients.
Method: This was a single-center, retrospective study. Univariate and multivariate Cox regression analyses were performed using 30-day mortality as the primary end point to establish associated hepatic risk factors. Regression-based prediction models were constructed using a series of modeling iterations with an escalating number of categorical terms. Model performance was evaluated using receiver operating characteristic (ROC) curves. Model accuracy was internally validated using bootstrapping-enhanced iterations.
Results: 858 patients admitted to hospital with COVID-19 were included. 78 were deceased by 30 days (9.09%). Cox regression (greater than 20 variables) showed the following core variables to be significant: INR (aHR 1.26 95%CI 1.06–1.49), AST (aHR 1.00 95%CI 1.00–1.00), age (aHR 1.05 95%CI 1.02–1.08), WBC (aHR 1.07 95%CI 1.03–1.11), lung cancer (aHR 3.38 95%CI 1.15–9.90), COPD (aHR 2.26 95%CI 1.21–4.22). Using these core variables and additional categorical terms, the following model iterations were constructed with their respective AUC; model 1 (core only): 0.82 95%CI 0.776–0.82, model 2 (core + demographics): 0.828 95%CI 0.785–0.828, model 3 (prior terms + additional biomarkers): 0.842 95%CI 0.799–0.842, model 4 (prior terms + comorbidities): 0.851 95%CI 0.809–0.851, model 5 (prior terms + life-sustaining therapies): 0.933 95%CI 0.91–0.933, model 6 (prior terms + COVID-19 medications): 0.934 95%CI 0.91–0.934. Model 1 demonstrated the following parameters at 0.91 TPR: 0.54 specificity, 0.17 PPV, 0.98 NPV. Bootstrapped iterations showed the following AUC for the respective models: model 1: 0.82 95%CI 0.765–0.882, model 2 0.828 95%CI 0.764–0.885, model 3 0.842 95%CI 0.779–0.883, model 4: 0.851 95%CI 0.808–0.914, model 5: 0.933 95%CI 0.901–0.957, model 6: 0.934 95%CI 0.901–0.961.



Conclusion: Model 1 displays high prediction performance (AUC >0.8) in both regression-based and bootstrapping-enhanced modeling iterations. Therefore, this model can be adopted for clinical use as a calculator to evaluate the risk of 30-day mortality in patients admitted with COVID-19.

THU226
Low health literacy is associated with higher healthcare service utilisation and costs among patients with cirrhosis

Patricia Valery[1], Christina Bernardes[1], Kelly Hayward[2,3], Gunter Hartel[1], Katelin Haynes[4], Louisa Gordon[1], Amy Johnson[2,3], Elizabeth Powell[2,3]. *[1]QIMR Berghofer Medical Research Institute, Herston, Australia; [2]Princess Alexandra Hospital, Woolloongabba, Australia; [3]The University of Queensland, Centre for Liver Disease Research, Faculty of Medicine, Woolloongabba, Australia; [4]Hepatitis Queensland, Coorparoo, Australia*
Email: patricia.valery@qimrberghofer.edu.au

Background and aims: Optimal management of cirrhosis is complex, and patients often lack knowledge and skills which can affect self-management. We assessed patient knowledge about cirrhosis and examined whether knowledge was associated with clinical outcomes, healthcare service utilisation, and healthcare costs.
Method: A cross-sectional 'knowledge survey' was conducted between Jun-2018 and Aug-2020 with 123 cirrhosis patients with cirrhosis (44.4% of 277 invited and eligible). The 'knowledge survey' questions were derived from prior studies, and an expert panel

unanimously deemed eight items to be "key knowledge" about cirrhosis. The proportion of correct answers were calculated ("key knowledge" score) and patients were categorized as having 'good knowledge' vs 'poor knowledge' (cut-off based on median score). Detailed clinical data (extracted from medical records and through linkage to hospital admissions, emergency department presentations), healthcare costs, and self-reported health-related quality of life (SF-36) were available. Cumulative overall survival (Kaplan-Meier), rates of hospital admissions, emergency presentations and costs were assessed according to "key knowledge." Incidence rate ratios (IRR; Poisson regression) were reported.

Results: Patients were aged 60.7 ± 10.8 years, 65.9% were male, 47.2% had formal education to Junior High School level or less, 43.9% lived in 'most disadvantaged' areas, alcohol was a cofactor for 65.9%, NAFLD was a cofactor for 50.4%, and 29.3% had decompensated cirrhosis. 58.5% of patients had 'good knowledge' about cirrhosis. In multivariable analysis, higher level of education was associated with over 5-fold odds of having 'good knowledge' about liver disease (adj-OR = 5.61, 95%CI 2.47–12.75). Patients with 'good knowledge' had a higher health status in the SF-36 domain related to physical functioning (p = 0.036) compared to those with 'poor knowledge'. Patients with 'good knowledge' had 73% fewer all-cause admissions (IRR = 0.27, 95%CI 0.23–0.33), 57% fewer emergency presentations for cirrhosis (IRR = 0.43, 95%CI 0.21–0.89), and more planned one-day cirrhosis admissions (IRR = 4.47, 95%CI 1.61–12.37; see Table). The total cost of cirrhosis admissions was 45% lower for patients with 'good knowledge' (IRR = 0.55, 95%CI 0.54–0.56) during the follow-up period.

Table: Incidence rate ratios and cost ratios by knowledge score

	IRR (95%CI)*	p-value
Data source: Queensland Hospital Admitted Patient Data Collection		
All-cause admission	0.27 (0.23-0.33)	**<0.001**
Cirrhosis admission	0.72 (0.44-1.19)	0.206
Planned one-day admission (cirrhosis admission)	4.47 (1.61-12.37)	**0.004**
Admitted via the emergency department (any admission)	0.59 (0.40-0.86)	**0.007**
Admitted via the emergency department (cirrhosis admission)	0.67 (0.39-1.17)	0.157
Data source: Emergency Data Collection	**IRR (95%CI)***	**p-value**
Emergency presentation (any reason)	0.68 (0.50-0.94)	**0.018**
Cirrhosis-related emergency presentation	0.43 (0.21-0.89)	**0.022**
Data source: National Hospital Cost Data Collection	**Cost ratio (95%CI)****	**p-value**
Total cost for any admission	0.08 (0.08-0.09)	**<0.001**
Total cost for cirrhosis admissions	0.55 (0.54-0.56)	**<0.001**

Note: Poor knowledge is the reference group; ‡ Two patients for whom we did not have hospital admission data were excluded from these analyses; * Multivariable Poisson regression model included education level, presence of complications of cirrhosis and duration of cirrhosis; ** Multivariable Poisson regression model included education level, presence of comorbidity, presence of complications of cirrhosis and duration of cirrhosis.

Conclusion: Low health literacy is associated with increased use of healthcare services and increased total cost of health care. This may reflect poorer health status and quality of life. Improving the health literacy of patients with cirrhosis may be an effective strategy to promote a more cost-effective use of healthcare services with fewer preventable emergency department visits and greater use of planned admissions.

A modelling approach to estimate alcohol-related liver morbidity and mortality in France

Claire Delacôte[1], Line Carolle Ntandja Wandji[1,2], Alexandre Louvet[1,2], Pierre Bauvin[1], Guillaume Lassailly[1,2], Massih Ningarhari[1,2], Sebastien Dharancy[1,2], Guillaume Clement[3], Amelie Bruandet[3], Xavier Lenne[3], Philippe Mathurin[1,2], Sylvie Deuffic-Burban[1,4].
[1]INSERM U1286-INFINITE, Lille, France; [2]CHU de Lille, Service des maladies de l'appareil digestif, Lille, France; [3]Lille University Hospital, Medical Information Department, Lille, France; [4]INSERM U1137-IAME, Paris, France
Email: claire.delacote@inserm.fr

Background and aims: Harmful alcohol use leads to the development of alcohol-related liver disease (ALD). In-depth knowledge of the natural history of ALD according to patterns of alcohol consumption is required to predict the future burden of ALD morbidity and mortality. This would allow to implement health policies targeting at-risk drinkers. Our aim was to integrate the relevant natural history data of ALD in a mathematical model. This model includes estimates of the incidence of at-risk drinking in order to predict morbidity and mortality related to ALD in France.

Method: First, we developed a Markov model simulating the trajectory of cohorts starting at-risk alcohol consumption until they die. It integrates the common risk factors associated with the progression of ALD (sex, age, amount of alcohol, genetic polymorphism). Unknown parameters of progression were back-calculated on the 2010–2018 alcohol-related decompensated cirrhosis and HCC mortality data provided by the French National Hospital Discharge database. Second, morbidity and mortality were predicted up to 2026.

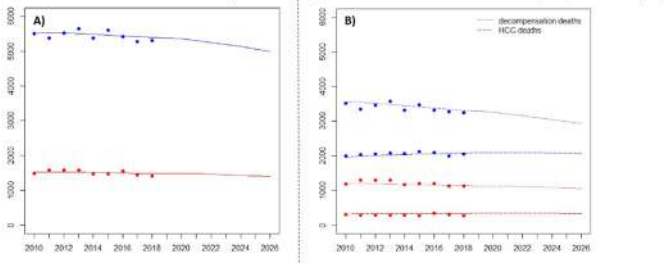
Results: The developed model fits the observed mortality data: 63, 016 deaths were predicted over 2010–2018 for 62, 934 observed in database (Fig. A). Prediction of deaths fits the observed mortality according to cause of death and sex (Fig. B), as well as age.

Between 2010 and 2021, annual ALD deaths decreased by 4%, from 7, 100 to 6, 700. However, while deaths by decompensation decreased from 4800 to 4, 300 (−10%), deaths by HCC rose from 2, 300 to 2, 400 (+4%) (Fig. B). Most of the ALD deaths occurred in men: 3 out 4 deaths by decompensation and 9 out 10 deaths by HCC.

In addition, the model estimated that, in 2021, 80, 000 French individuals have alcohol-related cirrhosis with 7, 900 incident cases. Decompensated cirrhosis and HCC are observed in around 33, 000 and 6, 000 cases, respectively. Women represent 30% of the cirrhotic individuals.

The decline of French per capita consumption would lead in 2026 to decrease in cirrhosis (∼70, 000) and liver related deaths (6, 400) compared to currently (Fig. B).

A) Annual alcohol-liver related deaths and B) annual cause-specific alcohol-liver related deaths in men (blue) and women (red)



Conclusion: The present model predicts future burden of ALD in the general French population, based on robust epidemiological data. This model allows to predict not only liver-related mortality but also burdens of cirrhosis and liver-related complications. It may help to propose new health policies targeting patients most at-risk in order to obtain further reductions in the burden of ALD.

THU228

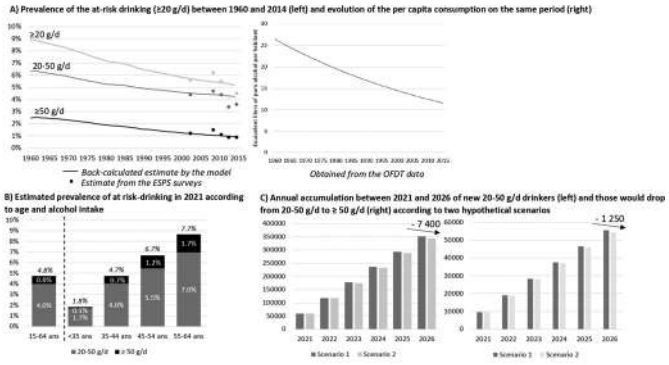
A model to predict drinking population at-risk of liver disease in France: a tool for decision-making public health policies

Claire Delacôte[1], Line Carolle Ntandja Wandji[1,2], Alexandre Louvet[1,2], Pierre Bauvin[1], Guillaume Lassailly[1,2], Massih Ningarhari[1,2], Sebastien Dharancy[1,2], Philippe Mathurin[1,2], Sylvie Deuffic-Burban[1,3].
[1]INSERM U1286-INFINITE, Lille, France; [2]CHU de Lille, Service des maladies de l'appareil digestif, Lille, France; [3]INSERM U1137-IAME, Paris, France
Email: claire.delacote@inserm.fr

Background and aims: In France, daily alcohol intake is decreasing among 15–64 y-o whereas consumption of ≥6 drinks per occasion (binge drinking) is becoming more common, especially among 15–35 y-o. Estimating the proportions of individuals with alcohol use with intermediate (20–50 g/d) or high (≥50 g/d) risks of alcohol-related liver disease (ALD) would allow to predict the incident cases of cirrhosis and provide new tool for decision-making public health policies. Our aim was to predict the incidence of French people having an alcohol intake ≥20 g/d.

Method: Daily alcohol intake was calculated from individual data from national surveys (ESPS), conducted on a representative sample

of 15–64 y-o French people. A Markov model was fitted to this data to estimate entry into risky drinking, according to the history of binge drinking or not. Incidences were back-calculated by sex, age and annual per capita consumption from ESPS 2002 to 2014 (n = 45, 054). The adequacy of the model was assessed by comparing the predicted alcohol patterns and prevalence to those estimated from ESPS. Entries into at liver-risk drinking were simulated between 1910 and 2014 considering competitive mortality. At liver-risk drinking incidences and prevalence were predicted until 2026 under 2 scenarios.
Annual distributions of predicted and observed prevalence were closed according to daily alcohol intake (Fig. A), sex and age.
Results: While per capita consumption dropped from 26L to 12L (-54%) over 1960–2014, prevalence of at liver-risk drinking among 15–64 y-o decreased from 8.8% to 5.1% (-42%) (Fig. A). The number of new intermediate and high at liver-risk drinkers had respectively decreased by 35% and 65%.
In 2021, ~5% of French people have an alcohol intake ≥20 g/d (8/10 are men). This prevalence increases with age (Fig. B). Each year, 60, 000 individuals become intermediate at liver-risk drinkers and 9, 500 switch from intermediate to high at-risk consumption.
If the current decrease in per capita consumption continues (scenario 1), it will be 10.6L in 2026 (-4.5% over 5 years) and there will be 350, 000 new at liver-risk drinkers over 2021–2026. If the per capita consumption significantly drops to 10L in 2026 (-10%, scenario 2), 7, 400 intermediate at liver-risk drinkers would be avoided and ~1, 200 intermediate at liver-risk drinkers will not switch into high at liver-risk drinking (Fig. C).



Conclusion: Although these 2 scenarios will allow differences in terms of incident cases, the expected prevalence will be little changed and 4.5% of the 15–64 y-o would be at-liver risk drinkers.
1/1000 French initiates an alcohol intake ≥20 g/d each year. In 2021, 1.9 million of French people have an alcohol consumption associated with a risk of cirrhosis and 310, 000 of them have a high risk (≥50 g/d). By quantifying for the 1st time the incidence of French people drinking ≥20 g/d, this model could help developing new public health strategies targeting the reduction of ALD morbidity and mortality.

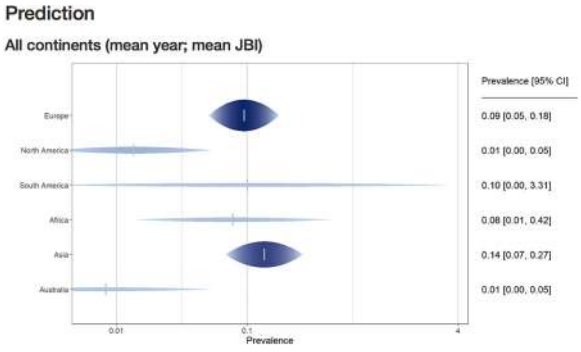
Blood donors in Europe have substantially higher risk of exposure to HEV than in North America: results from a systematic review and meta-analysis

Annika Wolski[1], Ann-Kathrin Ozga[2], Marylyn Addo[1], Samuel Huber[1], Ansgar W. Lohse[1], Sven Pischke[1], Thomas Horvatits[1]. [1]*University Medical Center Hamburg-Eppendorf, Center for Internal Medicine I. Medical Clinic and Polyclinic, Hamburg, Germany;* [2]*University Medical Center Hamburg-Eppendorf, Medicine Institute of Medical Biometry and Epidemiology, Hamburg, Germany*
Email: annika@wolski.at

Background and aims: The increasing number of diagnosed hepatitis E virus (HEV) infections in Europe, as well as the potentially fatal consequences in vulnerable patients resulting from this disease, led to the implementation of blood product-testing in various countries. However, many nations, including the U.S. have not yet implemented such screening efforts. To assess the need for HEV-screening in blood products worldwide, we conducted a systematic review and meta-analysis comparing the rate of HEV RNA positivity and anti-HEV seroprevalence in blood donors.
Method: Studies reporting the anti-HEV IgG and/or HEV-RNA positivity rates among blood donors worldwide were identified via predefined search terms ("Hepatitis e" OR "HEV") AND ("blood donors" OR "transfusion" OR " blood donation" OR "blood testing") in Pubmed and Scopus. Data were stratified by year of publication, country/continent, diagnostic assay and methodological quality (according to PRISMA). Estimates were calculated by pooling study data (separately for each country/continent) via multivariable linear mixed effects meta regression analysis.
Results: Out of 1, 103 studies, 151 (14%) were included in the final analysis. Estimated HEV viremia rate ranged from 0.01% to 0.14% worldwide (56 studies, 3, 438, 276 blood donors). Highest estimated HEV viremia rates were seen in Asia (0.14%), followed by South America (0.10%), Europe (0.09%), Africa (0.08%), Australia and North America (each 0.01%). In Europe highest rates could be found in Serbia (0.31%), closely followed by Germany (0.28%) and France (0.18%). Rate of HEV viremia as well as anti HEV seroprevalence were significantly lower in North America in comparison to Europe (OR = 0.14 [95% CI 0.03–0.58]; OR = 0.62 [95% CI 0.35–1.10]), independently of year of publication and methodological quality.



Conclusion: Our data demonstrate large regional differences regarding the risk of exposure to HEV. Considering the cost-benefit ratio, this supports blood-product screening programs in areas of high endemicity, such as Europe or Asia, in contrast to low-endemic regions, such as the U.S.

A population based-study of rates and trends of hepatitis C in immigrants and the Canadian-born in Quebec, Canada, 1998–2018

Ana Maria Passos-Castilho[1,2], Marina B. Klein[2,3], Julie Bruneau[4,5], Dimitra Panagiotoglou[6], Karine Blouin[7], Donald Murphy[8], Christina Greenaway[1,2,9]. [1]*Lady Davis Institute, Jewish General Hospital, Centre for Clinical Epidemiology, Montreal, Canada;* [2]*McGill University, Department of Medicine, Montreal, Canada;* [3]*McGill University Health Center, Division of Infectious Diseases, Montreal, Canada;* [4]*Centre Hospitalier de l'Université de Montréal, CHUM Research Centre, Montreal, Canada;* [5]*Université de Montréal, Department of Family and Emergency Medicine, Faculty of Medicine, Montreal, Canada;* [6]*McGill University, Department of Epidemiology, Biostatistics and Occupational Health, Montreal, Canada;* [7]*Institut National de Santé Publique du Québec, Unité des infections transmissibles sexuellement et par le sang, Québec, Canada;* [8]*Institut National de Santé Publique du Québec,*

Laboratoire de Santé Publique du Québec, Sainte-Anne-de-Bellevue, Canada; [9]Jewish General Hospital, Division of Infectious Diseases, Montreal, Canada
Email: anampassos@gmail.com

Background and aims: Immigrants bear a disproportionate hepatitis C (HCV) burden in Canada. They account for 30% of HCV cases and are at increased risk of end stage liver disease and liver cancer at the time of diagnosis. Determining sub-groups of immigrants at highest HCV risk will be essential to supporting micro-elimination efforts in this population. We estimated annual reported rates and trends of HCV over a 20-year period in Quebec.
Method: A population-based cohort of all HCV cases in Quebec from 1998 to 2018 reported to public health and the provincial reference laboratory were linked to the provincial health registry and the landed immigrant database. Immigrant status and country of birth were assigned through linkage to the immigrant database. Region of birth was classified by World Bank regions; East Asia/Pacific (SEA), South Asia (SA), Middle East/North Africa (MENA), Sub-Saharan Africa (SSA), Latin America/Caribbean (LAC), Western Europe (EUS), Other Europe/Central Asia (OECA) and North America/Australia/New Zealand (NAANZ)]. Annual reported crude cumulative incidence rates of HCV among immigrants and the Canadian-born were estimated using Quebec population census data during the study period. Comparative rate ratios (RR) with 95% confidence intervals (CI) and the trend of HCV rates over the study period stratified by immigrant status were estimated using Poisson regression.
Results: Among 34, 881 HCV cases identified, 13.5% (n = 4, 720) were immigrants. Immigrants were older (median 46.8 vs. 44.1 years; p < 0.001) and diagnosed a median of 9.3 (IQR 2.8–17.2) years after arrival in Quebec. Comparing immigrants with Canadian-born: the HCV average annual rate/100, 000 population was 33.1 vs. 30.8 and 18.4 vs. 12.3 during the periods 1998–2008 and 2009–2018, respectively; and the RR was 1.08 (1.03–1.12) in 1998–2008, and 1.50 (1.42–1.57) in 2009–2018. Between 2009 and 2018, subgroups of immigrants with higher HCV rates compared to the Canadian-born were those from OECA [rate; RR (95% CI); 45.6; 3.7 (2.0–7.0)], SSA [44.7; 3.6 (1.9–6.8)], and SA [28.8; 2.3 (1.2–4.6)]. Rates decreased more slowly over the study period among immigrants vs. Canadian-born [-4.84% (-6.17–3.49%) vs. – 7.74% (-9.22–6.24%)] per year.

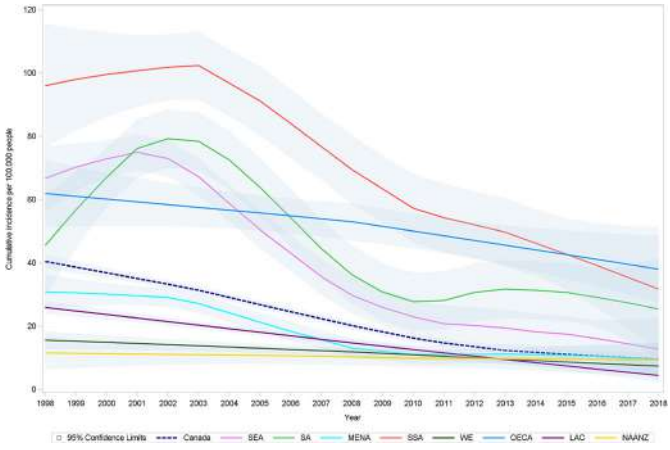

Figure: Reported rates of HCV cases per 100, 000 people by region of origin (1998–2018). Smoothed (loess) reported crude cumulative incidence with 95% confidence bounds.

Conclusion: High rates of HCV among immigrants and long delays to HCV diagnosis after arrival in Canada highlight important gaps in HCV screening among immigrants. These data can be used to inform micro elimination efforts among the immigrant population in Quebec and Canada.

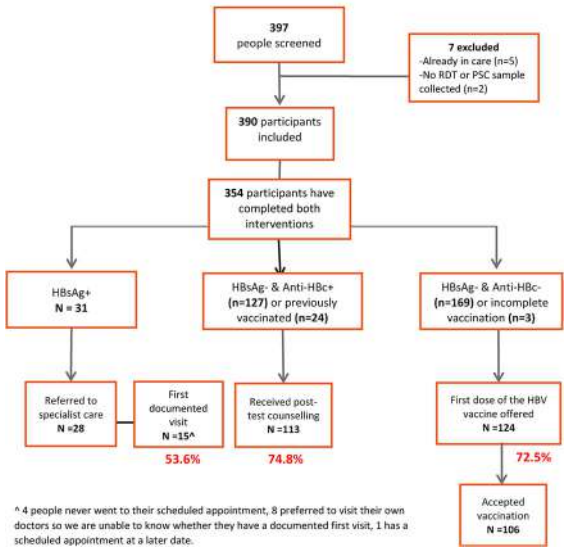
THU231

HBV screening in west african migrant community and faith-based organizations increases HBV vaccination among this high-risk population in greater Barcelona, Spain

Camila Picchio[1], Ariadna Rando-Segura[2], Emma Fernandez[1], Nélida López[1], Silvia Gómez Araujo[1], Daniel Kwakye Nomah[3], Omar Diatta[1,4], Sergio Rodriguez-Tajes[5,6], Sabela Lens[5,6], Xavier Forns[5,6], Francisco Rodríguez-Frías[2], Maria Buti[6,7], Jeffrey Lazarus[1]. *[1]Barcelona Institute for Global Health (ISGlobal), Hospital Clínic, University of Barcelona, Barcelona, Spain; [2]Liver Pathology Unit, Biochemistry and Microbiology Service, Hospital Universitari Vall d'Hebron, Barcelona, Spain; [3]Center for Epidemiological Studies on HIV/AIDS and STIs in Catalonia (CEEISCAT), Badalona, Spain; [4]Community and Public Health Unit, Department of International Health Drassanes-Hospital Universitari Vall d'Hebrón. Programa de Salut Internacional de l'Institut Català de la Salut (PROSICS), Spain; [5]Liver Unit, Hospital Clínic, IDIBAPS, University of Barcelona, Barcelona, Spain; [6]CIBER Hepatic and Digestive Diseases (CIBERehd), Instituto Carlos III, Madrid, Spain; [7]Liver Unit, Hospital Universitari Vall d'Hebron, Barcelona, Spain*
Email: camila.picchio@isglobal.org

Background and aims: African migrant populations living in Europe are disproportionately affected by HBV infection and oftentimes use health services at lower rates due to structural and/or cultural/linguistic barriers. Efforts to scale up prevention, testing, and treatment are needed to reach the 2030 hepatitis elimination targets set by the WHO. The HBV-COMSAVA study aims to use point-of-care testing with simplified diagnostic tools in community settings to identify and link to care or vaccinate west African migrants in the greater Barcelona area.
Method: 393 study participants were offered HBV screening in a "pop-up" clinic in a community setting from 21/11/20–13/11/21. Rapid tests to screen for the presence of HBsAg were used and a blood sample was collected using plasma separation cards and analyzed in a laboratory. The interactive tool, *HeparJoc*, was used to increase HBV knowledge, which was co-created by migrant populations. HBsAg+ patients were given a referral to a specialist on the spot. Remaining patients received their results during a second pre-programmed visit and were offered: post-test counselling (PTC) or vaccination of the first dose of the HBV vaccine *in situ*. Vaccination cards and referrals to their primary care center for subsequent doses were provided to all who received first doses. Sociodemographic and linkage to care data were collected and basic standard descriptive statistics were utilized using STATA software.
Results: 354 were included for analysis. 75.1% returned to receive their results and were linked to care or offered PTC with 44.6% (n = 158) showing evidence of past or current HBV infection. The overall HBsAg prevalence was 8.8% (n = 31). Of those who were HBsAg-, anti-HBc positivity was detected in 35.9% (n = 127). The majority (n = 172) required vaccination against HBV, followed by post-test counselling (n = 151) and referral to a specialist (n = 31) **(**Figure 1**).** The HBV vaccination acceptance rate was 85.4% and the main reason for not accepting included having results picked up by a family member and not being physically present (38, 9%, n = 7).

Figure 1. Flow chart of HBV-COMSAVA participants and overall linkage to care



Conclusion: Despite the COVID-19 pandemic, by employing a community-based model of care utilizing novel simplified diagnostic tools, the HBV-COMSAVA study demonstrated the possibility to screen and vaccinate African migrants who may otherwise not have received care, reducing the possible pool of new infections among this high-risk group.

THU232

Community-based HBV testing among west african migrants in greater Barcelona, Spain increases linkage to specialist care and vaccination: the HBV-COMSAVA model

Camila Picchio[1], Daniel Kwakye Nomah[2], Ariadna Rando-Segura[3], Silvia Gómez Araujo[1], Emma Fernandez[1], Omar Diatta[1,4], Maria Buti[5,6], Sergio Rodriguez-Tajes[6,7], Sabela Lens[6,7], Xavier Forns[6,7], Nélida López[1], Francisco Rodríguez-Frías[3], Jeffrey Lazarus[1]. *[1]Barcelona Institute for Global Health (ISGlobal), Hospital Clínic, University of Barcelona, Barcelona, Spain; [2]Center for Epidemiological Studies on HIV/AIDS and STIs in Catalonia (CEEISCAT), Badalona, Spain; [3]Liver Pathology Unit, Biochemistry and Microbiology Service, Hospital Universitari Vall d'Hebron, Barcelona, Spain; [4]Community and Public Health Unit, Department of International Health Drassanes-Hospital Universitari Vall d'Hebrón. Programa de Salut Internacional de l'Institut Català de la Salut (PROSICS), Barcelona, Spain; [5]Liver Unit, Hospital Universitari Vall d'Hebron, Barcelona, Spain; [6]CIBER Hepatic and Digestive Diseases (CIBERehd), Instituto Carlos III, Madrid, Spain; [7]Liver Unit, Hospital Clínic, IDIBAPS, University of Barcelona, Barcelona, Spain*
Email: camila.picchio@isglobal.org

Background and aims: Hepatitis B virus (HBV) infection affects an estimated 250 million people worldwide. Sub-Saharan Africa is disproportionately affected, particularly west and central African countries. Migrants arriving to Europe from these high-endemic areas may be unaware of their HBV status due to the unreliable testing and vaccination strategies in their home countries and underutilization of the host country health services, delaying timely diagnosis and linkage to care. The HBV-COMSAVA study aims to use point-of-care testing with simplified diagnostic tools in community settings to identify and link to care or vaccinate west African migrants in the greater Barcelona area. We report the HBV prevalence, associated risk factors, and the continuum of care.

Method: From 21/11/20–13/11/21, 397 people were offered HBV testing in community settings in greater Barcelona. Participants were first tested with an HBsAg rapid detection test (DETERMINE™ HBsAg 2, Abbott Inc.). Then a whole blood sample (140 µl per spot) was collected utilizing a plasma separation card (PSC) (cobas® PSC, Roche Diagnostics) which was air-dried and transported to the laboratory. Those who tested positive for HBsAg were provided an instant referral to one of two collaborating tertiary hospitals where a full work-up was done, including liver function tests and liver fibrosis assessment (Fibroscan®). The proportion of participants with different HBV-serological status analyzed as of November 16, 2021 are reported using descriptive stats (STATA 16.0).

Results: 379 participants are included; 314 (82.8%) were Ghanaian with a mean age of 41.1 years (SD = 10.0), and 41.9% (n = 159) were female. The overall HBsAg prevalence was 9.0% (n = 34) of which 14 (41.2%) had detectable HBV-DNA and two (5.9%) had anti-HDV antibodies, none were HBeAg+. The mean HBV-DNA and HBsAg levels among patients attending a first specialist visit (n = 17) was 125, 834 UI/ml and 8, 190 UI/ml, respectively. Evidence of past resolved infection (anti-HBc+) was seen in 35.6% (n = 135) of those who were HBsAg- (Table 1).

Table 1. Description of participants who were HBsAg+, HBsAg-/anti-HBc+, and HBsAg-/anti-HBc-.

	HBsAg+ (n=34)	HBsAg-/ Anti-HBc+ (n=135)	HBsAg-/ anti-HBc- (n=204)

Conclusion: This ongoing community-based HBV screening program provides an effective model of identifying and providing care to migrant populations at high risk of HBV infection in the greater

Barcelona area. who otherwise may not have been previously engaged in care. Community screening initiatives can increase testing, vaccination, and linkage to care, helping to reach the 2030 WHO HBV elimination targets.

THU233

The impact of COVID-19 pandemic control measures on HCV treatment initiation in British Columbia, Canada

Naveed Janjua[1,2], Stanley Wong[1], Dahn Jeong[1,2], Mawuena Binka[1], Terri Buller-Tylor[1], Sofia Bartlett[1], Prince Adu[1], Hector Velasquez[1], Makuza Jean Damascene[2], Amanda Yu[1], Maria Alvarez[1], Jason Wong[1], Mel Krajden[1]. *[1]BC Centre for Disease Control, Vancouver, Canada; [2]The University of British Columbia, School of Population and Public Health, Vancouver, Canada*
Email: naveed.janjua@bccdc.ca

Background and aims: Coronavirus disease 2019 (COVID-19) and measures taken to limit the transmission of severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) have directly and indirectly restricted access to healthcare services worldwide. We assessed the impact of these measures, first introduced in British Columbia (BC), Canada in March 2020, on hepatitis C (HCV) treatment initiation.
Method: We used data from the BC Hepatitis Testers Cohort, a large population-based cohort integrating data on HCV testing, primary care visits, hospitalizations, and medication dispensations. We compared the monthly HCV treatment initiations during 2020 with those in 2018 and 2019. We compared the sociodemographic and clinical characteristics of people initiating HCV treatment during pre-pandemic time period (Jan 2018-Feb 2020) to those initiating treatment during pandemic time period (Apr-Aug 2020).
Results: There was a declining trend in HCV treatment initiations pre-pandemic from 3, 172 in 2018 to 2, 331 in 2019 (26% reduction). However, there was a higher decline in 2020 to 1, 475 treatment initiations (37% reduction from 2019). HCV treatment initiations decreased immediately following the imposition of pandemic control measures; monthly pre-pandemic average treatment initiations fell from 172 to 106 during the pandemic (38% change).
There were slight decreases in treatment initiations for the 1945–64 birth cohort (56% to 45%) and for people with HIV coinfection (5.9% to 4.3%) or HBV co-infection (5% to 4.3%). However, there was a slight increase in treatment initiation among the ≥1975 birth cohort (19% to 29%), people who inject drugs (44% to 49%), and people with problematic alcohol use (32% to 37%) between pre-pandemic and pandemic time periods, respectively.

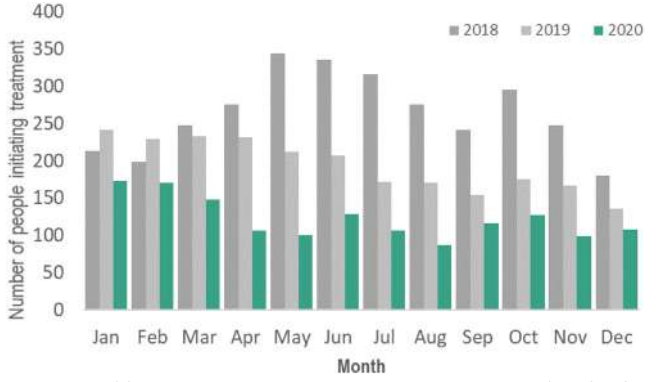

Figure: Monthly HCV treatment initiations 2018–2020, British Columbia, Canada

Conclusion: Similar to other healthcare services and HCV testing, there was a reduction in HCV treatment initiation following the introduction of control measures. Pandemic-related disruptions and the overall decline of treatment initiations could have a negative impact on progress towards HCV elimination goals.

THU234

Negative impact of COVID-19 infection related to life disruption events and health scores on patients with chronic liver disease

Zobair Younossi[1,2,3], Yusuf Yılmaz[4], Mohamed El Kassas[5], Ajay Kumar Duseja[6], Saeed Sadiq Hamid[7], Gamal Esmat[8], Nahum Méndez-Sánchez[9], Wah-Kheong Chan[10], Ashwani Singal[11], Janus Ong[12], Brian Lam[1,2], Sean Felix[1], Elena Younossi[1], Manisha Verma[1,2], Jillian Price[1], Fatema Nader[13], Issah Younossi[13], Andrei Racila[1,2,3], Maria Stepanova[2]. *[1]Betty and Guy Beatty Center for Integrated Research, IHS; [2]Center for Liver Disease, Inova Medicine; [3]Inova Health System, Medicine Service Line; [4]Department of Gastroenterology, Marmara University, Turkey; [5]Helwan University; [6]Postgraduate Institute of Medical Education and Research; [7]Department of Medicine, Aga Khan University; [8]Endemic Medicine and Hepatogastroenterology Department, Cairo University; [9]Medica Sur Clinic and Foundation; [10]University of Malaysia, Gastroenterology and Hepatology Unit; [11]University of South Dakota and Avera Transplant Institute; [12]University of the Philippines, College of Medicine; [13]Center for Outcomes Research in Liver Disease*
Email: zobair.younossi@inova.org

Background and aims: Patients with chronic liver disease (CLD) may experience a substantial burden from COVID-19 infection as well as disruption of life and routine healthcare associated with the pandemic. We assessed the impact of COVID-19 pandemic on patients with CLD.
Method: Patients with CLD enrolled in our Global Liver Registry since 2018 completed a specifically designed 23-item COVID-19 survey between March 2020-November 2021. Questions included patients' COVID-19 infection status and, if infected, characteristics of the illness, along with various aspects of pandemic-related life disruptions for everyone regardless of the infection.
Results: As of November 2021, from 11, 200 historic enrollees, 2635 from 7 countries completed the survey: 21% chronic hepatitis B, 14% chronic hepatitis C, and 66% non-alcoholic fatty liver disease; mean (SD) age 49 ± 13 years, 53% male. Of all survey completers, 10.3% reported having had COVID-19. Of those infected, 87% reported being diagnosed by a laboratory test, 94% had least one symptom, and 73% received treatment for their symptoms. The mean (SD) duration of their illness was 12.5 ± 10.7 days, 66% reported receiving antiviral treatment, 19% were hospitalized, 13% needed oxygen support but no one was put on mechanical ventilation. Of all included CLD patients regardless of COVID-19 infection, 11.4% reported that the pandemic had an impact on their liver disease ($p = 0.45$ between those who were and were not infected); the majority of those (75%) reported delays in follow-up care. The Life Disruption Event Perception (LDEP) questionnaire confirmed that 80% of COVID-19-infected patients vs. 69% patients without history of COVID-19 infection ($p = 0.0001$) experienced worsening in at least one aspect of their life (food/nutrition, exercise, social life, vocation/education, financial situation, housing, or healthcare). The most substantial worsening was observed for social life (73% in infected vs. 61% in not infected), exercise (49% vs. 42%), and financial situation (36% vs. 30%) (all $p < 0.05$). Self-assessed health scores were lower in patients with history of COVID-19 than in those not infected: 6.8 ± 2.1 vs. 7.4 ± 2.2 (on a 1–10 scale with 10 indicating perfect health) ($p < 0.0001$) despite similar scores reported before the pandemic (8.5 ± 1.4 vs. 8.4 ± 1.6, $p = 0.77$). In multivariate regression analysis, after adjustment for country of enrollment, liver disease etiology and severity (assessed by FIB-4 score), age, sex, BMI, diabetes, and history of psychiatric comorbidities, having had COVID was found to be independently associated with lower self-assessed health scores (beta = −0.62 ± 0.13, $p < 0.0001$).
Conclusion: Patients with CLD experienced a substantial burden of COVID-19 pandemic on their daily lives regardless of actual infection history. Self-reported health scores were lower in patients with history of COVID-19 infection.

THU235

Associations of food insecurity and fast-food consumption with diet quality in adults with non-alcoholic fatty liver disease in a large population-based U.S. cohort

Ani Kardashian[1], Jennifer Dodge[1,2], Norah Terrault[1]. [1]*University of Southern California, Division of Gastrointestinal and Liver Diseases, Los Angeles, United States;* [2]*University of Southern California, Department of Population and Public Health Sciences, Los Angeles*
Email: ani.kardashian@med.usc.edu

Background and aims: Food insecurity (FIS) impacts the quality of foods consumed and is associated with greater risk of non-alcoholic fatty liver disease (NAFLD). While racial-ethnic disparities in NAFLD risk have been reported, the interplay between FIS, diet quality (DQ) and fast food (FF) consumption in different racial-ethnic groups with NAFLD has not been explored.
Method: A cross-sectional analysis of adults (≥20 years) in the U.S. National Health and Nutrition Examination Survey 2017–2018 with valid transient elastography and food security (FS) measurements using the U.S. Department of Agriculture Food Security Survey Module was performed. NAFLD was defined as controlled attenuated parameter score≥280 decibels/meter without other known liver disease. Diet quality (DQ) was assessed by the healthy eating index (HEI)-2015 (score range 0–100), with poor DQ defined as <25th percentile of possible scores. We used multivariable linear and logistic regression to examine associations of FIS, FF consumption, and race/ethnicity with DQ and its individual components.
Results: In total, 1, 420 adults had NAFLD, of whom 520 (37)% were food insecure. Food insecure compared to food secure adults were more likely to be non-Hispanic (NH) black (11% vs 7%), Hispanic (33% vs 13%), foreign born (28% vs 15%), live in poverty (31% vs 4%), or have public/no insurance (59% vs 27%). Mean (standard error) DQ score was 49.1 (0.9) and 46.7 (1.2) for food secure and insecure groups, respectively. Controlling for age, gender, race/ethnicity, poverty, education, and alcohol use, FIS was associated with a 2.5-unit lower DQ score, though did not reach statistical significance (95%CI:-5.7 to 0.7). However, FF consumption was associated with a – 0.7 unit lower DQ score (per additional FF meal consumed weekly; 95%CI:-1.0 to – 0.4). NH blacks (+2.9 units, 95%CI[0.3–5.4]), NH Asians (+9.3[5.1–13.6]), and Hispanics (+5.2[1.1–9.2]) all had significantly better overall mean DQ than NW whites. Odds ratios of poor DQ for individual components are shown in the table. NH blacks, Asians, and Hispanics had lower odds of saturated fat consumption compared to NH whites, but differences between groups were also seen for total vegetables, whole fruits, whole grains, and total protein. The largest differences in individual DQ components by FS were seen among NH whites; in this group, food insecure (vs secure) adults had a greater proportion of poorer scores for seafood/plant proteins (60% vs 46%) and added sugars (29% vs 11%).

Table. Multivariable logistic regression* evaluating the association of race/ethnicity with odds of poorer diet quality components compared to NH Whites

Race/ ethnicity	Total vegetables	Whole fruits	Whole grains	Total protein	Saturated fats	Added sugars
	OR (95% CI)	OR (95% CI)	OR (95% CI)	OR (95% CI)	OR (95% CI)	OR (95% CI)
NH white	reference	reference	reference	reference	reference	reference
NH black	1.06 (0.76-1.48)	0.94 (0.51-1.73)	1.04 (0.55-1.97)	1.07 (0.56-2.07)	**0.37 (0.25-0.56)**	1.13 (0.68-1.87)
NH Asian	0.80 (0.40-1.60)	**0.44 (0.22-0.89)**	**0.50 (0.27-0.94)**	**2.74 (1.03-7.29)**	**0.41 (0.18-0.91)**	0.64 (0.27-1.56)
Hispanic	**0.59 (0.36-0.94)**	**0.40 (0.22-0.73)**	0.99 (0.60-1.63)	0.67 (0.20-2.22)	**0.40 (0.26-0.62)**	0.66 (0.37-1.17)

*model also controlled for food security status, poverty, age, gender, education level, alcohol use

Conclusion: There was a trend towards worse DQ in food insecure adults with NAFLD. Fast-food consumption was also associated with lower DQ in NAFLD. NH whites had the lowest DQ with food insecurity potentiating poor DQ. Exploration of the sociocultural factors contributing to the observed differences in DQ by race/ethnicity may offer the potential opportunity to mitigate NAFLD disparities and reduce disease burden.

THU236

Implementation of HCV screening in the 1969–1989 birth-cohort undergoing COVID-19 vaccination: a pivotal study in Italy

Roberta D'Ambrosio[1], Giuliano Rizzardini[2], Massimo Puoti[3], Stefano Fagiuoli[4], Maria Paola Anolli[1], Claudia Gabiati[5], Federico D'Amico[3], Luisa Pasulo[4], Massimo Colombo[6], Pietro Lampertico[1,7]. [1]*Foundation IRCCS Ca' Granda Ospedale Maggiore Policlinico, Gastroenterology and Hepatology, Milan, Italy;* [2]*ASST Fatebenefratelli-Sacco, First Division of Infectious Diseases, Milan, Italy;* [3]*ASST Grande Ospedale Metropolitano Niguarda, Division of Infectious Diseases, Milan, Italy;* [4]*AAST Papa Giovanni XXIII, Gastroenterology, Hepatology and Transplantation, Bergamo, Italy;* [5]*ASST Fatebenefratelli-Sacco, Internal Medicine, Italy;* [6]*Ospedale San Raffaele, Liver Center, Milan, Italy;* [7]*University of Milan, CRC "A. M. and A. Migliavacca" Center for Liver Disease, Department of Pathophysiology and Transplantation*
Email: roberta.dambrosio@policlinico.mi.it

Background and aims: The World Health Organization (WHO) goal of hepatitis C virus (HCV) elimination by 2030 relies on the scaling-up of policies of both identification and treatment of the infected population, worldwide. In Italy, it has been estimated that at least 200, 000 people are unaware of their HCV infection thus reinforcing the need for broadening population access to effective screening programs.
Method: A pivotal screening program targeting subjects born between 1969 and 1989 has been conducted in Lombardy, Northern Italy, where point-of-care (POC) testing was offered for free concomitantly to COVID-19 vaccination.
Result: Overall, 7, 219 subjects underwent HCV screening in 4 vaccination hubs. Characteristics of the screened cohort and pivotal strategies are reported in Table. Seven (0.1%) subjects tested anti-HCV positive and 5 (0.07%) were HCV-RNA positive by standard confirmation tests. Patients with HCV infection were all males, aged 41–46 years; only one of them came from Italy. Clinical data were available for 3 patients: all of them have altered transaminases, without HBV or HIV co-infection; HCV genotypes were 1b, 3 and 4, and liver stiffness ranged between 4.5 and 10.3 kPa. All patients underwent DAA therapies.

Table: Pivotal screening strategies according to each participating Center

	Milan Policlinico (N = 4, 000)	Milan FBF-Sacco (N = 1, 222)	Milan Niguarda (N = 1, 000)	Bergamo (N = 997)
Time spent for screening program, hours	53	25	128	16
Daily vaccinations§				
Any birth-cohort	7, 081 (5, 833–9, 440)	1, 803 (427–1, 978)	694 (260–894)	2, 365 (2, 080–2, 650)
1969–1989 birth-cohort	2, 726 (2, 077–3, 447)	766 (183–923)	336 (80–605)	1, 355 (1, 325–1, 385)
Proposed anti-HCV POC	4, 721	1, 629	NA	1, 575
Accepted anti-HCV POC	4, 000 (85%)	1, 222 (75%)	1, 000 (NA %)	997 (63%)
Age, years	42 (32–52)	44 (32–52)	44 (32–52)	43 (32–52)
Males	1, 840 (46%)	745 (61%)	432 (43%)	NA
Screening Team (per day)	9–12	5–6	2–3	9–11
Physicians	3–4	2	1	2
Nurses	3–4	2–3	0–1	3–4
Others	3–4 Research Assistants	1 Auxiliary Nurse	0–1 Research Assistant	4–5 Volunteers*
Anti-HCV positive by POC test	6 (0.15%)	0	0	1 (0.10%)
Lost to follow-up after POC test	1 (0.01%)	–	–	0
Anti-HCV positive by confirmatory test	4 (0.10%)	–	–	1 (0.10%)
HCV-RNA positive	3 (0.08%)	–	–	1 (0.10%)

Results are reported as number (n) and percentages (%) or median (range).
HCV: Hepatitis C Virus; POC: Point-of-Care; NA: Not Available
§refers only to screening days, in each vaccination hub;
*all from patients' alliance

Conclusion: This pivotal study demonstrated the feasibility of a POC-based anti-HCV screening program in young adults undergoing

COVID-19 vaccination. The prevalence of HCV infection in subjects born in the 1969–1989 cohort in Italy seems to be lower than previously estimated, thus raising the question whether more HCV carriers can be identified if screening is moved up to embrace subjects born before 1969.

THU237

Real life pooling of plasma samples for hepatitis C RNA detection as a screening strategy of hepatitis C active chronic infection

A. Aguilera[1,2,3], M. Cea[1,2,3], A. Fuentes[4,5], S. Pereira[1,2,3], L. Vinuela[4,5], Federico Garcia Garcia[4,5,6]. [1]*University Hospital of Santiago de Compostela, Microbiology, Santiago de Compostela, Spain;* [2]*University of Santiago de Compostela, Microbiology, Santiago de Compostela, Spain;* [3]*Instituto de Investigación Sanitaria de Santiago, Santiago de Compostela, Spain;* [4]*University Hospital Cinic San Cecilio, Microbiology, Granada, Spain;* [5]*Instituto de Investigación Biosanitario Ibs. Granada, Granada, Spain;* [6]*Ciber Enfermedades Infecciosas ISCIII, Granada*
Email: antonio.aguilera.guirao@sergas.es

Background and aims: The diagnosis of active hepatitis C virus (HCV) infection is the necessary first step for its elimination. In most countries, universal population screening and/or screening by age groups have not been adopted due to cost and cost-effectiveness considerations. Here we show a real-life sample pooling diagnosis strategy to overcome this challenge, and to contribute to increase the diagnostic capacity of clinical laboratories and expand access to massive screening of hepatitis C.

Method: we have analyzed consecutive samples submitted to microbiology services of CHUS (Santiago de Compostela, Spain) and HUCSC (Granada, Spain) for hepatitis C diagnosis during the first three weeks of November 2022. Samples were tested for HCV antibodies and, in parallel and in a blinded way, were pooled into 100 samples with the following strategy: first, 10 pools of 10 samples were built (a); second, two pools comprising five of the previous were made (b); finally, these two were pooled together and tested for HCV-RNA using Cobas® HCV 6800 (Roche Diagnostics) at CHUS and both Xpert HCV Viral load (Cepheid) and Cobas® HCV 6800 at HUCSC. When positive, the previous two pools (b) were tested and after, a strategy to unmask the positive (s) sample (s) that needed up to 15 total HCV-RNA tests was used.

Results: A total of 1700 samples (17 pools) were analyzed, 800 at CHUS and 900 at HUCSC. The overall anti HCV and HCV-RNA prevalence was 0, 24% (4/1700). After our pooling strategy, we could detect all samples previously detected by standard diagnosis (anti-HCV followed by reflex HCV-RNA testing). While 13 master pools were negative, we needed to unmask 4 master pools, resulting in 60 total HCV-RNA tests to finally unmask the positive sample for each master pool. Specificity and sensitivity of the pooling strategy were 100%. Given median current prices on the market in Spain for anti-HCV (3€) and HCV-RNA (30€), testing with the pooling strategy would have resulted in 3420 € save (5220 € by traditional testing vs 1800 € by the pooling strategy), and a cost of 1, 05€ per patient screened.

Conclusion: The strategy of pooling samples for the diagnosis of active HCV infection has advantages that should be exploited with the aim of eliminating HCV as a public health threat. Here we demonstrate that in settings with a low prevalence of chronic infection, by substantially improving cost-effectiveness, this strategy enables and provides the necessary sustainability for use in large-scale diagnosis of HCV.

THU238

Epidemiology of hepatocellular carcinoma in Portugal

Mario Jorge Silva[1,2], Guilherme Simões[1], Rita Catarina Saraiva[1], Filipe Calinas[1], Paulo Nogueira[3,4,5,6]. [1]*Centro Hospitalar Universitário Lisboa Central, Gastroenterology, Lisboa, Portugal;* [2]*NOVA Medical School, Lisboa, Portugal;* [3]*Faculdade de Medicina da Universidade de Lisboa, Instituto de Medicina Preventiva e Saúde Pública, Lisboa, Portugal;* [4]*Faculdade de Medicina da Universidade de Lisboa, Instituto de Saúde Ambiental, Lisboa, Portugal;* [5]*Faculdade de Medicina da Universidade de Lisboa, Área Disciplinar Autónoma de Bioestatística;* [6]*Universidade NOVA de Lisboa, NOVA National School of Public Health, Comprehensive Health Research Center*
Email: mariojorgesilva01@gmail.com

Background and aims: There is scarce data on the burden of hepatocellular carcinoma (HCC) in Portugal. We aim to characterize the recent epidemiology of HCC in Portugal.

Method: We evaluated HCC-related hospital admissions and mortality in Portugal between 2010 and 2017. We analyzed all hospital admissions from patients with HCC in public hospitals (data from Portuguese Health System's Central Administration) and mortality due to HCC (data from National Statistics Institute)-coded with 155.0 (International Classification of Diseases-ICD-9-CM) or C22.0 (ICD-10). Additional analyses were performed to evaluate longitudinal trends and regional differences.

Results: Between 2010 and 2017, there were 20, 704 hospital admissions of patients with HCC, ranging annually from 2, 086 in 2010 to 2, 989 in 2015. In-hospital mortality rate during admission was 16.7%.

Considering individual patients admitted with HCC, the number of patients admitted annually varied from 1, 046 in 2010 to 1, 560 in 2017. 7, 739 individual patients were admitted during the 8-year period: 80.1% males and with mean age 66 ± 12.2 years.

In the whole country, both in-hospital and ambulatory, the annual number of deaths ranged from 471 in 2010 to 620 in 2017 (4, 316 deaths during the 8 years). Potential years of life lost ranged annually from 2477 in 2010 to 3838 in 2017.

Annual number of admissions, admitted patients, mortality and potential years of life lost are detailed in the table.

The mean annual mortality rate due to HCC, considering the 8-year period, was 5.2/100, 000 inhabitants (9.0/100, 000 inhabitants among males and 1.8/100, 000 inhabitants among females). The highest regional mortality rate was observed in the Lisbon metropolitan area (6.3/100, 000 inhabitants overall, 11.2/100, 000 inhabitants among males and 2.0/100, 000 inhabitants among females).

	2010	2011	2012	2013	2014	2015	2016	2017	Longitudinal trend 2010–2017 (p value)
Hospital admissions (n)	2086	2600	2425	2641	2694	2989	2793	2476	(p = 0.125)
Admitted patients (n)	1046	1205	1220	1376	1371	1511	1560	1410	Increasing (p = 0.003)
Deaths (n)	461	557	558	496	535	536	553	620	(p = 0.073)
Potential years of life lost (n)	2477	3215	3340	2955	3228	3005	3013	3838	(p = 0.126)

Conclusion: The burden of HCC in Portugal is high and had an increasing trend between 2010 and 2017.

THU239

"Zero C" hospital project: an innovative screening and referral model in hospitalized patients at different divisions

Valerio Rosato[1], Loreta Kondili[2], Riccardo Nevola[1], Alessio Aghemo[3], Pasquale Perillo[1], Ruben Napolitano[4], Antonio Sciambra[5], Davide Mastrocinque[1], Ernesto Claar[1]. [1]*Ospedale Evangelico Betania, Liver Unit, Naples, Italy;* [2]*Istituto Superiore di Sanità, Center for Global Health, Roma, Italy;* [3]*Humanitas Clinical and Research Center IRCCS, Division of Internal Medicine and Hepatology, Department of Gastroenterology, Rozzano, Italy;* [4]*Ospedale Evangelico Betania, Laboratory Medicine Unit, Naples, Italy;* [5]*Ospedale Evangelico Betania, Health Management, Naples, Italy*
Email: valeriorosato@gmail.com

Background and aims: Chronic hepatitis C is a major public health problem in Southern Italy. Screening strategies in key populations and birth cohort 1969–1989 has been addressed for free of charge screening in Italy. However, larger birth population cohorts need to be screened due to expected high HCV prevalence. We conducted a hospital-based mass screening in order to assess the HCV active infection prevalence and address the feasibility of the opportunistic screening in the linkage to care of the infected patients.
Method: From January 2020 to May 2021 all consecutive in-patients were screened for HCV antibody (HCV Ab) at hospital admission throughout all divisions in the Evangelic Hospital Betania of Naples. HCV-Ab positive patients were evaluated for previous HCV treatment. HCV RNA testing was required for those not previously treated. In patients with active infection the linkage to care and treatment start were planned within the hospital admission.
Results: Of 12.665 inpatients consecutively screened, 510 (4%) were HCV Ab positive. The HCV Ab positivity increased with age with the highest prevalence in those born before 1947 (9, 49%). In each birth cohort, 20–30% of patients have been previously treated whereas 30–45% were discharged and not tested for HCV RNA. 194 (38% of HCV +) patients were tested for HCV RNA and 91 patients (46.2%) had active HCV infection. 87 patients were treated during hospital admission, while 4 were not evaluated for treatment due to severe comorbidities. All patients treated achieved sustained virological response at week 12 (SVR 12). Among HCV RNA tested patients, 47% of 1969–1989 birth cohort, 35% of 1948–1968 birth cohort and 53% of those born before 1947 had active infection. Among 91 HCV RNA positive patients, 33 (36%) were admitted to liver unit for known liver damage without being HCV diagnosed or linked to care (all, except one, were born before 1968). The remaining 58 patients were admitted for comorbidities in cardiology, internal medicine, ophthalmology, surgery, orthopedics, senology and intensive care unit. Among them, 49 (54%) belonged to patients born before 1968 and 9 (10%) to 1969–1989 cohort. All available patients underwent linkage to care and treatment start during hospital admission. (Figure 1)

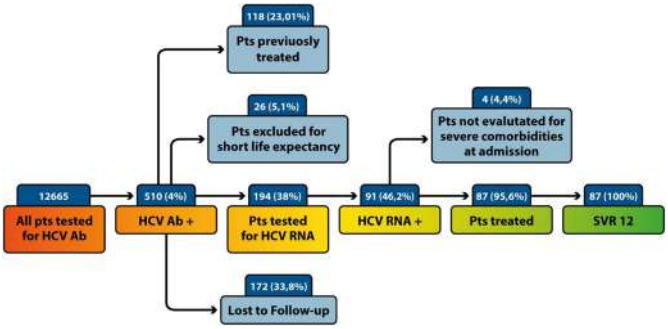

Figure 1: A care cascade during the opportunistic screening in Evangelic Hospital Betania of Naples (Italy) 2010–2020.

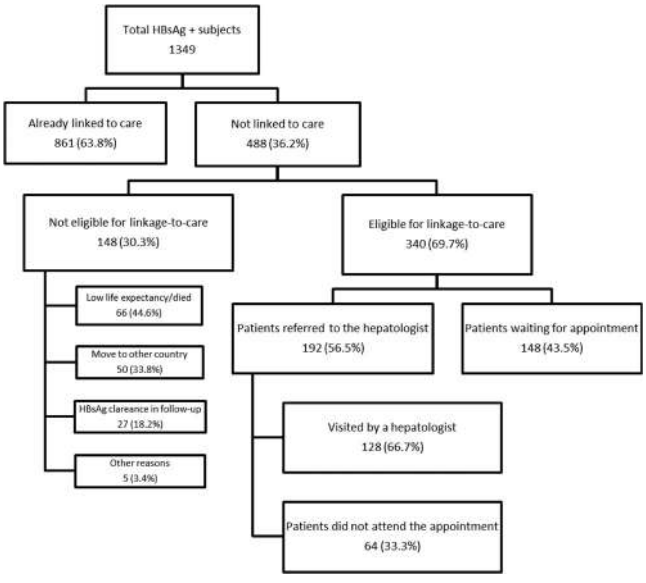
Conclusion: A high prevalence of active infection is observed in patients with comorbidities in Southern Italy. The possibility of active infection testing in less than 50% of HCV Ab positive patients underline the importance of reflex testing for identifying active infection. HCV elimination requires increase of screening in patients who are unaware of the HCV status, but also of the screening and linkage to care in those with known liver damage yet unaddressed.

THU240

LINK-B: a hepatitis B program to test and link to care patients lost of follow-up

Ana Barreira[1,2], Ariadna Rando-Segura[3], Anna Feliu-Prius[1], Francisco Rodríguez-Frías[2,3], Elena Vargas Accarino[1], Judit Vico-Romero[1], Mar Riveiro Barciela[1,2], Adriana Palom[1], Rafael Esteban[1,2], Maria Buti[1,2]. [1]*Hospital Universitario Vall de Hebrón, LIver Unit;* [2]*Instituto de Salud Carlos III., Centro de Investigación Biomédica en Red de Enfemerdades Hepáticas y Digestivas (CIBERehd);* [3]*Hospital Universitario Vall de Hebrón, Microbiology Department*
Email: mbuti@vhebron.net

Background and aims: Hepatitis B affects more than 250 million people worldwide. In Spain an estimated 320, 000 people are living with hepatitis B. Most HBsAg-positive individuals are not linked to care in our setting, and this is an obstacle to receiving treatment and controlling hepatitis B in the population. The primary aim of this research was to promote adequate linkage-to-care and treatment of HBsAg-positive individuals lost to follow-up.
Method: This is a single-center retrospective and prospective search of all HBsAg-positive cases in the microbiology database of the Northern Health Area of Barcelona (450, 000 inhabitants). The retrospective phase included all HBsAg cases seen between 2018 and 2020 and the prospective phase covered January 2021 to end 2022. Medical records were reviewed to identify and retrieve HbsAg-positive cases not linked to care. Candidates for contacting were called to offer disease assessment.
Results: Here, we present the data from January 2018 to end April 2019 (retrospective), and the first month of 2021 (prospective). In total, 1349 HBsAg-positive individuals were detected by the laboratory. The flowchart of patients is summarized in the Figure. After the initial assessment, 192 patients were referred to a hepatologist: 128 (66.7%) attended the visit and 33.3% did not. Overall baseline characteristics: mainly males (57.8%), median age 45 (± 14) years. Overall, 82.3% (152) were inactive carriers, 6 HBeAg-positive chronic hepatitis, 4 immune-tolerant and 12 (6.3%) could not be classified in a single determination. Baseline characteristics were similar between patients who attended the visit and those who did not.



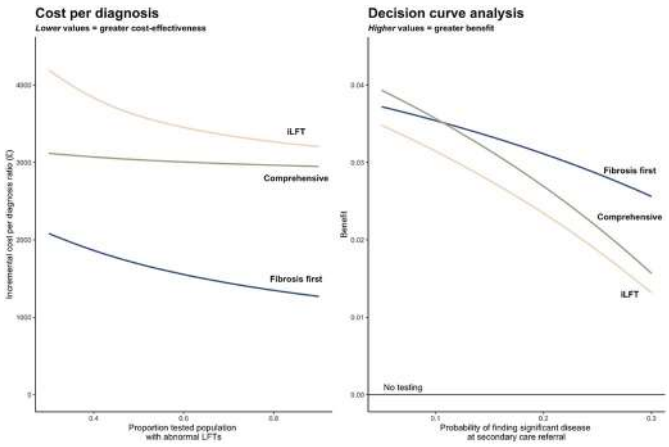
Conclusion: The link B strategy showed that more than one-third of known HBsAg-positive individuals had not been linked to care, and enabled the retrieval of a large number of patients.

THU241

Testing for liver disease in primary case: fibrosis first

Ian Rowe[1,2], Richard Parker[2]. [1]*University of Leeds, Leeds Institute for Medical Research, United Kingdom;* [2]*St James's Hospital, Leeds Liver Unit, United Kingdom*
Email: i.a.c.rowe@leeds.ac.uk

Background and aims: The optimal method to identify persons with liver disease in primary care is unknown. Approaches to diagnose all persons with abnormal liver blood tests, e.g. intelligent liver function tests (iLFT), or screening all those with specific risk factors have been proposed but each incompletely identifies the population being tested in primary care. The aim of this study was to define testing strategies to identify persons with treatable liver disease and/or advanced fibrosis in primary care using unified pathways.
Method: A decision model was developed to assess 3 approaches to testing in comparison to the current practice of limited testing for liver disease and liver fibrosis in primary care. The outcomes considered were the incremental cost per diagnosis ratio and the net benefit of each pathway. Diagnosis was defined by treatable liver disease (viral hepatitis, metabolic liver disease, or autoimmune liver disease) and advanced fibrosis (in the case of alcohol-related liver disease or non-alcoholic fatty liver disease). The tested approaches were: 1. "iLFT" (full aetiology testing of persons with abnormal LFTs); 2. "Comprehensive" (full aetiology testing for abnormal LFTs and non-invasive fibrosis tests for all persons tested); 3. "Fibrosis first" (abbreviated aetiology testing [HBV, HCV, iron studies] and non-invasive fibrosis testing for all). These approaches were compared with current practice patterns where 20% of persons with newly abnormal LFTs undergo downstream testing. Parameters were estimated from literature data and costs were derived from the UK NHS.
Results: All tested approaches identified more persons with treatable liver disease ± advanced liver fibrosis than the current standard of care. In the base case scenario, where 80% of the tested population had abnormal LFTs, the fibrosis first approach made a diagnosis of treatable disease/advanced fibrosis in 3.9% of the total population compared with 3.8% for iLFT and 4.3% in the comprehensive approach. Fibrosis first had the lowest incremental cost per diagnosis ratio: fibrosis first, £1349 (€1590); iLFT £3247 (€3828); and comprehensive, £2964 (€3494). The number of secondary care referrals was increased in all approaches above current testing, greatest in the comprehensive strategy. Considering these trade-offs the net benefit was greatest for the fibrosis first approach (Figure).



Conclusion: Current testing for liver disease is inadequate. Pathways that streamline testing, including testing of persons with normal liver blood tests but that are at risk of significant liver disease, will increase the yield of testing for liver disease in primary care. A "fibrosis first" pathway, taking a fast and frugal approach to identify persons with prognostically significant liver disease, warrants testing in comparison to comprehensive evaluation in primary care.

Hepatitis C care cascade analysis among adult women in Georgia

Ketevan Stvilia[1], Shaun Shadaker[2], Amiran Gamkrelidze[3], Irma Khonelidze[3], Maia Tsereteli[3], Vladimer Getia[3], Paige A Armstrong[2]. [1]*National Center for Disease Control and Public Health, Tbilisi, Georgia;* [2]*Centers for Disease Control, Department of Viral hepatitis, United States;* [3]*National Center for Disease Control and Public Health, Tbilisi, Georgia*
Email: stviliak@gmail.com

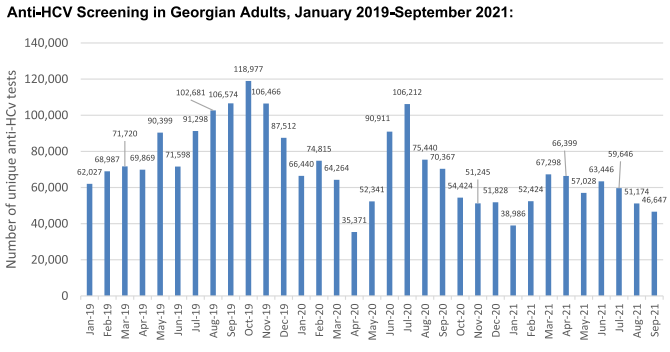
Background and aims: According to the National HCV seroprevalence study of 2015, 3.8% of women in Georgia are positive for hepatitis C virus (HCV) antibodies; however, female-targeted interventions to promote HCV testing and treatment have been lacking. Further, women of reproductive age can transmit HCV during pregnancy, making outreach to this population particularly important. We constructed the HCV care cascade for women age ≥18 years, screened for anti-HCV within the National Hepatitis C Elimination Program during January 2015-October 2021 to compare progress in care and treatment and to assess gaps in the cascade of HCV care and treatment.
Method: The seven stages of HCV care recommend by WHO were assessed for women who tested positive for anti-HCV: (1) HCV antibody positive; (2) tested for viremia; (3) confirmed active infection; (4) initiated HCV treatment; (5) eligible for test for sustained virologic response (SVR), (6) tested for SVR and (7) achieved SVR. HCV care cascade results were assessed for women by age group to define gaps, and proportion retained at each step in the care cascade.
Results: As of October 2021, 2.1 million adults with known sex were screened for anti-HCV, including 1.1 million women. Among them, 38, 881 (3.4%) were positive for anti-HCV, and the majority (65.0%) were aged ≥50 years. Overall, 77.3% of women who screened anti-HCV positive were tested for viremia. The positivity rate for active HCV infection was 73.2% (21, 978) among all females, ranging from 62.7% among those aged 18–29 years to 75.8% among those aged 40–49 years. Overall, 76.1% (16, 729) of women with HCV viremia initiated treatment, including 63.0% of women aged ≥60 years, and ≥84.0% of women in all other age groups. Of women enrolled in treatment, 95.6% (15, 986) completed the regimen, and 98.2% of those women were eligible for an SVR test. Women have demonstrated high uptake of SVR testing; 82.0% were tested for SVR across all age groups with an overall cure rate of 99.4%.
Conclusion: To reach elimination of hepatitis C by 2025 it is important to improve access to and support uptake of viremia testing and enrollment in treatment among anti-HCV positive women in Georgia, with special attention to ensuring the large proportion of anti-HCV positive women over 50 years complete viremia testing. Once enrolled in treatment, Georgian women with active HCV infection show high rates of compliance resulting in more than 99% of cases cured.

THU243

Progress in HCV screening in the national hepatitis C elimination program in Georgia during the COVID-19 pandemic, 2019–2021

Amiran Gamkrelidze[1], Alexander Turdziladze[1], Maia Tsreteli[1], Vladimer Getia[1], Ana Aslanikashvili[1], Tinatin Kuchuloria[2], Irina Tskhomelidze[2], Sophia Surguladze[2], Lia Gvinjilia[3], Senad Handanagic[4], Shaun Shadaker[4], Paige A Armstrong[4]. [1]*National Center for Disease Control and Public Health Georgia, Tbilisi, Georgia;* [2]*The Task Force for Global Health, Tbilisi, Georgia;* [3]*Eastern Europe and Central Asia (EECA) Regional Office, Centers for Disease Control and Prevention, Tbilisi, Georgia;* [4]*Division of Viral Hepatitis, Centers for Disease Control and Prevention, Atlanta, United States*
Email: a.gamkrelidze@ncdc.ge

Background and aims: Georgia, with a population of 3.7 million, had an estimated 150, 000 adults living with chronic hepatitis C virus (HCV) infection based on a serosurvey conducted in 2015. The same year, the country initiated the world's first national HCV elimination program, with free screening and treatment available to all citizens. Despite great progress, the COVID-19 pandemic has created new challenges for the program. This analysis describes the progress made in HCV screening since program initiation and the impact of the COVID-19 pandemic on HCV screening.
Method: The Hepatitis C Elimination Program tracks testing and treatment data using two databases, the national HCV Screening Registry, and the HCV treatment database. These databases are linked by the national ID. This analysis uses data from both databases and the 2014 general population census.
Results: As of September 30th, 2021, 2, 081, 548 adults have been screened for antibody to HCV (anti-HCV) (75% of the adult population), of whom 144, 857 (6.9%) were anti-HCV positive. Overall, 118, 398 (81.7%) anti-HCV positive individuals received follow-up viremia testing, and 94, 315 (79.7%) were found to have active HCV infection. The number of anti-HCV tests performed among adult persons dropped as restrictions were imposed in March of 2020 from 74, 815 tests in February 2020 to just 35, 371 in April of the same year. Screening increased in the summer, with 106, 212 tests performed in July, due in part to relaxed restrictions and intensified integrated screening programs (HCV, tuberculosis, and HIV). Compared to 2019, the number of tests performed in 2020 decreased by 24% (1, 048, 108 vs. 793, 658). As the pandemic progresses, the number of tests performed for HCV during January – September 2021 remained lower than in the same period in 2020 (503, 048 vs. 636, 161).



Conclusion: Although the program has made significant progress towards HCV elimination, the ongoing pandemic has led to a decline in screening for HCV infection, with numbers continuing to decline in 2021. In response, Georgia intends to increase integrated screening, and seek active approaches to link patients to HCV care and treatment. The impact of the pandemic on the HCV elimination program demonstrates how a pandemic can be challenging for different public health programs and highlights the need to employ innovative strategies to avoid slowing of progress towards HCV elimination.

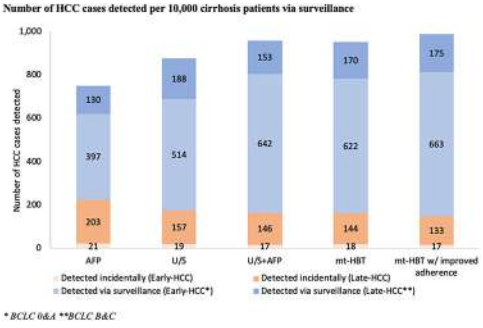
Could a multi-target blood test make hepatocellular carcinoma surveillance programs more effective? A modelling-based virtual trial

Jagpreet Chhatwal[1,2,3], Sumeyye Samur[4], Ju Dong Yang[5], Lewis Roberts[6], Mindie Nguyen[7], A. Burak Ozbay[8], Turgay Ayer[9,10], Neehar D. Parikh[11], Amit Singal[12]. [1]*Harvard Medical School, Boston, United States;* [2]*Mass General Hospital, Boston, United States;* [3]*Harvard Medical School, Boston, United States;* [4]*Value Analytics Labs, Boston, United States;* [5]*Cedars-Sinai Medical Center, Los Angeles, United States;* [6]*Mayo Clinic, Rochester, United States;* [7]*Stanford University School of Medicine, Stanford, United States;* [8]*Exact Sciences Corporation, Madison, United States;* [9]*Georgia Institute of Technology, Atlanta, United States;* [10]*Emory University-School of Medicine, Atlanta, United States;* [11]*University of Michigan Medical School, Ann Arbor, United States;* [12]*UT Southwestern, Dallas, United States*
Email: jagchhatwal@mgh.harvard.edu

Background and aims: Hepatocellular carcinoma (HCC) is among the fastest rising causes of cancer mortality in the Western world. Although guidelines recommend biannual ultrasound (U/S)-based HCC surveillance in at-risk patients, utilization in practice remains poor in practice. A recently validated, multi-target HCC blood test (mt-HBT), may potentially improve adherence to surveillance by forgoing the need for U/S. Our objective was to evaluate the comparative effectiveness of mt-HBT with the current surveillance strategy in cirrhosis patients.
Method: We simulated a virtual trial by developing a clinically valid microsimulation model of HCC natural history in compensated cirrhosis patients. Model parameters, including tumor progression, competing risks of mortality, and real-world adherence, were estimated from the literature. Test performance characteristics of U/S, AFP, and mt-HBT were informed from a network meta-analysis. We simulated the life course of cirrhosis patients and compared biannual surveillance using (1) AFP only, (2) U/S only, (3) U/S+AFP, and (4) mt-HBT only. We also simulated a scenario where mt-HBT would improve adherence by 10% (~4% absolute improvement) compared to current utilization.
Results: Per 10, 000 cirrhosis patients simulated in each arm, mt-HBT detected 225 (+57%) more early-stage HCC cases compared with AFP, 108 (+21%) more early-stage HCC compared with U/S, and 20 (-3%) less early-stage HCC compared with U/S+AFP. In contrast, mt-HBT with improved adherence detected 21 (+3%) more early-stage HCC compared with U/S+AFP (Figure). The remaining HCC cases were either symptomatically identified or patients died from competing causes prior to detection. mt-HBT increased life years by 709 per 10, 000 patients screened compared with AFP, 360 compared with U/S, but decreased life years by 19 compared with U/S+AFP. Of note, mt-HBT with improved adherence increased life years by 52 compared with U/S+AFP.



Conclusion: mt-HBT as a single blood test offers similar diagnostic efficacy for early HCC detection compared with the combination of U/S+AFP. Potential improved adherence with use of blood-based biomarkers, such as mt-HBT, would likely further increase real-world effectiveness of HCC surveillance.

Evaluation of immune response and disease flares in metabolic-associated fatty liver disease patients following SARS-CoV-2 vaccination: a prospective cohort study

Junping Shi[1], Qianru Zhu[2,3], Jin Gao[4], Jiaping Gu[5], Lu Shen[5], Jing Liu[6], Yu Song[7], Xiying Gong[7], Yutong Chen[5], Jie Liao[7], Yining He[5], Siyi Zhang[5], Li Shao[3,5], Yee Hui Yeo[8], Jie Li[9,10]. *[1]The Affiliated Hospital of Hangzhou Normal University, Department of Hepatology and infectious Disease, Hangzhou, China; [2]Macau University of Science and Technology, Faculty of Chinese Medicine, Macau, China; [3]The Affiliated Hospital of Hangzhou Normal University, Department of Translation Medicine Platform, Hangzhou, China; [4]The Affiliated Hospital of Hangzhou Normal University, Department of Clinical Laboratory, Hangzhou, China; [5]Hangzhou Normal University, Medical college, Hangzhou, China; [6]The Affiliated Hospital of Hangzhou Normal University, Department of Hepatology and infectious Disease, Hangzhou, China; [7]Zhejiang Chinese Medical University, The Fourth School of Clinical Medicine, Hangzhou, China; [8]Cedars-Sinai Medical Center, Division of General Internal Medicine, United States; [9]Nanjing University, Institute of Viruses and Infectious Diseases, Nangjing, China; [10]The Affiliated Hospital of Nanjing University Medical School, Department of Infectious Diseases, Nangjing, China*
Email: 20131004@hznu.edu.cn

Background and aims: The safety and efficacy profile of Covid-19 vaccines in patients with MAFLD (metabolic associated fatty liver disease) remains unclear. We aimed to determine the safety and immunogenicity of an inactivated vaccine in MAFLD.
Method: In this prospective cohort, 50 participants with MAFLD and 114 healthy controls received two doses of CoronaVac with a 28-day interval between doses and underwent blood sample collection on days 0, 28, 57, and 180. Baseline vibration-controlled transient elastography as well as the level of neutralizing antibody against the SARS-CoV-2 spike receptor-binding domain, fasting metabolic markers, and liver function test on four assessment dates were assessed. Repeated measures ANCOVA was used to estimate the magnitude of change of these markers throughout study period.
Results: No significant difference in proportion of patients with neutralizing antibody was observed between two groups. The proportions of adverse event and liver injury was similar between both groups. There was no difference between the two groups in the change of most biomarkers throughout study period. On multivariable analysis, age and waist circumference were negatively associated with seropositivity of neutralizing antibody on day 57 while RBC and lymphocyte count were independent positive predictors on day 180 (Table).

Table: Factors associated with seropositive of neutralizing antibody on days 57 and 180, respectively.

Conclusion: CoronaVac vaccination in MAFLD patients was safe and well tolerated. MAFLD patients showed a similar immune response to health controls.

THU246

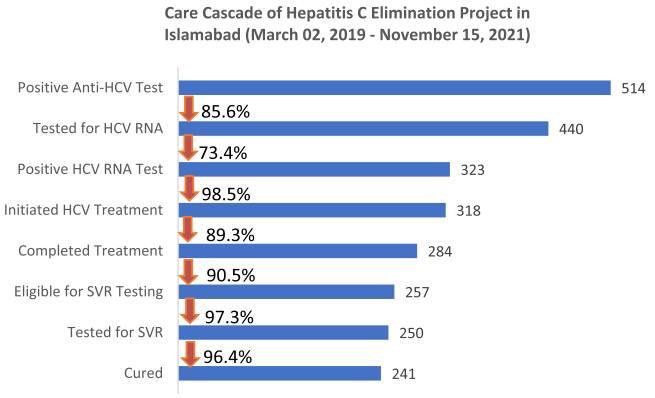
A model, screen test and treat hepatitis C elimination project among under-served communities in Islamabad-the federal capital of Pakistan

Huma Qureshi[1], Hassan Mahmood[2], Nabil Ahmed[3], Lillian Lou[4], Francisco Averhoff[5], Ameer Abutaleb[6], Shyamasundaran Kottilil[6]. *[1]Integral Global (IG), Pakistan; [2]Integral Global (IG), Public Health, Islamabad, Pakistan; [3]Integral Global (IG), Atlanta, United States; [4]John C. Martin Foundation, United States; [5]Abbott Diagnostics, United States; [6]University of Maryland, United States*
Email: drhumapmrc@gmail.com

Background and aims: Pakistan has a large burden of hepatitis C virus (HCV) infection, and access to care and treatment is limited. In order to increase access for underserved populations, a same-day testing and treatment initiation model program for adults in marginalized communities (i.e *slums*) in Islamabad was launched on March 02, 2019. We describe the results of the program.
Method: A total of 17 slums with an estimated total population of 50,000 in Islamabad have been selected by the Ministry of National Health Services, Regulations and Coordination for the project. This project includes free hepatitis C testing and treatment and utilizes trained community health workers (CHWs). The CHWs visit every dwelling in the slum and offer household members aged ≥18 years screening for hepatitis C by a rapid hepatitis C antibody (anti-HCV) test. Those that test positive are referred to an established clinic for diagnosis of active HCV infection (RNA) by GeneXpert. RNA results are made available to patients within two hours. If found to be HCV RNA Positive, the Aspartate to Aminotransferase (AST) to Platelet Ratio Index (APRI) is calculated, subjects receive counseling, and their first 4-week supply of sofosbuvir plus daclatasvir and the first of three doses of hepatitis B vaccine during the initial clinic visit. A treatment regimen of 12 weeks for non-cirrhotic (APRI<1.5) patients is prescribed. Patients with an APRI ≥1.5 are referred to specialists.

Patients are seen every 4 weeks at the clinic and given refills on their medications and queried about adverse reactions, until the end of treatment. RNA testing is conducted at 12 weeks following completion of treatment to determine viral clearance (cure). The CHWs ensure referral and follow-up of HCV infected persons.

Results: As of November 15, 2021; a total of 24, 216 participants have been screened from seventeen *slums*, 514 (2.12%) tested positive for anti-HCV and were referred to receive testing for HCVRNA. Of those, 440 (85.6%) got tested for HCV RNA and 323 (73.4%) had detected RNA. Three hundred and eighteen individuals (98.5%) had initiated treatment, of which 284 (89.3%) had completed treatment. To date, 257 (90.5%) patients are eligible to test for Sustained Virologic Response (SVR), out of which 250 (97.3%) were tested; 241 (96.4%) were HCV RNA negative, four (1.6%) were loss to follow-up and five patients were (2%) HCV RNA positive. Those five patients were given Sofosbuvir and Velpatasvir and are on treatment.



Conclusion: Same day hepatitis C testing and treatment initiation is feasible among underserved communities in urban slums in Pakistan. CHWs can be effective in reaching "*hard-to-reach*" populations with limited access to health services and achieving high rates of linkage to care and adherence with treatment for hepatitis C.

THU247

Hepatitis B and hepatitis C testing practices and seroconversions among dialysis facilities in Georgia

Maia Butsashvili[1], George Kanchelashvili[1], Ana Aslanikashvili[2], Tinatin Kuchuloria[3], Shaun Shadaker[4], Irina Tskhomelidze[3], Maia Tsereteli[2], George Kamkamidze[1], Priti Patel[4], Paige A Armstrong[4]. *[1]Health Research Union, Tbilisi, Georgia; [2]National Center for Disease Control and Public Health, Tbilisi, Georgia; [3]The Task Force for Global Health, Tbilisi, Georgia; [4]Centers for Disease Control and Prevention, Atlanta, United States*
Email: maiabutsashvili@gmail.com

Background and aims: Hemodialysis can facilitate transmission of hepatitis C and hepatitis B as a result of a large number of patients receiving treatment in a shared space. Strict adherence to infection prevention and control practices is essential to prevent transmission through contaminated equipment and surfaces. Despite a comprehensive hepatitis C Elimination Program in Georgia, there is currently no system in place to adequately capture the prevalence of chronic HBV infection or chronic HCV infection and to promptly identify cases of HCV and HBV seroconversion among persons receiving dialysis. This study evaluates HCV and HBV testing practices among patients receiving dialysis and estimates the number of seroconversion cases in dialysis units in Georgia.

Method: All 27 dialysis centers in the country were invited to participate. Facility questionnaires were completed by the infection control representatives at each center from April to June, 2021. Respondents were asked about HBV and HCV screening practices, and the number of seroconversions among facility patients in the preceding year. Data entry, management and analyses were conducted using the statistical package SPSS v.22.0.

Results: A total of 22 (81.5%) dialysis centers participated in the survey. HBV screening is routinely performed upon admission at 21 facilities (95.5%). Susceptible patients are routinely vaccinated with the hepatitis B vaccine at about half (13; 59.1%) of facilities. Anti-HCV screening is performed at 15 institutions (68.2%) upon admission to the center, and anti-HCV screening is performed once every 6 months in 12 (54.5%) clinics for patients who were previously anti-HCV negative.

Ten (45.5%) of the dialysis facilities included in the study reported HBV and HCV seroconversions in the prior year. A total of 31 HBV seroconversions from 8 facilities and 39 HCV seroconversions from 7 facilities occurred. The largest number in a single facility was 25 total seroconversions of HBV or HCV infection.

Conclusion: The high seroconversion rate of HBV and HCV infections at dialysis units suggests opportunities for improved infection prevention practices and need for increased hepatitis B vaccination efforts. Surveillance could help identify cases and clusters early and contribute to preventing infection in this high-risk population.

THU248

Innovative linkage model to re-engage loss-to-follow-up individuals in the national hepatitis C elimination program of Georgia

Amiran Gamkrelidze[1], Alexander Turdziladze[1], Maia Tsreteli[1], Vladimer Getia[1], Ana Aslanikashvili[1], Sophia Surguladze[2], Irina Tskhomelidze[2], Shaun Shadaker[3], Paige A Armstrong[3]. *[1]National Center for Disease Control and Public Health Georgia, Tbilisi, Georgia; [2]The Task Force for Global Health, Tbilisi, Georgia; [3]Division of Viral Hepatitis, National Center for HIV, Viral Hepatitis, STD and TB Prevention, CDC, Atlanta, United States*
Email: a.gamkrelidze@ncdc.ge

Background and aims: The National Hepatitis C Elimination Program has made notable progress in Georgia. However, in the setting of COVID-19 related limitations, the number of individuals registering in the treatment program has declined over time, from an average of 996 per month in 2019 to 339 per month in 2021. As of September 30, 2021, 75% (n = 2, 081, 548) of the adult population of Georgia has been screened for hepatitis C virus (HCV), but among antibody positive adults, 20, 913 (15%) had not completed a viremia test.

In 2019, the National Center for Disease Control and Public Health Georgia piloted a project to link to care those individuals who screened positive for anti-HCV but had not completed a viremia test. After success of the initial pilot, the model will be scaled up across Georgia.

Method: All anti-HCV positive adults (aged ≥18 years) who did not have record of viremia testing in the national HCV electronic database 3 months from the date of a positive result, and who were not registered in the HIV/AIDS program or with a correctional facility, were eligible for follow-up.

Using the phone number listed in the database, individuals were contacted by phone or home visit by patient navigators (trained epidemiologists and primary healthcare physicians) and referred to HCV care and treatment. If the first attempt was unsuccessful, one repeat attempt was made to contact the individual. Incentives were

provided to regional health personnel for each patient that was successfully linked to care, defined as presenting for viremia testing.
Results: As of October 1, 2020, 18, 030 persons were not linked to care; patient navigators attempted to reach 8, 907 (49%) with phone numbers in the database; 6, 718 (75%) were reached. The remaining 2, 189 could not be reached, had moved, or emigrated. Of those contacted, 1, 546 (23%) presented for viremia testing, and 811 (52%) were positive for HCV RNA or core antigen. Overall, 419 (52%) persons with chronic HCV infection were enrolled in the HCV treatment program as a result of this effort.
Conclusion: Program-wide implementation of the piloted model showed that this can be scaled up and is effective for re-engaging people in care. The main challenge in Georgia remains linkage-to-care, which is essential to meet elimination goals. Innovative approaches are necessary to reinforce linkage to care. This is especially important during the COVID-19 pandemic when there is an increased need for programs that can re-engage people in HCV care.

Email: Jeffrey.Lazarus@isglobal.org

Background and aims: The COVID-19 pandemic has hindered efforts to address HIV and hepatitis c virus (HCV) by reducing testing, particularly in marginalised groups, who have some of the highest rates of HIV and HCV and lowest rates of COVID-19 vaccination. This study aimed to explore the acceptability of combining HIV and HCV testing with COVID-19 vaccination in a mobile testing unit (MTU) in Madrid, Spain.
Method: From 9/28/2021 to 10/26/2021, 101 individuals from high-risk populations (e.g., homeless people, those with substance use and/or mental disorders, sex workers, refugees, undocumented migrants) were invited to get the COVID-19 vaccine at the MTU. If HCV antibody (Ab) positive, they were offered HCV-RNA point-of-care testing to confirm active infection. HIV and HCV-RNA-positive patients were offered linkage to care.
Results: All 101 participants accepted the combined intervention of which 69.3% were male, 30.7% of Spanish origin, most reported a precarious living situation or being homeless (59.4%) and being unemployed (70.3%), and 28.7% a history of incarceration. The mean age was 35.6 (SD: 11.9). Of the total, 11.9% reported a previous COVID-19 diagnosis, none had been vaccinated for COVID-19 and all subsequently received the Janssen vaccine without any adverse events (Figure). All individuals were tested for HIV and HCV Ab and 8.9% (n = 9) and 14.9% (n = 15) tested positive, respectively. Of those HIV positive, none were new diagnoses, and most (55.6%, n = 5) had abandoned antiretroviral therapy. Of those HCV Ab positive, all were tested for HCV-RNA and 60.0% (n = 9) tested positive, of which most (55.6%, n = 5) reported that the most likely route of transmission was injecting drug use, 44.4% (n = 4) were reinfection cases and 33.3% (n = 3) were HIV co-infected. Everyone with an active infection was offered linkage to care and to date 44.4% (n = 4) have started treatment for HCV. The average intervention duration was 20 minutes (minimum: 7; maximum: 60).

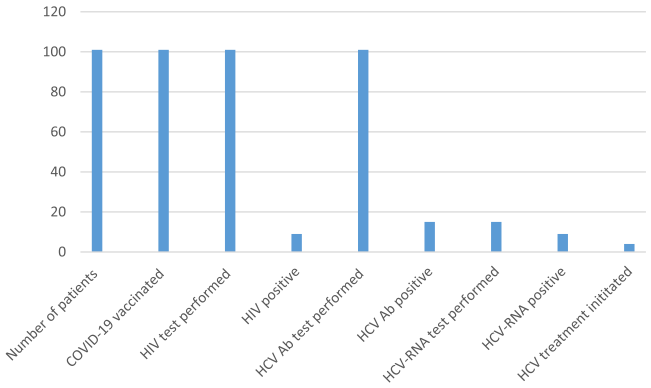

Figure: Analysis of the combined COVID-19 vaccination and HIV and HCV screening intervention at the MTU in Madrid
Abbreviations: Ab, antibody; HCV, hepatitis C virus; MTU, mobile testing unit.

Conclusion: Combining HIV and HCV testing with COVID-19 vaccination in high-risk individuals at the MTU was effective, with an acceptability rate of 100%, and safe since there were no adverse events. The process was also efficient, since it maximised the use of time that participants would have spent waiting for HIV and/or HCV test results or post-vaccine administration. This intervention can serve as an example of a novel model of care to increase HIV and HCV screening and linkage to care as well as COVID-19 vaccination in high-risk populations.

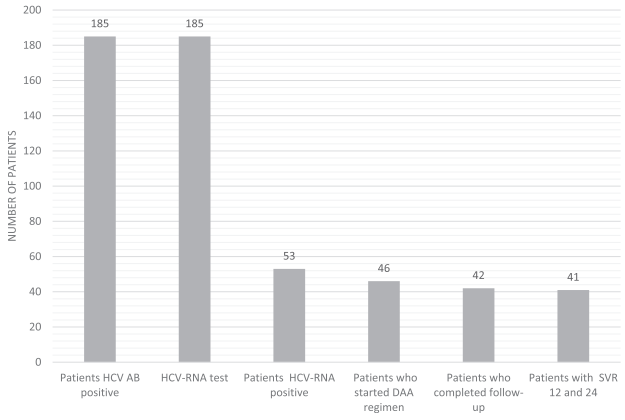
THU250

A model to eradicate HCV in undocumented migrants and low-income refugees in Italy

Mariantonietta Pisaturo[1], Margherita Macera[2], Loredana Alessio[2], Stefania de Pascalis[2], Lorenzo Onorato[1], Maria Stanzione[2], Gianfranca Stornaiuolo[2], Vincenzo Messina[3], Nicola Coppola[1]. *[1]university of Campania L.vanvitelli, mental health and preventive medicine, Naples, Italy; [2]Vanvitelli hospital, Naples, Italy; [3]Caserta Hospital, Caserta, Italy*
Email: mariantonietta.pisaturo@unicampania.it

Background and aims: To validate an innovative eradication model for HCV infection in undocumented migrants and low-income refugees living Southern Italy.
Method: a prospective, multicenter, collaborative study was started in June 2018 with The study was stopped in February 2020 due to the outbreak of SARS-CoV-2 infection in Italy and was resumed in February 2021. At the six 1st level centers participating to the study volunteer associations that deal with the first needs of disadvantaged people performed the enrolment and the screening for anti-HCV, HBsAg and anti-HIV; epidemiological data were collected in an electronic database. Anti-HCV-positive subjects were sent to two 3rd level centers for the clinical, virological and therapeutic evaluation. For the HCV-RNA-positive subjects HCV genotyping and a clinical, biochemical and ultrasound staging was performed. The HCV RNA-positive subjects have been treated with sofosbuvir-velpatasvir for 12 weeks and followed for 12 months from the end of therapy.
Results: Of the 3, 991 migrants observed in the study period, 3, 897 (97.6%) accepted to be screened. They were young (median age 26 years), predominantly male (85.9%) and came from North Africa (3.8%), from Sub-Saharan Africa (68.4%), from Eastern Europe (8.1%), from Indo-Pakistan (17%) and from other countries (2.7%). Of the 3, 897 enrolled subjects, 185 (4.7%) resulted anti-HCV positive. The Figure shows the HCV-cure cascade. All the 185 anti-HCV-positive subjects were linked to care at 3rdID and tested for HCV RNA and 53 (28.6%) resulted HCV-RNA positive. Of these, 46 (86.8%) started DAA regimen with sofosbuvir plus velpatasvir (15 with GT 1b, 10 with 1a, 16 with 3, 3 with 4 and 2 with 2). Forty-two completed the follow-up and 4 was still pending. Of these 42 subjects, 41 (97.6%) showed a

SVR12 and SVR 24, and one dropped-out in follow-up after the stop of DAA treatment. No subject had adverse event.



Conclusion: This model seems to be effective to eradicate HCV infection among a difficult-to-manage population, such as undocumented migrants and low-income refugees

THU251

Enhancing the cascade of hepatitis C care in community-recruited high-risk people who inject drugs during the COVID-19 pandemic: the Alexandros program

Vana Sypsa[1], Sotiris Roussos[2], Efrossini Tsirogianni[3,4], Despina Trafali[5], Dimitra Tsiagka[5], Athena Gavalaki[5], Zafiris Papanikolaou[5], Ioanna Papagiouvanni[3,5], Athena Tampaki[5], Dimitrios Paraskevis[2], George Kalamitsis[6], Ioannis Goulis[7], Angelos Hatzakis[1,5]. *[1]Medical School of National and Kapodistrian University of Athens, Department of Hygiene, Epidemiology and Medical Statistics, Athens, Greece; [2]Medical School of National and Kapodistrian University of Athens, Department of Hygiene, Epidemiology and Medical Statistics, Athens, Greece; [3]Fourth Department of Internal Medicine, Hippokratio Hospital, Aristotle University of Thessaloniki; [4]Greek Organisation Against Drugs; [5]Hellenic Scientific Society for the Study of AIDS and Sexually Transmitted Diseases and Emerging Diseases, Athens, Greece; [6]Hellenic Liver Patients Association "Prometheus"; [7]Fourth Department of Internal Medicine, Hippokratio Hospital, Aristotle University of Thessaloniki, Thessaloniki, Greece*
Email: vsipsa@med.uoa.gr

Background and aims: Despite the availability of effective treatment for chronic hepatitis C, treatment initiation rates remain low among People Who Inject Drugs (PWID) worldwide, especially among those not linked to opioid substitution treatment programs (OST). A community-based program was implemented in Thessaloniki (the second largest city in Greece) during September 2019-August 2021 with the aim to screen for HCV/HIV and improve access to care among high-risk PWID. We aim to provide data on the cascade of HCV care in this population.
Method: ALEXANDROS was a "seek-test-treat" community-based program where PWID were recruited using peer-driven chain referral with monetary incentives (Respondent-Driven Sampling). The program was implemented in five consecutive rounds during September 2019-August 2021 and PWID could participate in multiple rounds but only once in each round. Participation included interviewing, counselling, rapid HCV/HIV test and blood sample collection for testing of anti-HCV (+) participants (HCV genotype/biochemical evaluation). PWID eligible for DAAs with available social security number were entered to the national HCV treatment registry and visited the program site for their prescriptions and assessment of sustained virological response. The personnel of the program, including a peer-navigator, assisted patients through all stages.
Results: In total, 1, 101 unique PWID were recruited. The majority of participants were current PWID (54.0% with injection in the past 30 days), 15.0% were homeless and 79.7% were not linked to OST. Anti-HCV prevalence was 62.9% and 6.9% were HCV/HIV coinfected. Only 9.7% of anti-HCV (+) PWID reported previous treatment with DAAs. Chronic HCV prevalence in anti-HCV (+) PWID was 67.6%. Among PWID which chronic HCV monoinfection, it was possible to identify the social security number for 97.4% of them, 96.9% were entered to the national HCV treatment registry to apply for free treatment with DAAs, 61.8% were linked to HCV care and 53.6% initiated treatment by September 2021.
Conclusion: Despite the disruptions due to the COVID-19 pandemic, ALEXANDROS was successful in reaching rapidly a population of PWID most in need (current injectors, homeless, low OST coverage) and in offering HCV testing, linkage to care as well as in encouraging HCV treatment initiation.

THU252

SVR4 and SVR12 monitoring by using dried blood spot test: is it the best alternative for people who use drugs?

Andrea Herranz[1], María Victoria Fernández-Baca[2], Maria Dolores Macia Romero[3], María Paz Díaz[2], Maria Carmen Gallegos Alvarez[2], Ricardo M Arcay[3], Francisco Salvà[3], Adoración Hurtado[4], Maria Buti[5,6], Àngels Vilella[7], Jeffrey Lazarus[1,8]. *[1]Barcelona Institute for Global Health (ISGlobal), Hospital Clínic, University of Barcelona, Barcelona, Spain; [2]Hospital Universitari Son Llàtzer, Microbiology Service, Palma, Spain; [3]Hospital Universitari Son Espases, Microbiology Service, Palma, Spain; [4]Hospital Can Misses, Microbiology Service, Eivissa, Spain; [5]Universitari Vall d'Hebron, Liver Unit, Barcelona, Spain; [6]Instituto Carlos III, CIBER Hepatic and Digestive Diseases (CIBERehd), Madrid, Spain; [7]Hospital Universitari Son Llàtzer, Department of Gastroenterology, Palma, Spain; [8]University of Barcelona, Faculty of Medicine, Barcelona, Spain*
Email: Jeffrey.Lazarus@isglobal.org

Background and aims: People who use drugs (PWUD) are one of the key at-risk population groups for hepatitis C virus (HCV) infection and typically have difficulties in being linked to care and are often lost to follow-up. The *Hepatitis C Free Balears* project carries out micro-elimination strategies to facilitate the screening, treatment and follow-up of this population.
Method: This project has been implemented in 13 of 17 addiction service centres in the Balearic Islands and consists of four phases: 1) recruitment and HCV screening onsite via a point-of-care anti-HCV antibody test (Oraquick®) and a dried blood spot (DBS) test or blood analysis to confirm viremia (HCV-RNA) and detect HBsAg and HIV antigen/antibody; 2) linkage to care; 3) treatment prescription via telemedicine; and 4) monitoring onsite via DBS test of sustained virological response (SVR) at 4 and 12 weeks after treatment and for reinfection monitoring after a year. DBS samples are analyzed in the microbiology laboratories of the two majors Balearic hospitals with chemiluminescent technology for the serological determinations and reverse transcription-polymerase chain reaction assay for the HCV viral load quantification.
Results: Out of 395 recruited patients, 150 (38%) were anti-HCV+, 1 (0.3%) was HBV-Ag+, 25 (6%) were anti-HIV+ and 60 (15%) had an active HCV infection. Of these 60, 43 (73%) initiated treatment, 17 (28%) are pending and 21 (35%) have already finished it. SVR4 and SVR12 monitoring were performed in 15 (75%) and 5 (25%) of those patients who completed treatment, respectively. Three (14%) SVR4 and three (14%) SVR12 tests were not performed, as the patients did

not show up at the settled appointments, and 3 (14%) SVR4 tests and 13 (62%) SVR12 tests are pending. The 93% (n = 14) SVR4 monitoring tests and the 100% (n = 5) SVR12 monitoring tests showed undetectable HCV-RNA. At the moment, only four patients performed both SVR4 and SVR12 tests, and all of them had concordant results.
Conclusion: DBS testing has been proven to be an alternative for HCV screening in PWUD by the *Hepatitis C Free Balears* team, since it is performed onsite and facilitates screening of drug users who otherwise would have not either reached or received care. It is also useful as a follow-up control method, since it simplifies circuits and reduces difficulties faced by PWUD. Although the SVR4 and SVR12 control tests results were concordant, more data are needed to know if the SVR4 control performed with DBS test is an alternative to lost to follow-up of this vulnerable population.

THU253

Collateral benefit of Georgia national hepatitis C elimination program-improving blood transfusion safety in the country of Georgia

Maia Alkhazashvili[1], Evan Bloch[2], Shaun Shadaker[3], Tinatin Kuchuloria[4], Tamar Samadashvili[1], Vladimer Getia[1], Alexander Turdziladze[1], Jan Drobeniuc[3], Paige A Armstrong[3], Amiran Gamkrelidze[1]. *[1]National Center for Disease Control and Public Health of Georgia, Tbilisi, Georgia; [2]Johns Hopkins School of Medicine, Baltimore, United States; [3]Centers for Disease Control and Prevention, Atlanta, United States; [4]The Task Force for Global Health, Tbilisi, Georgia*
Email: doctormaiko@gmail.com

Background and aims: In 2015, a national seroprevalence survey identified blood transfusion as a risk factor for transmission of hepatitis C virus (HCV) and hepatitis B virus (HBV) in Georgia. Based on recommendations from the HCV elimination program's Technical Advisory Group, the EU-funded Technical Assistance and Information Exchange (TAIEX) with the support of the Global Fund, centralized nucleic acid testing (NAT) was implemented at the Richard Lugar Center for Public Health Research at the National Center for Disease Control and Public Health, Tbilisi, Georgia.
Method: One year of blood donor screening data (January-December, 2020) was analysed from the Unified Electronic Donor Database. Two samples were collected from all donors, one for primary serological testing by blood centers, and a second for NAT using the Procleix®Ultrio Elite Assay (multiplex for HCV, HBV, and HIV). In the event of a discordant result between NAT and serology (NAT positive, serology negative), additional discriminatory testing was performed. A subset of the discordant samples was retested using ARCHITECT i2000SR immunoassay for HBV surface antigen, HBV core antibody, HCV antibody, and HIV 1/2 Ab/Ag.
Results: A total of 54, 116 donations representing 39, 164 unique donors were evaluated. Overall, 671 donors (1.7%) tested positive for at least one infectious marker by serology or NAT. Sixty donations were serology/NAT discordant (serology-/NAT+). Discordance was more likely among females vs. males (adjusted odds ratio [aOR] 2.06; 95% confidence interval [95%CI]: 1.05–4.05), paid (aOR 10.15; 95%CI: 2.80–36.86) or voluntary (aOR 4.30; 95%CI: 1.27–14.56) vs. replacement donors, and repeat vs. first time (aOR 13.98; 95%CI: 4.06–48.12) donors. After repeat serologic testing was performed to confirm blood center reported results, a total of 12 donations (6 HBV+ donations, 5 HCV+ donations and 1 HIV+) were deemed NAT yield and would not have been detected with serology. Out of the total 54, 116 donations, the final NAT yield rate was 1 in 9, 019 for HBV, 1 in 10, 823 for HCV, and 1 in 54, 116 for HIV.

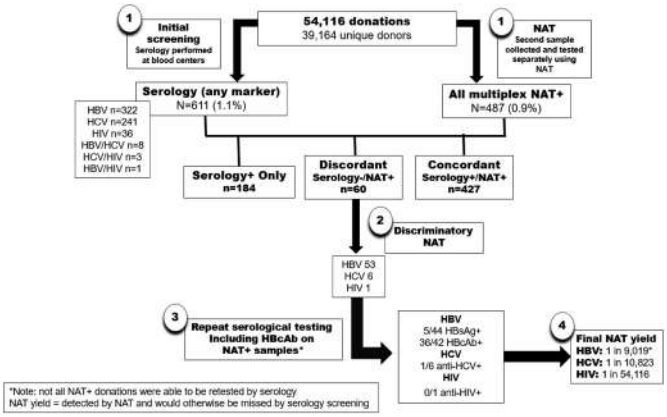


Figure: Study overview of testing and composition and results

Conclusion: This project offers a regional model for NAT implementation, demonstrating the feasibility and clinical utility in a nationwide blood screening program. NAT is resource intensive and expensive to implement system-wide, and may not be feasible in all settings. Balancing cost and yield is important, and countries with high prevalence may benefit more from NAT testing implementation.

THU254

Outcomes of a community led comprehensive HCV and HBV care provision model, including same-day "test and treat" to facilitate micro-elimination of HCV among people who inject drugs in Manipur, India

Khumukcham Lokeshwar Singh[1], Thangjam Dhabali[2], Rajkumari Rosie[3], Rajkumar Nalinikanta[4], Samurailatpam Rajesh Sharma[1], Sanjay Sarin[5], Giten Khwairakpam[6], Sonjelle Shilton[5]. *[1]Jawaharlal Nehru Institute of Medical Sciences, Manipur, India; [2]Babina Diagnostics, Manipur, India; [3]Department of Health Services, Government of Manipur, India; [4]CoNE, Manipur, India; [5]FIND, the global alliance for diagostics, Geneva, Switzerland; [6]TREAT Asia/amfAR, Thailand*
Email: sonjelle.shilton@finddx.org

Background and aims: The prevalence of hepatitis C virus (HCV) infection among people who inject drugs (PWID) in the state capital of Manipur, India, is 65%; however, access to and uptake of HCV care is poor, largely due to lengthy pre-treatment processes. We piloted a community-led, comprehensive, simplified hepatitis care model that includes same-day HCV testing and treatment initiation ("test and treat") at drug rehabilitation centres in Manipur, to expand access to care for chronic hepatitis.
Method: Participants were screened using HCV antibody (Ab) and hepatitis B virus (HBV) surface antigen (HBsAg) rapid diagnostic tests. Positive HCV Ab samples were tested using a point of care platform for HCV RNA (Molbio TrueNat). HCV RNA-positive participants eligible for treatment under national guidelines were initiated on sofosbuvir and daclastasvir on the same day and are followed until tests of cure (SVR). Participants who were HBsAg negative received HBV vaccine per the WHO rapid regimen. Positive HBsAg samples were sent to a referral lab for HBV DNA tests; and will be referred for treatment per national guidelines.
Results: Between 12–22 November 2021, 133 individuals were approached, of whom 103 (77%) were eligible and all consented to participate. To date, 98 (95%) participants have been screened; all were male and identified as PWID and had a median age of 27 (IQR 22–32) years. A total of 39 (40%) were HCV Ab positive; all were tested for HCV RNA, of whom 24 (61.5%) were HCV RNA positive. Of those with viremia, 23 (96%) were initiated on treatment on the same day,

with 1 awaiting HBV DNA results to be initiated on treatment. The median time from screening to HCV treatment initiation was 8 hours and 12 minutes (range 6:03–9:58). First SVR tests for sustained virologic response are due in April 2022. A total of 6 (6.1%) were HBsAg-positive. Of the 92 participants with negative HBsAg tests, 89 (97%) had not previously been vaccinated and all have completed at least 1 dose of the HBV vaccine.

Conclusion: Preliminary results show that community led comprehensive hepatitis care which incorporates same day "test and treat" for HCV is feasible and effective in this context. HBV screening identified a large proportion who had not been vaccinated. Additional follow-up and implementation research would inform how this model could be replicable in other settings to increase equity in access to HCV and HBV screening, treatment, and prevention.

THU255

A novel hepatitis C intervention in Denmark to test and treat people who inject drugs

Jeffrey Lazarus[1,2], Anne Øvrehus[3], Jonas Demant[4], Louise Krohn-Hehli[5], Jannet van der Veen[4], Nina Weis[5,6]. *[1]Barcelona Institute for Global Health (ISGlobal), Hospital Clínic, University of Barcelona, Barcelona, Spain; [2]University of Barcelona, Faculty of Medicine, Barcelona, Spain; [3]Odense University Hospital, Odense, Denmark; [4]Users Academy, Copenhagen, Denmark; [5]Copenhagen University Hospital, Department of Infectious Diseases, Hvidovre, Denmark; [6]University of Copenhagen, Department of Clinical Medicine, Faculty of Health and Medical Sciences, Copenhagen, Denmark*
Email: Jeffrey.Lazarus@isglobal.org

Background and aims: Providing testing and treatment for hepatitis C (HCV) for people who inject drugs (PWID) is critical in eliminating HCV, but reaching this population with traditional healthcare services can be challenging. Combining point-of-care (PoC) testing with peer support and counselling is a model of care (MoC) that can be effective for PWID. This study aims to investigate if a peer-led mobile van equipped with rapid PoC tests for HCV antibodies (Ab) and RNA could simplify testing and link PWID to care and treatment.

Method: In Copenhagen, Denmark, a peer-led mobile service providing counselling, Ab testing (In-Tec™) and linkage to standard of care was equipped with a PoC HCV-RNA finger-prick test (Xpert HCV Viral Load Finger-Stick Point-of-Care Assay, Cepheid). Eligible HCV-RNA+ individuals were offered assisted referral to a fast-track hospital clinic for evaluation and treatment, with peer support available if needed.

Results: From 1 May 2019 to 25 October 2021, 1013 people were tested for HCV-RNA and 10.2% (n = 103) were positive. Nine additional individuals with HCV infection contacted the service to be linked to care. Of the 112 individuals with chronic HCV infection, 72.3% (n = 81) were evaluated for treatment at the hospital clinic, of whom 86.4% (n = 70) initiated direct-acting antiviral therapy and 3.7% (n = 3) are waiting to initiate treatment. Major reasons for not being evaluated for treatment included being undocumented (38.7%; n = 12) and being lost to follow-up (32.3%; n = 10). Among those who initiated treatment, 20.0% (n = 14) were connected to drug addiction treatment services. The peer-led service assisted all treated with communication with the hospital nurse, collection of treatment medicine and accompaniment to follow-up visits.

Conclusion: We found that a peer-led mobile PoC service is an MoC that can engage PWID in HCV testing and link them to treatment, even during the COVID-19 pandemic. We identified being an undocumented migrant as a major cause for not accessing care. This poses a challenge for HCV elimination in Denmark due to the risk of onward transmission. Next steps include engaging with health authorities to provide care for these migrants.

THU256

Peer-led hepatitis C services reach poorly served populations at scale: a model for tackling health inequalities

Leila Reid[1], Rachel Halford[1,2], Stuart Smith[1], Sean Cox[1]. *[1]The Hepatitis C Trust, London, United Kingdom; [2]World Hepatitis Alliance, Geneva, Switzerland*
Email: leila.reid@hepctrust.org.uk

Background and aims: England's approach to HCV elimination includes significant involvement-including leadership-from people with lived experience of hepatitis C. This is unique worldwide, and is proving very effective, in particular in engaging, diagnosing and treating groups typically excluded from health services. This large-scale, national programme bears out emerging evidence on peer-based models for tackling health inequalities.

Method: England's elimination programme tasked drug companies to not only treat but find people with HCV. This responds to a key challenge in the UK and many other countries: most people with HCV are hard to engage and undiagnosed.

Led by The Hepatitis C Trust, a national charity led by people with lived experience, England's HCV peers work together nationally as well as forming part of local NHS HCV delivery networks to engage marginalised populations. Launched in 2019, the model has three core components:

Peer Support: at its core, HCT provide patient support from another person (a peer) with lived experience of HCV, drug use and/or prison. The Peer provides a bespoke approach, support from testing to diagnosis to treatment and with other conditions.

Partnership: collaboration is paramount to improving systems. Working closely with services and clinicians, HCT's peer workers shorten pathways, ensure accessible clinics, improve patient understanding, and move services ever closer to those who need them most.

Patient-centred innovation: developed from patient feedback, HCT places the needs of people with HCV at the centre, regularly seeking feedback, adapting and innovating to reach new populations.

Results: Since 2019 HCT's peer teams have:

engaged almost 75, 000 people at risk of HCV: 33, 324 through outreach and 39, 333 in prisons.

Trained 15, 401 health, care and prison staff

tested 18, 467 people in the community, and 17, 691 in prison. 15% of community tests find markers for current/past HCV (prison data is being collated).

Received 6, 517 referrals for support

62% have started treatment, and 94% for whom an SVR has been obtained (n = 1018) are cured

Feedback is consistently positive; patients highlight one to one relationships, shared experience and trust as pivotal to engagement.

Conclusion: HCT's highly assertive outreach, partnership-based model has seen peers embedded in NHS and prison systems. Links across the peers-who work as part of regional teams and as a national body-generates innovation, rapid sharing of good practice and excellent reach.

People experiencing marginalisation and often very complex needs engage with the peer model, often their first experience of sustained service engagement.

This is an effective, transferable and likely cost-effective approach (a study is planned), which stimulates both system-level and individual-level change, both positively impacting health inequalities.

THU257

Cost-effectiveness of integrated treatment for hepatitis C virus among people who inject drugs in Norway: an economic evaluation of the INTRO-HCV trial

Aaron G. Lim[1], Christer F. Aas[2,3], Ege Su Çağlar[2,3], Jørn-Henrik Vold[2,3], Lars Thore Fadnes[2,3], Kjell Arne Johansson[2,3], Peter Vickerman[1].
[1]University of Bristol, Population Health Sciences, Bristol Medical School, United Kingdom; [2]Haukeland University Hospital, Norway; [3]University of Bergen, Norway
Email: aaron.lim@bristol.ac.uk

Background and aims: People who inject drugs (PWID) have the highest burden of hepatitis C virus (HCV) globally, but are often undertreated due to stigma and lack of access to services. Implementing efficient treatment algorithms for PWID is required to reach this population. The INTRO-HCV randomised control trial conducted in Norway over 2017–2019 found that integrating HCV treatment, using direct-acting antivirals (DAAs), into community settings improved treatment outcomes, but did not compare the longer-term health economic benefits. This study analyses the cost-effectiveness of integrated treatment compared to the standard referral pathway of care.
Method: A health state transition Markov model of HCV disease progression and treatment was developed based on the INTRO-HCV trial. Treatment cost and outcome data were analysed from the trial. Parameters related to disease progression came from published literature. The incremental cost-effectiveness ratio (ICER) was calculated in terms of cost per quality-adjusted life year (QALY) gained from the health provider's perspective over a lifetime horizon and compared against a conventional (NOK 500, 000) willingness-to-pay (WTP) threshold for Norway. Probabilistic and univariate sensitivity analyses were undertaken.
Results: Preliminary results suggest that compared to the standard treatment pathway, integrated treatment resulted in an ICER of NOK 305, 000 per QALY gained, with an 80.7% probability of being cost-effective against the conventional WTP threshold. Sensitivity analyses suggest that the cost of DAA medications strongly affected the ICER, with a 30% lower DAA price resulting in integrated treatment having an ICER of NOK 176, 000 per QALY gained and a 95.8% probability of being cost-effective. A 60% lower DAA price led to an ICER of NOK 10, 400 per QALY gained, with a 99.8% probability of being cost-effective and a 42.4% probability of being cost-saving.
Conclusion: Integrating HCV treatment for PWID in community settings is likely to be highly cost-effective and may become cost-saving even with moderate reductions in DAA price.

THU258

Characterization of HCV recent infections and re-infections among high-risk population from Georgia using global hepatitis outbreak and surveillance technology

Adam Kotorashvili[1], Amiran Gamkrelidze[1], Nato Kotaria[1], Maia Tsereteli[1], Ana Papkiauri[1], Ketevan Galdavadze[1], Maia Alkhazashvili[1], Paata Imnadze[1], Tinatin Kuchuloria[2], Lilia Ganova-Raeva[3], Sumathi Ramachandran[3], Saleem Kamili[3], Shaun Shadaker[3], Paige A Armstrong[3], Yury Khudyakov[3]. *[1]National Center for Disease Control and Public Health (NCDC), Tbilisi Georgia, Georgia; [2]The Task Force for Global Health, Tbilisi, Georgia; [3]Centers for Disease Control and Prevention (CDC), Atlanta, GA, United States*
Email: adam.kotorashvili@gmail.com

Background and aims: Global Hepatitis Outbreak and Surveillance Technology (GHOST), is a novel technology that identifies transmission links between specimens, creating a graphic display. GHOST was developed by the Centers for Disease Control and Prevention, and the National Center for Disease Control and Public Health of Georgia became the first GHOST center outside of the United States.
The study aimed to gain insight into the variability of the hepatitis C virus (HCV) and potential transmission networks using GHOST in recently seroconverted and reinfected cases in persons who inject drugs (PWID) in selected Georgian harm reduction (HR) sites.
Method: GHOST uses next-generation deep sequencing of Hyper Variable Region 1 (HVR1) of HCV. Genotypes of the HCV strains were determined by HVR1 sequence data analysis. Two HR sites in the cities of Tbilisi and Zugdidi were selected. Samples were collected from HR beneficiaries with documented reinfection or seroconversion. All participants provided written informed consent for participation and completed a questionnaire on the relevant epidemiological information.
Overall, 58 people with a history of injecting drugs were invited to participate, including 33 (57%) in Tbilisi and 25 (43%) in Zugdidi; 52% agreed to participate (n = 30/58).
Results: Among the 30 enrolled participants, 17 (57%) had HCV reinfection and 13 (43%) seroconverted during the observation. In the 6 months prior to the study, 27 participants (90%) reported injecting drugs and 3 (10%) reported needle sharing. Among reinfected participants (n = 17), one (6%) received a blood transfusion, 13 (76.4%) had an invasive medical procedure, and 4 (23.5%) were incarcerated. Among participants with new infection, 5 (38.4%) received blood transfusion, 8 (62%) had an invasive medical procedure more than 1 year ago, and 5 (38%) were incarcerated prior to seroconversion.
Genotype 1a was predominant (n = 8, 44%), followed by 2k/1b recombinant (n = 4, 22%), 2a (n = 3, 17%), 2c (n = 2, 11%), and 1b (n = 1, 6%). Using GHOST transmission detection module, a transmission cluster consisting of 2 participants reinfected with HCV genotype 2c was identified in Tbilisi. Although no cluster was found in Zugdidi alone, a reinfected participant from Zugdidi and seroconverted participant from Tbilisi formed another small transmission cluster. The Tbilisi participant carried mixed HCV genotype infection. Additionally, we found two mixed infections, one in each city, indicating a very high rate of exposure.
Conclusion: This is the first molecular epidemiological report among the high risk PWID population of Georgia using GHOST. The detected transmission clusters and mixed genotype infections indicate a very high rate of exposure in studied communities. GHOST can be utilized for surveillance for early intervention on networks as well as successfully applied to other infectious diseases including HBV, HAV, and HIV.

THU259

Prevalence and predictors of significant liver fibrosis : a population-based cross-sectional study

Aayushi Rastogi[1], Manya Prasad[1], Umesh Kapil[1], Ekta Gupta[2], Sherin Sarah Thomas[3], Chhagan Bihari[4], Shiv Kumar Sarin[5]. *[1]Institute of Liver and Biliary Sciences, Epidemiology, Delhi, India; [2]Institute of Liver and Biliary Sciences, Virology, Delhi, India; [3]Institute of Liver and Biliary Sciences, Biochemistry, Delhi, India; [4]Institute of Liver and Biliary Sciences, Pathology, Delhi, India; [5]Institute of Liver and Biliary Sciences, Hepatology, Delhi, India*
Email: rastogiaayushi6@gmail.com

Background and aims: Liver fibrosis is one of the most common chronic liver diseases worldwide caused due to alcohol consumptions, viruses, diabetes and other metabolic disorders. Steatosis is a common feature of several liver diseases resulting from different etiologies. Early detection of liver fibrosis can help timely interventions to reduce progression to cirrhosis and hepatocellular carcinoma. Aim: The present study was aimed at assessing the prevalence and predictors of significant liver fibrosis among asymptomatic adults in general population.
Method: A cross-sectional study was undertaken between 26 June 2021 to 15 November 2021 in the randomly selected primary health clinics of Delhi; the Mohalla Clinics. A mobile screening unit with trained research staff screened the population in the catchment areas of the clinics. A brief questionnaire was administered which assessed the medical and family history, information on life style factors such

as physical activity and alcohol consumption of the participants. In addition, anthropometric measurements, transient elastography and blood samples were collected for biochemical tests such as ALT, AST, total bilirubin, cholesterol, triglycerides and fasting blood sugar in participants who volunteered for screening. Liver stiffness measurement (LSM) of ≥8kPa was used to define significant liver fibrosis. Univariable and multivariable analysis was done to determine the factors associated with liver fibrosis.

Results: A total of 2863 participants were screened with mean age of 43 ± 13.6 years, with 56% being males. Mean fasting blood sugar was 114.5 ± 49.78 mg/dl whereas median triglyceride was found to be 130.2 mg/dl (IQR: 95.4–181.2). The prevalence of significant liver fibrosis in the general population was 7.6% (95%CI:6.65%-8.64%). The following factors were found to have a statistically significant (p < 0.001) association with significant liver fibrosis after adjusting for other factors: age (aOR:1.03; 95%CI: 1.01–1.04), male gender (aOR:1.73; 95%CI: 1.22–2.43), diabetes (aOR:3.15; 95%CI: 2.23–4.44), morbid obesity (aOR:7.53; 95%CI: 2.28–24.8) as seen in Table 1.

Table 1: Univariate and multi-variate analysis for predictors of liver fibrosis

Predictors	OR (95%CI)	p-values	aOR (95%CI)	p-values
Diabetes				
No	1	<0.001	1	<0.001
Yes	4.56 (3.37 - 6.18)		3.15 (2.23 – 4.44)	
Hypertension				
No	1	<0.001	1	0.554
Yes	2.51 (1.83 - 3.44)		1.11 (0.77 – 1.60)	
BMI Category				
Underweight (<18.5)	1	<0.001	1	
Normal (18.5–23.9)	1.79 (0.52 - 6.09)		1.27 (0.37 - 4.4)	0.698
Overweight (24–24.9)	2.3 (0.68 - 7.76)		1.39 (0.40 – 4.82)	0.601
Obese 1 (25-29.9)	4.9 (1.5 - 15.7)		2.93 (0.89 – 9.57)	0.075
Obese 2 (>30.0)	11.5 (3.6 - 36.9)		7.53 (2.28 - 24.81)	0.001
Physical Activity				
Low	1		1	
Moderate	0.7 (0.49 - 0.93)	0.024	0.72 (0.51 – 1.01)	0.060
High	0.7 (0.46 - 0.99)		0.79 (0.52 -1.21)	0.282
Gender				
Female	1	0.22	1	
Male	1.19 (0.89 - 1.58)		1.73 (1.23 – 2.43)	0.002
Alcohol consumption				
No	1	0.066	1	0.068
Yes	1.51 (0.97 - 2.35)		1.59 (0.96-2.62)	
Age			1.03 (1.01- 1.04)	<0.001

OR: Odds ratio
aOR: Adjusted Odds ratio

Conclusion: There is high prevalence of fibrosis in the general population screened for the present study. There is a need for large scale public health interventions with high-risk approach to detect and treat liver fibrosis and prevent its complications.

THU261

Prognostic value of liver function test for COVID-19 hospitalized patients with respiratory disease

Carlos Alventosa Mateu[1], Elena Guillen Botaya[1], Cecilia Albert-Antequera[2], Irene Perez Alvarez[1], Alejandro Fernandez Soro[1], Eva Sanchez Ramos[1], Salvador Benlloch[2], Juan Jose Urquijo Ponce[1], Francesc Puchades Gimeno[3], Francisco Sanz Herrero[4], Miguel García Deltoro[5], Mercedes Latorre Sánchez[1], Inmaculada Castelló Miralles[1], Dolores Ocete Mochon[6], Concepcion Gimeno Cardona[6], Moises Diago[1]. *[1]Consorcio Hospital General Universitario Valencia, Digestive Diseases, Valencia, Spain; [2]Hospital Arnau de Vilanova, Digestive Diseases, Valencia, Spain; [3]Consorcio Hospital General Universitario Valencia, Internal Medicine, Valencia, Spain; [4]Consorcio Hospital General Universitario Valencia, Respiratory Diseases, Valencia, Spain; [5]Consorcio Hospital General Universitario Valencia, Infectious Diseases, Valencia, Spain; [6]Consorcio Hospital General Universitario Valencia, Microbiology, Valencia, Spain*
Email: almacar84@hotmail.com

Background and aims: Abnormal liver function tests (ALFT) have been associated with worse evolution in COVID-19 hospitalized patients with respiratory disease, but it is unclear if it is an independent prognostic factor. Our aim is to determine whether ALFT have a direct impact on the prognosis of these patients.

Method: A single-center, retrospective study of COVID-19 hospitalized patients with respiratory disease from February 15th, 2020, to February 28th, 2021. Patients with already known liver diseases were excluded. ALFT were defined as elevated total bilirubin (TBIL), aspartate transferase (AST), alanine transferase (ALT), alkaline phosphatase (ALP) and/or gamma-glutamyltransferase (GGT) above the upper limit of normality (ULN) in our laboratory.

COVID-19 respiratory disease was classified as mild (no pneumonia), moderate (pneumonia) and severe (pneumonia with respiratory failure). Worsening of respiratory disease was defined as mild/moderate to severe respiratory disease progression or death. An association of ALFT with moderate/severe disease, worsening of respiratory disease, hospital stay, need for intensive care unit (ICU) admission and mortality was assessed. Statistical analysis was based on T-test and logistic regression. They included an adjusted multivariant model for age, sex, Charlson Comorbidities Index (CCI) and liver steatosis and fibrosis prior to hospital admission (defined by Hepatic Steatosis Index and FIB-4 scores respectively). Significance was set at p <0.05.

Results: The data of 2075 patients (51.5% males), average age 66.5 (SD 17.8) years, were analyzed. Despite excluding patients with already known liver diseases, the overall prevalence of liver steatosis was 57.8% and that of fibrosis was 18.4%. 1225 patients (51.9%) presented ALFT at hospital admission and 1572 (75.8%) during hospital stay. ALFT were significantly associated with moderate/severe disease, likelihood of worsening of respiratory disease, longer hospital stay (8 vs 11.9 days, p < 0.001) and higher rate of ICU admission, but not with higher mortality. Higher FIB-4 was also significantly associated with worsening of respiratory disease (OR = 1.98, p < 0.001). Age and CCI were associated with higher mortality. Female sex was a protective factor against unfavorable events. Among ALFT, TBIL was the most associated with worsening of respiratory disease (OR = 2.4, p < 0.001) and ALT with ICU admission (OR = 1.42, p < 0.001) and mortality (OR = 1.03, p = 0.04). The exclusion of patients with elevated ALT/AST prior to admission did not change the results.

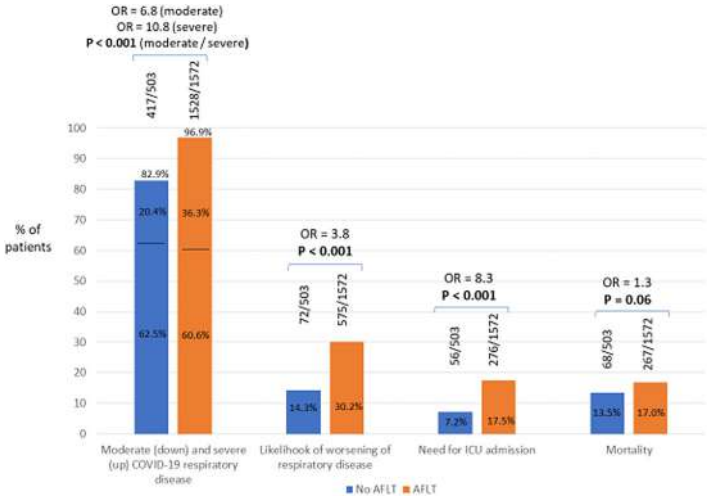

Figure: Association of ALFT with the different clinical events.

Conclusion: According to our study, ALFT can be considered as an independent risk factor for worse evolution in COVID-19 hospitalized patients with respiratory disease. Liver fibrosis had only influence in worsening of respiratory disease.

THU262

Effectiveness of COVID-19 viral vector vaccine Ad.26.COV2.S vaccine and comparison with mRNA vaccines in patients with cirrhosis

Binu John[1,2], Akash Doshi[3], Yangyang Deng[4], Natalie Mansour[2], A. Sidney Barritt[5], Andrew Moon[5], George Ioannou[6], Paul Martin[1], Hann-Hsiang Chao[7], Tamar H Taddei[8], David Kaplan[9], Bassam Dahman[4]. *[1]University of Miami Hospital And Clinics | UHealth Tower, Miami, United States; [2]Miami VA Medical Center, Miami, United States; [3]University of Miami, Coral Gables, United States; [4]Virginia Commonwealth University Health, Richmond, United States; [5]University of North Carolina at Chapel Hill, Chapel Hill, United States; [6]University of Washington, Seattle, United States; [7]Hunter Holmes McGuire VA Medical Center, Richmond, United States; [8]Yale University, New Haven, United States; [9]University of Pennsylvania, Philadelphia, United States*
Email: binu.john@gmail.com

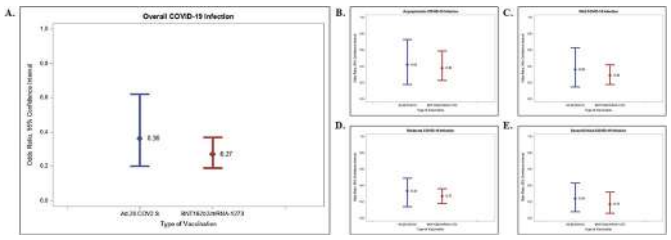
Background and aims: Viral vector COVID-19 vaccines have been administered more commonly worldwide but their effectiveness in participants with cirrhosis is unknown. We explored the effectiveness of vaccination with the Janssen Ad.26.COV2.S compared to the mRNA Pfizer BNT162b2 or Moderna 1273-mRNA vaccine in participants with cirrhosis.

Method: This was a test-negative case control study among participants with cirrhosis. This study design is widely used in evaluations of vaccine effectiveness and has the advantage of minimizing biases associated with access to vaccination or health care. Cases were those who were SARS CoV2 PCR positive, controls were those who tested negative during the study period between March 15, 2021 and October 3, 2021. Participants who did not undergo SARS CoV2 PCR testing, who had COVID-19 before the study period, or received a liver transplant, were excluded. COVID-19 was classified based on individual chart review using the National Institute of Health (NIH) COVID-19 severity scale as asymptomatic, mild, moderate, severe or critical illness.

Propensity score matching was used to match test positive cases and test negative controls. The propensity score of having COVID-19 were derived from a logistic regression that adjusted for the participant's sex, age, date of testing, race/ethnicity, location, alcohol as the etiology of liver disease, body mass index (BMI), diabetes mellitus, current tobacco use, current alcohol use, co-morbidities, and the Child Turcotte Pugh score. Multinomial logistic regression models were fit for COVID-19, to assess the adjusted effect from vaccination with either the Ad.26.COV2.S or the mRNA-1273 or BNT162b2 vaccines.

Results: A total of 955 cases and 955 matched controls were included in the study population. The two groups were well matched to all baseline characteristics.

The Ad.26.COV2.S vaccine had an effectiveness of 64% against COVID-19 (adjusted Odds Ratio [aOR] 0.36, 95% CI 0.20–0.62, p = 0.005). Effectiveness was lowest with asymptomatic illness (aOR 0.42, 0.18–0.73, p = 0.03), and higher against mild (aOR 0.36, 0.15–0.63, p = 0.006), moderate (aOR 0.33, 0.14–0.49, p = 0.002) and severe/critical (aOR 0.24, 0.08–0.83, p = 0.04) COVID-19. In the same period, mRNA vaccines had a 73% effectiveness against overall COVID-19 (aOR 0.27, 0.19–0.37, p < 0.0001), progressively higher from asymptomatic (aOR 0.38, 0.23–0.59, p = 0.0004) to mild (aOR 0.29, 0.18–0.42, p < 0.0001), moderate (aOR 0.27, 0.18–0.36, p < 0.0001), and severe or critical illness (aOR 0.17, 0.06–0.32, p < 0.0001). There were no statistically significant differences between the viral vector and mRNA vaccines.



Conclusion: In participants with cirrhosis, the Ad.26.COV2.S demonstrated a 64% effectiveness against COVID-19, and a 74% effectiveness against severe or critical COVID-19, similar to that associated with mRNA vaccines.

THU263

Humoral, cellular, clinical responses and safety to SARS-CoV-2 messanger RNA vaccines in patients with compensated and decompensated cirrhosis: a long-term single center prospective study

Massimo Iavarone[1], Giulia Tosetti[1], Floriana Facchetti[1], Matilde Topa[1], Andrea Lombardi[2], Roberta D'Ambrosio[1], Elisabetta Degasperi[1], Alessandro Loglio[1], Chiara Oggioni[3], Alessandra Bandera[2], Andrea Gori[2], Ferruccio Ceriotti[4], Luigia Scudeller[5], Antonio Bertoletti[6], Pietro Lampertico[1]. *[1]Foundation IRCCS Ca' Granda Ospedale Maggiore Policlinico, Division of Gastroenterology and Hepatology, MILANO, Italy; [2]Foundation IRCCS Ca' Granda Ospedale Maggiore Policlinico, Division of Infectious Disease; [3]IRCCS Humanitas Research Hospital, Quality and Patient Safety Unit, Rozzano, Italy; [4]Foundation IRCCS Ca' Granda Ospedale Maggiore Policlinico, Clinical Laboratory, MILANO, Italy; [5]IRCCS Azienda Ospedaliero-Universitaria di Bologna, Research and Innovation Unit, Bologna, Italy; [6]Duke-NUS Medical School, Programme in Emerging Infectious Diseases, Singapore, Singapore*
Email: massimo.iavarone@gmail.com

Background and aims: SARS-CoV-2 mRNA vaccines have been approved to prevent COVID-19 in the general population but little is known in patients with cirrhosis. We assessed immunogenicity, effectiveness and safety of vaccines in patients with compensated and decompesated cirrhosis with different aetiologies.

Method: This is a prospective single center study assessing humoral and cellular response, incidence post-vaccination SARS-CoV-2 infections and adverse events to mRNA vaccines in cirrhotics compared to healthy controls, according to previous SARS-CoV-2 infection. Antibodies against the spike- and nucleocapside-protein (anti-S and anti-N) of SARS-CoV-2 were tested at baseline, 21 days after the first and 21 days after the second doses and during follow-up in both patients and healthy controls. Longitudinal assessment of quantity of spike-specific T-cells was conducted by a test based on the stimulation of whole blood with peptides covering the SARS-CoV-2 spike protein, followed by cytokine (IFN-γ, IL-2) measurement. Side effects after vaccination were recorded.

Results: 182 cirrhotics (61 years, 75% males, 45% viral-related, 74% Child-Pugh A, 31% HCC) and 38 healthy unmatched subjects were enrolled. 15% cirrhotics and 32% controls had previously SARS-CoV-2 infection. In both groups, individuals with previous SARS-CoV-2 infection showed higher anti-S titres at all time points after vaccination. Among COVID-19 naïve subjects, patients with cirrhosis showed significantly lower anti-S titres compared to controls [998.5 (0.4–12, 500) *vs* 1, 520 (259–12, 500) U/ml, p = 0.048]. In COVID-19 naïve cirrhotics, anti-S titres significantly decreased after a median of 133 (70–182) days [536 (0.4–8, 777) U/ml, p < 0.0001]. Decompensated cirrhotics showed lower anti-S titres compared to compensated ones [632 (0.4–12, 500) *vs* 1, 377 (0.4–12, 500) U/ml, p = 0.028]. By multivariable analysis in COVID-19 naïve cirrhotics, independent predictors of lower anti-S titres after second dose, were: active HCC, immunocompromised conditions, Pfizer vaccine and

lower anti-S after first dose. The spike-specific T cell response was evaluated in 14 cirrhotics, showing a heterogeneous magnitude of response, but on average the quantity and kinetics of decline of the spike-specific cellular responses diverged in cirrhotics compared to controls, with lower concentrations of both IFN-γ and IL-2, at all time-points. During follow-up, 4/133 (3%) COVID-19 naïve cirrhotics tested positive for anti-N: all asymptomatic, no hospitalization required. Neither unexpected nor severe adverse events emerged in our patients.

Conclusion: In COVID-19 naïve patients with cirrhosis undergoing SARS-CoV-2 mRNA vaccine, humoral and cellular responses appeared suboptimal compared to healthy controls, but the rates of post vaccination infection remained low. The response after the third dose will be also presented.

THU264

The protective role of dairy protein on sarcopenic obesity in middle-aged and older women: a community-based, 12-year, prospective cohort study

Jun-Hyuk Lee[1], Joo Hyun Oh[2], Sang Bong Ahn[2], Huiyul Park[3], Joo Hyun Sohn[4], Bo-Kyeong Kang[5], Mi Mi Kim[5], Chul-min Lee[5], Dae Won Jun[6], Eileen Yoon[6], Hyo Young Lee[7], Hyunwoo Oh[7]. *[1]Nowon Eulji Medical Center, Eulji University School of Medicine, Department of Family medicine, Seoul, Korea, Rep. of South; [2]Nowon Eulji Medical Center, Eulji University School of Medicine, Department of Medicine, Seoul, Korea, Rep. of South; [3]Uijeongbu Eulji Medical Center, Department of Family medicine, Gyeonggi-do, Korea, Rep. of South; [4]Hanyang University Guri Hospital, Hanyang University College of Medicine, Department of Medicine, Gyeonggi-do, Korea, Rep. of South; [5]Hanyang University College of Medicine, Department of Radiology, Seoul, Korea, Rep. of South; [6]Hanyang University College of Medicine, Department of Medicine, Seoul, Korea, Rep. of South; [7]Uijeongbu Eulji Medical Center, Department of Medicine, Gyeonggi-do, Korea, Rep. of South*
Email: dr486@eulji.ac.kr

Background and aims: Changes in body composition during aging include decreased muscle mass and increased fat mass, especially in women. Individuals with sarcopenic obesity (SO) could be at higher risk of morbidities and mortality than those with either sarcopenia or obesity alone. Dairy products, which contain whey protein and all essential amino acids, could have a beneficial role in preserving muscle mass and reducing obesity. We aimed to analyze the effect of dairy protein on the development of SO in women using a large-scale, community-based prospective cohort.

Method: Our analysis included 4251 women from the Korean Genome and Epidemiology Study. Participants were categorized into three groups by the tertile of dairy protein intake, which was assessed using a semi-quantitative 103-food item food frequency questionnaire. Appendicular skeletal muscle mass was estimated using the anthropometric equation. Obesity was defined as a body mass index of 25 kg/m^2 or greater. Multiple Cox hazard regression analysis was conducted to examine associations between dairy protein intake and incident SO.

Results: During follow-up (mean, 9.6 years), 280 women newly developed SO. Using Cox proportional regression models, the hazard ratios (95% confidence interval) for incident SO of the middle and highest tertiles were 0.93 (0.70–1.24) and 0.72 (0.52–0.98) compared with lowest tertile after adjusting for confounding variables.

Conclusion: These findings indicate high dairy protein intake is inversely related to SO development in Korean women. Dairy protein intake could be an effective strategy to prevent incident SO.

Keywords: dairy protein; sarcopenia; obesity; sarcopenic obesity; women

THU265

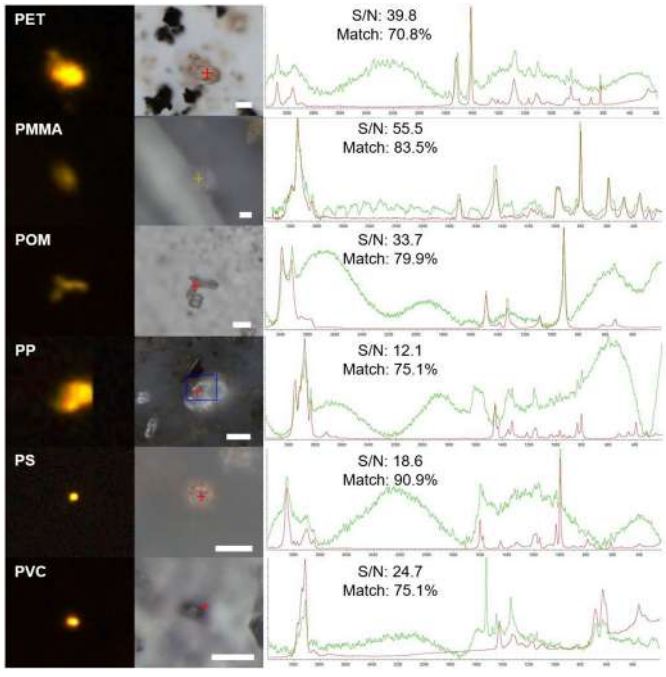
Detection of microplastics in cirrhotic liver tissue

Thomas Horvatits[1], Matthias Tamminga[2], Beibei Liu[1], Marcial Sebode[1], Klaus Püschel[3], Ansgar Lohse[1], Samuel Huber[1], Elke Fischer[2]. *[1]University Medical Center Hamburg-Eppendorf, I. Department of Medicine, Gastroenterology and Hepatology, Hamburg, Germany; [2]University of Hamburg, Center for Earth System Research and Sustainability (CEN), Hamburg, Germany; [3]University Medical Centre Hamburg-Eppendorf, Institute of Legal Medicine, Hamburg, Germany*
Email: t.horvatits@uke.de

Background and aims: The contamination of ecosystem compartments by microplastics (MPs) is an ubiquitous problem. Tissue accumulation of MPs has been observed in mice, and recently MPs have been observed in human stool and placenta. However, whether MPs accumulate in human tissues, and the resulting consequences are still unclear. Aim of this study was to examine various human tissue samples for the presence of MPs, and to determine whether MPs may deposit in the liver, kidney or spleen.

Method: This proof-of-concept case series was conducted in Hamburg, northern Germany, Europe. Tissue samples from 6 patients with liver cirrhosis and portal hypertension and from 7 individuals without underlying liver disease were assessed. A reliable method for detection of MP particles in human tissue was developed. A total of 17 samples (11 human liver, 3 kidney and 3 spleen samples) were analysed according to the final protocol. Chemical digestion of the tissue samples, staining with Nile red, subsequent fluorescent microscopy and Raman spectroscopy were performed. Procedural blanks were processed and analysed during each series of analyses. Shape, size and types of MP polymers were assessed in all tissue samples.

Results: Considering the limit of detection, all samples (liver, spleen, kidney) from patients without liver disease tested negative for MPs (n = n.s.), whereas MPs in liver samples from patients with cirrhosis tested positive and MP concentrations (5 to 12 particles per g tissue) were significantly higher than those from blank samples (n = 6, p = 0.009, α = 0.05). Six different microplastic polymers (polystyrene (PS), polyvinyl chloride (PVC), polyethylene terephthalate (PET), polymethyl methacrylate (PMMA), polyoxymethylene (POM), and polypropylene (PP)) ranging from 4 to 30 µm in size have been detected, see figure 1.



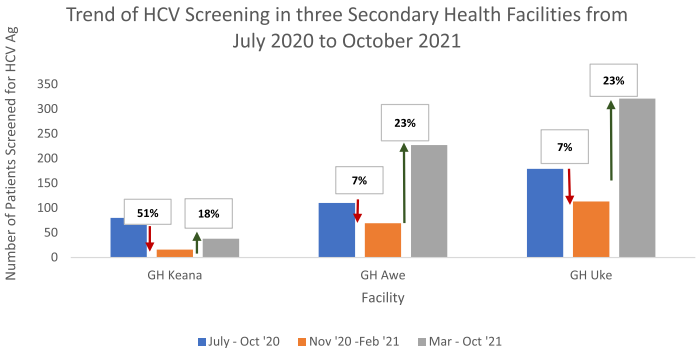
Conclusion: This is the first study, assessing MPs in different types of human tissues. MPs were found only in liver tissues from patients with cirrhosis. Hepatic deposition may be the consequence of impaired intestinal barrier function due to portal hypertension and portal enteropathy. Future studies on the possible effects on human health are urgently needed.
Examples of MP particles found in human tissue samples displayed as fluorescence images (left column) and true colour microscope images (mid column) as well as related Raman-spectra. White scale bar indicates 10 µm, library reference spectra are displayed in red, particle spectra are given in green. S/N: signal to noise ratio

THU266

Patient Navigators: an innovative approach to improve hepatitis c case finding leveraging existing human immunodeficiency virus service delivery models to reach last mile patients in Nasarawa State, Nigeria

Chukwuemeka Agwuocha[1,2], Olayinka Adisa[1], Onyeka Nwobi[1], Muhammad-Mujtaba Akanmu[1], Caroline Boeke[3], Magdalena Witschi[3], Amy Azania[3], Jibrin Kama[1], Folu Lufadeju[1], Owens Wiwa[1]. *[1]Clinton health access initiative, Abuja, Nigeria; [2]Clinton Health Access Initiative, Abuja, Nigeria; [3]Clinton health access initiative, United States*
Email: cagwuocha@clintonhealthaccess.org

Background and aims: The natural history of Hepatitis C Virus (HCV) demonstrates an asymptomatic disease that often leads to liver degeneration in approximately three decades. In HIV/HCV coinfection, liver degeneration is accelerated with decompensated cirrhosis occurring in less than two decades resulting in higher mortality rates. The asymptomatic nature of HCV, increased rate of disease progression in HIV, low awareness, and poor care seeking behaviour emphasizes the need to improve HCV case finding in People Living with HIV (PLHIV).
In Nigeria, the Nasarawa State Government has committed to HCV elimination, with an initial focus on PLHIV, necessitating integration of services to screen ART patients for HCV. However, due to the COVID pandemic and the resultant scale-up of Differentiated Service Delivery (DSD) models within the HIV program, screening yield from facility-based case finding reduced significantly. To ensure last mile linkage to HCV screening, the Patient Navigator pilot was conducted from March-October 2021. This analysis aims to assess screening coverage before and during this pilot period.
Method: One healthcare worker across three secondary facilities i.e., General Hospitals Keana, Awe, and Uke, labelled patient navigator (PN) was charged with the responsibility of identifying unscreened PLHIV using facility screening records and enrolment data. These PNs were HIV program defaulter trackers, consequently integrating this service within the HIV program. The PN employed strategic patient tracking approaches like phone calls, community engagements and peer group meetings. Using laboratory screening registers, screening progress was compared pre-intervention (July 2020 to February 2021) versus during the intervention (March to October 2021).
Results: A total of 125, 560, and 923 were active on ART care as of January 2020 in General Hospitals Keana, Awe, and Uke respectively. Across sites, the first 4 months of the pre-intervention phase saw high screening numbers as all available patients presenting to facilities were screened. Subsequently, a decline in screening numbers across all facilities. However, the intervention phase demonstrated extended coverage, reaching the last mile patients leading to an increase in case finding by 18% in GH Keana, and 23% in GH Awe and GH Uke respectively.



Conclusion: The use of patient navigators demonstrates the feasibility and cost-effectiveness of increasing case-finding through HCV/HIV program integration.

THU267

The Community Pop-Up Clinic (CPC): a unique strategy to achieve HCV elimination in the inner city

Brian Conway[1,2], Shawn Sharma[1], Leo Yamamoto[1], Rossitta Yung[1], David Truong[1]. *[1]Vancouver Infectious Diseases Centre, Vancouver, Canada; [2]Simon Fraser University, Burnaby, Canada*
Email: bconway5538@gmail.com

Background and aims: A number of strategies have been proposed to help identify HCV-infected inner-city residents, engage them in care, provide them with Hepatitis C Virus (HCV) therapy, and achieve and measure cure. While many programs have successfully identified large numbers of subjects eligible for treatment, the rate of successful completion and cure is highly variable. The most relevant outcome measure for such programs may be the number of HCV cures achieved over time, and programmatic changes should be implemented and evaluated according to this metric. We have evaluated our Community Pop-Up (CPC) program in terms of this outcome measure, as a function of the resources required for its implementation.
Method: On a weekly basis, a team consisting of a physician, nurse and three support staff interact with up to 30 individuals over 4 hours in the inner city of Vancouver, at a community centre or single room occupancy dwelling to provide point-of-care HCV testing or ascertainment of previously identified HCV infection status. Treatment for HCV infection is offered in the context of a low-barrier treatment program, with medications delivered daily/weekly, at the place of residence, local pharmacy or at our community clinic. Strategies are in place to limit loss to follow-up and maximize engagement in care throughout treatment and thereafter, to ascertain if cure has been achieved.
Results: From 07/20–09/21 (15 months), we conducted 55 community pop-up clinics and screened a total of 774 individuals for their HCV status. Of 280 HCV-infected individuals by antibody test, 99 (35.4%) had documented HCV viral load result. Key demographic characteristics include: median age 43 (28–86) years, 77.5% male, F0/F1 (22, 55%), opioid antagonist therapy 26 (65%), HIV co-infected 2 (5%), fentanyl/cocaine/amphetamine use (24/12/18, 60%/30%/45%). Of 40 individuals on treatment, none have been lost to follow-up, 26 have demonstrated cure, with outcome results pending in the other 14 subjects. Strategies are in place to engage the remaining 49 viremic individuals in HCV treatment

Conclusion: In the context of an established, multidisciplinary clinic serving the inner city, a 4 hour/week initiative staffed with 2 health care providers and 3 support staff led to successful HCV treatment of 40 individuals, with none lost to follow-up once treatment has been initiated and the possibility of 40–50 additional treatment starts in the short term. This represents a very cost effective and productive initiative to address HCV infection in similar populations.

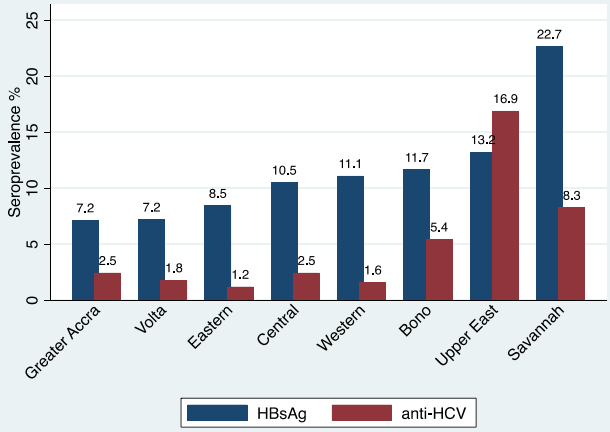
THU268

Age, gender and region-specific HBsAg and anti-HCV seroprevalence in Ghana: a nationwide hospital based cross-sectional study

Yvonne Nartey[1,2]. [1]*Cape Coast Teaching Hospital, Internal Medicine, Cape Coast, Ghana;* [2]*Karolinska Institute, Medical Epidemiology and Biostatistics, Stockholm, Sweden*
Email: yvonne.nartey@ki.se

Background and aims: Hepatitis B (HBV) and Hepatitis C (HCV) viral infection continue to pose a significant global health burden and are responsible for high morbidity and mortality worldwide due to sequalae of end stage liver disease. Previous estimates in Ghana report a seroprevalence of anti-HCV of 3.3% and HBsAg of roughly 9%. These estimates fall short of describing age and gender-specific rates and have relied on small sample sizes in few centers. Particularly for HCV, there is a paucity of data from several regions in Ghana. Numerous challenges, including lack of focused and definitive testing and treatment strategies and policies limit the impact of current elimination efforts. Providing a robust programmatic foundation requires a scale-up of hepatitis testing nationwide, and this in turn requires up-to-date epidemiologic data to understand the burden of disease in all parts of the country and across all age groups. This study aimed to perform an epidemiological assessment of HBV and HCV infection in Ghana to determine age, gender, and region specific seroprevalence. Additionally, it aimed to convene a coalition of local stakeholders for policy development in Ghana.
Method: A nationwide cross-sectional study using de-identified data was collated from January 1st to October 30th 2021. Data from health information management systems for 2017–2021 was reviewed from 20 centers including teaching, regional, and district hospitals in 11 regions in Ghana. Sixty thousand labour ward, 54, 000 blood bank, and 48, 000 laboratory-based records were reviewed and analyzed for age and gender-specific HBV and HCV prevalence. Regional differences in seroprevalence were also determined.
Results: A stakeholder meeting was held in Accra, Ghana bringing together key players from the public and private sector involved in viral hepatitis elimination for policy planning. Crude prevalence among pregnant women was 6.36% (95% CI 5.70–7.02) for HBsAg; among blood donors was 5.09% (95% CI 4.91–5.28) for HBsAg and 3.22% (95% CI 3.08–3.38) for anti-HCV. From laboratory-based registers, overall seroprevalence was 8.90 (95% CI 8.65–9.16%) for HBsAg and 3.39 (95% CI 3.17–3.63) for anti-HCV. Prevalence of both HBV and HCV were significantly higher in the northern Ghana. HBsAg prevalence was higher in males (9.70%) than females (8.20%) $p < 0.05$, but there was no difference in gender-specific seroprevalence for anti-HCV. The highest age preponderance was among 40–49 (13.53%) year olds for HBsAg and 60+ year olds (7.59%) for anti-HCV. Seroprevalence in children <5 years was 1.87% for HBsAg and 1.53% for anti-HCV.

Figure 1. Region specific crude HBsAg and anti-HCV seroprevalence among hospital lab attendants in Ghana



Conclusion: Ghana remains a region of high endemicity for HBV and moderate-high endemicity for HCV. Northern Ghana consistently demonstrates a higher disease burden than the rest of the country. Focused and targeted policies are essential to reach elimination targets.

THU269

The elimination of hepatitis C in the cherokee Nation: the impact of harm reduction

Jorge Mera[1], Whitney Essex[1], Molly Feder[2], Homie Razavi[3], Devin Razavi-Shearer[3]. [1]*Cherokee Nation Outpatient Health Center, Tahlequah, United States;* [2]*Cardea Services, Seattle, United States;* [3]*Center for Disease Analysis Foundation, Lafayette, United States*
Email: drazavishearer@cdafound.org

Background and aims: In the United States, American Indians/Alaskan Natives have the highest rates of HCV incidence, liver cancer and mortality compared to all other racial/ethnic groups.
The Cherokee Nation (CN) a sovereign tribal nation, began a hepatitis C (HCV) elimination program in 2015 with a 6-fold increase in treatment in 2016. The primary aim of this study is to estimate what would need to be done to meet the World Health Organization's (WHO) 2030 targets by 2025. In addition to examining increase in treatment, the implementation and lack of syringe service programs (SSP) were considered in the analysis.
Method: CN specific input data populated a dynamic Markov model. Three scenarios were considered. The Base scenario examined the impact of maintaining the current treatment and diagnosis levels into the future. The 2025 w/o SSP scenario examined how much treatment would need to be increased to attempt to meet the 2030 targets in 2025 without access to SSP. The 2025 w/SSP scenario examined the accompanying treatment uptake necessary to meet the 2030 goals in 2025 with a robust SSP program.
Results: In the Base scenario, it was estimated that the 90% diagnosis and 80% treatment targets would be met prior to 2025. By 2030, there is estimated to be an 84% reduction in mortality and a 50% reduction in incidence when compared to 2015 (Figure 1). 2025 w/o SSP required a large increase in treatment, from 162 to 400 annually. This scenario resulted in an 89% reduction in mortality by 2025 but only a 50% reduction in incidence by 2025. The 2025 w/SSP scenario required a modest increase in treatment to 255 individuals annually. This resulted in a 65% reduction in mortality and an 86% reduction in incidence by 2025 thus meeting all targets.

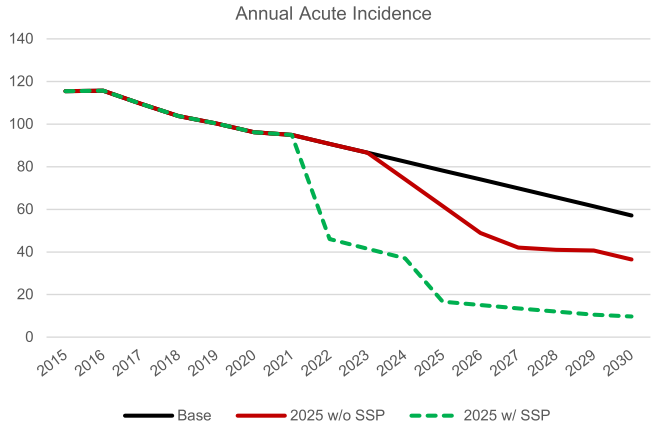


Figure: Annual Acute Incidence of HCV on The Cherokee Nation, 2015–2030

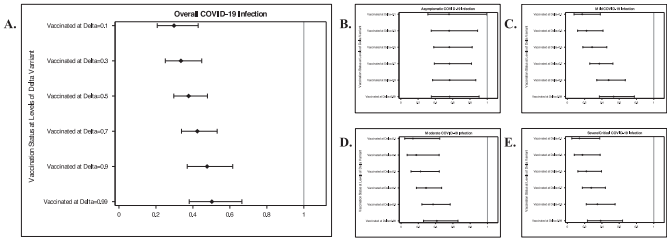
Conclusion: The current HCV elimination program would meet almost all of the WHO targets prior to 2030. However, in the absence of SSP that provide access to all of those that need it, it is estimated that the incidence would not drop substantially enough by 2030. With the CN approving SSP an opportunity has opened for the CN to meet all targets by 2025. In the first year of the elimination program 222 individuals were treated thus increasing treatment to 255 for three years would be within the capacity of the program. To achieve this goal the CN should have a swift broad rollout of SSP. This combined with a slight increase in treatment will lead to early elimination and a positive impact on the population health of the CN.

THU270

Effectiveness of mRNA vaccines in patients with cirrhosis with rising prevalence of SARS-CoV-2 delta variant

Binu John[1,2], Raphaella Ferreira[1], Dustin Bastaich[3], Akash Doshi[4], Tamar H Taddei[5], David Kaplan[6], Seth Spector[1,4], Bassam Dahman[3]. [1]*Miami VA Medical Center, Miami, United States;* [2]*University of Miami Hospital And Clinics | UHealth Tower, Miami, United States;* [3]*Virginia Commonwealth University, Graduate School, Richmond, United States;* [4]*University of Miami, Coral Gables, United States;* [5]*Yale University, New Haven, United States;* [6]*University of Pennsylvania, Philadelphia, United States*
Email: binu.john@gmail.com

Background and aims: The effectiveness of COVID-19 vaccines with the increasing prevalence of SARS CoV2 B.1.617.2 delta variant among patients with cirrhosis is unknown. The aim of the study was to investigate the effectiveness of COVID-19 vaccination at varying community prevalence of the B.1.617.2 variant among patients with cirrhosis.
Method: This study used was a test-negative case control design, where adults with cirrhosis who had a diagnosis of COVID-19 as documented by a positive SARS-CoV-2 Polymerase Chain Reaction (PCR) were considered as cases, and those with a negative SARS CoV2 PCR were considered controls. This study design is widely used in evaluations of vaccine effectiveness and has the advantage of minimizing biases associated with access to vaccination or health care. Participants who did not undergo SARS CoV2 PCR testing, who had COVID-19 before the study period, received a vaccine other than an mRNA vaccine, or received a liver transplant, were excluded. Patients were considered fully vaccinated 14 days after receipt of either the Pfizer BNT162b2 or the Moderna 1273-mRNA vaccine. COVID-19 was classified based on individual chart review using the National Institute of Health (NIH) COVID-19 severity scale as asymptomatic, mild, moderate, severe or critical illness. The weekly proportion of the delta variant in the United States was obtained using data from the Center for Disease Control COVID-19 genomic surveillance data.
Propensity score matching was used to match test positive cases and test negative controls. The propensity score of having COVID-19 were derived from a logistic regression that adjusted for the participant's baseline variables.
Results: The study sample included 1, 720 participants, including 860 cases and 860 controls. The effectiveness of mRNA vaccines against COVID-19 was inversely related to the community prevalence of the B.1.617.2 variant. For every 10% increase in the community prevalence of delta, the likelihood of COVID-19 after full vaccination increased by 5% (aOR 1.05, 1.02–1.07, p = 0.0001). At community delta prevalence of 10%, mRNA vaccines were 70% effective (aOR 0.30, 0.21–0.43, p < 0.0001). Vaccine effectiveness dropped to 62% (aOR 0.38, 0.30–0.48, p < 0.0001) when the community prevalence of the delta variant increased to 50%, to 52% (aOR 0.50, 0.38–0.67, p < 0.0001) at a community delta prevalence of 90% and to 50% (aOR 0.38–0.67, p < 0.0001) with a community delta prevalence of 99%.



Conclusion: Vaccine effectiveness is inversely associated with community prevalence of the delta variant, with effectiveness dropping from 30% at delta prevalence of 10%, down to 50% with a community delta prevalence of 99%. Further studies are needed to understand if booster doses are able to overcome the drop in vaccine effectiveness with increasing prevalence of delta variant, among patients with cirrhosis.

THU271

Epidemiology and management of hepatitis B and C in primary care in the Netherlands-data from the Rijnmond primary care database

Sylvia Brakenhoff[1], Robert De Man[1], Robert De Knegt[1], Patrick Bindels[2], Evelien de Schepper[2]. [1]*Erasmus MC, University Medical Center, Gastroenterology and Hepatology, Rotterdam, Netherlands;* [2]*Erasmus MC, University Medical Center, General Practice, Rotterdam, Netherlands*
Email: s.brakenhoff@erasmusmc.nl

Background and aims: The Dutch guideline for general practitioners (GPs) advises biannual surveillance of hepatitis B (HBV) patients and referral of every hepatitis C (HCV) patient. We aimed to study the prevalence, incidence and the management of hepatitis B and C in primary care.
Method: This is a retrospective cohort study using the Rijnmond Primary Care database (RPCD), including healthcare data of medical records of GPs of approximately 200, 000 patients in the area of Rotterdam, the Netherlands. Patient records were selected based on laboratory results, International Classification of Primary Care (ICPC) codes and free text words.
Results: In total, 977 patients were included; 717 HBV, 252 HCV, and 8 HBV/HCV co-infected patients. Between 2013 and 2019, the prevalence of HBV and HCV declined from 5.21 to 2.99/1, 000 person years (PYs; – 43%) and 1.50 to 0.70/1, 000 PYs (-53%) respectively. We observed that the majority of the patients had been referred to a medical specialist at least once (71% HBV and 89% HCV patients). However, among the 406 chronic hepatitis B patients, we observed that 36.2% of the patients did not receive adequate surveillance by their GP (≥2 ALT checks within 3 years) or by a medical specialist. In addition, among the 153 chronic hepatitis C patients, 113 (73.9%)

received antiviral therapy. However, 68 patients (44.4%) had no record about successful antiviral treatment and might still be chronically infected on 31.12.2019.
Conclusion: This study demonstrated a declining prevalence in viral hepatitis B and C in primary care in the Netherlands. However, a substantial of the patients did not receive adequate surveillance or antiviral therapy. It is therefore crucial to involve GPs in the road to elimination.

THU272
Point of care testing for hepatitis C in the priority settings of mental health, prisons and drug and alcohol facilities
Catherine Ferguson[1], Lucy Ralton[1], Erin McCartney[1], Joshua Dawe[2], Jacqui Richmond[2], Edmund Tse[3], Alan Wigg[4], Victoria Cock[5], Tom Rees[6], David Shaw[1]. *[1]Royal Adelaide Hospital, Infectious Diseases, Adelaide, Australia; [2]Burnet Institute, Melbourne, Australia; [3]Royal Adelaide Hospital, Hepatology, Adelaide, Australia; [4]Flinders Medical Center, Gastroenterology and Hepatology, Adelaide, Australia; [5]Drug and Alcohol Services South Australia, Adelaide, Australia; [6]Communicable Disease Control Branch, SA Health, Adelaide, Australia*
Email: erin.mccartney@sa.gov.au

Background and aims: A key barrier to hepatitis C (HCV) diagnosis and treatment is the multi-stage process of conventional testing that requires multiple visits to pathology services and healthcare providers to obtain a HCV antibody (Ab) test, HCV RNA test, diagnosis, and linkage into care to commence treatment. Point of care testing for hepatitis C in the priority settings of mental health, prisons and drug and alcohol facilities (PROMPt) aims to overcome critical roadblocks to HCV treatment in the community by providing HCV point-of-care testing (POCT) and direct referral into treatment. Over a 12 month period PROMPt aims to evaluate the effect of POCT on HCV testing rates, linkage to care and explore the acceptability of HCV POCT in facilities and services for individuals at high risk of HCV infection. Primary end points: 1. Number/proportion of participants who receive rapid POCT HCV Ab plus POC RNA. HCV Ab/RNA positivity at each site 2. Number/proportion of HCV RNA positive participants who are linked to care. Secondary end points: 1. Acceptability of HCV POCT to participants in each setting.
Method: Participants are offered POC HCV diagnostic testing using SD Bioline fingerstick Ab assay and those returning a positive HCV Ab result are offered a Cepheid finger stick HCV RNA Xpert assay. Project staff, including peer support workers, provide HCV education, pre- and post-test counselling, and linkage to care at the time of diagnosis.
Results: Interim analysis at 6 months reports 707 participants recruited across all 3 priority settings. 125/707 (18%) positive HCV Ab participants were reflexed to HCV RNA testing, resulting in 35 positive RNA participants 35/125 (28%). To date 27/35 (77%) RNA positive participants have commenced treatment.
The complete 12 months of recruitment and final analysis of end points will be presented.

	HCV Ab Test	% Ab Positive	% RNA Test	% RNA Positive	RNA Positivity
Remand Prison	409	76/409 (19%)	76/409 (19%)	25/409 (6%)	25/76 (33%)
Inpatient AOD	207	36/207 (17%)	36/207 (17%)	4/207 (2%)	4/36 (11%)
Inpatient Mental Health Service	91	13/91 (14%)	13/91 (14%)	6/91 (7%)	6/13 (46%)
Overall	707	125/707 (18%)	125/707 (18%)	35/707 (5%)	35/125 (28%)

Conclusion: PROMPt has demonstrated high rates of HCV POC testing and acceptability in 3 high priority settings. The hepatitis C infection rates have been lower than anticipated and the combined HCV Ab and RNA POCT approach to testing has allowed for efficient and economical testing scale up in each site.

THU273
Association of novel lifestyle- and whole foods base inflammation scores with metabolic dysfunction-associated fatty liver disease: a population-based study among iranian adults
Ehsaneh Taheri[1], Roberd M Bostick[2], Behzad Hatami[1], Mohammadamin Pourhoseingholi[1], Hamid Asadzadeh Aghdaei[1], Alireza Moslem[3], Alireza MosusaviJarahi[4], Mohammadreza Zali[1]. *[1]Shahid beheshti university of medical sciences, Research institute for gastroenterology and liver disease center, Tehran, Iran; [2]Emory University, Epidemiology, Atlanta, United States; [3]Sabzevar university of medical sciences, Cellular and molecular research center, Sabzevar, Iran; [4]Shahid beheshti university of medical sciences, Department of community medicine, Tehran, Iran*
Email: ehsaneh_taheri@yahoo.com

Background and aims: Chronic inflammation, associated with lifestyle and dietary patterns, may contribute to metabolic dysfunction-associated fatty liver disease (MAFLD) risk. Recently, a novel dietary inflammatory score based on weighted inflammatory scores of 19 components (whole foods) from food frequency questionnaire (FFQ) and lifestyle inflammatory score based on weighted inflammatory scores of 4 components of lifestyle (physical activity, adiposity, alcohol, and smoking) were proposed. The main aim of this study was to evaluate the associations of these novel inflammatory scores with MAFLD risk. The secondary aim of our study was to compare novel dietary- and lifestyle inflammatory scores-MAFLD associations with previous dietary inflammatory scores.
Method: We investigated associations of 19-component dietary and 4-component lifestyle inflammatory separately and jointly with MAFLD risk among Iranian adults aged 35–70 years of age at baseline phase of PERSIAN cohort study in Sabzevar city. MAFLD was defined as having a fatty liver index (FLI) ≥60, plus one of the following: being overweight or obese (body mass index [BMI] ≥25 kg/m2), a Type II diabetes mellitus (T2DM) diagnosis, or having any evidence of metabolic dysregulation. We also calculated previous well-known diet-related inflammatory markers such as dietary inflammatory index (DII) and empirical dietary inflammatory pattern (EDIP) using information from 115-item FFQ. Higher score were considered more inflammatory status. We assessed inflammatory scores-MAFLD associations using multivariable unconditional logistic regression.
Results: Of 4241 participants of Persian Sabzevar Cohort study, 968 patients with MAFLD and 964 age- and gender adjusted controls were recruited in this nested case-control study. Among participants in the highest relative to the lowest dietary- and lifestyle inflammatory score tertiles, the adjusted odds ratios (OR) and their 95% confidence intervals (CI) were 1.84 (1.61–2.07; p-trend <0.001)) and 1.96 (1.69–2.21; p-trend <0.001), respectively. Among those in the highest relative to the lowest joint dietary- and lifestyle inflammatory score tertiles, the adjusted OR (95% CI) was 2.56 (95% CI: 2.19–2.93; p-interaction <0.001). The third tertile ORs (95% CI) for the DII- and EDIP-MAFLD associations were 1.63 (1.05–5.62) and 1.71 (1.17–4.62), respectively.
Conclusion: More pro-inflammatory diets and lifestyles, separately and particularly jointly, are associated with higher risk of having MAFLD among adults. The associations of novel dietary- and lifestyle inflammatory with MAFLD were stronger than DII- or EDIP- MAFLD associations.

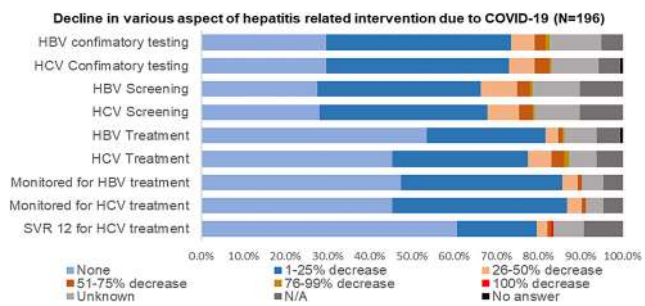
Assessment of COVID-19 impact and response on hepatitis B virus and hepatitis C virus prevention and treatment from nationwide survey in Japan

Md Razeen Ashraf Hussain[1], Aya Sugiyama[1], Lindsey Hiebert[1,2], Serge Ouoba[1,3], Bunthen E[1,4], Ko Ko[1], Tomoyuki Akita[1], Shuichi Kaneko[5], Tatsuya Kanto[6], John Ward[2], Junko Tanaka[1].
[1]Hiroshima University, Department of Epidemiology: Infectious Disease Control and Prevention, Graduate School of Biomedical and Health Sciences, Hiroshima, Japan; [2]The Task Force for Global Health, Coalition for Global Hepatitis Elimination, Georgia, United States; [3]Institut de Recherche en Science de la Santé (IRSS), Unité de Recherche Clinique de Nanoro (URCN), Nanoro, Burkina Faso; [4]Ministry of Health, Payment Certification Agency, Cambodia; [5]Kanazawa University, Department of Gastroenterology, Graduate School of Medical Science, Japan; [6]National Center for Global Health and Medicine, The Research Center for Hepatitis and Immunology, Tokyo, Japan
Email: jun-tanaka@hiroshima-u.ac.jp

Background and aims: Elimination of Hepatitis B Virus (HBV) and Hepatitis C Virus (HCV) requires continuous diagnosis and treatment. Ongoing pandemic COVID-19 has been affecting on health care system including on preventive care and testing of HBV and HCV. This study aimed to assess the impact of COVID-19 on hepatitis prevention and treatment in Japan. This international joint research conducted by three research groups of Ministry of Health, Labour and Welfare of Japan with the Task Force for Global Health and in cooperation with Japan Society of Hepatology (JSH).
Method: We conducted this cross-sectional study by a questionnaire survey in Japanese and English language on online Microsoft forms platform from 24 August to 03 October 2021. The electronic version of the questionnaire was disseminated by e-mail to all the members of JSH. The questionnaire was designed to address the impact of COVID-19 on hepatitis testing, screening, treatment; mitigation strategies; response to COVID-19; and perceived benefits of COVID-19.
Results: Total 196 medical doctors participated from 35 prefectures of whom 49.5% are in administrative positions. 55.6% of participants responded about no interruption while 11.7% reported supply chain disruptions during the survey period. 1–25% decrease in HBV screening and confirmatory testing was reported by 38.8% and 43.9% participants, respectively. Decrease of 1–25% in HCV screening and confirmatory testing was reported by 39.8% and 43.4% participants, respectively. However, no decline to initiate HBV and HCV treatment were reported by 53.6% and 45.4%, respectively, but extension of hospital visits was reported by 65.3%. The response illustrated the decrease in patients' imaging (65.8%), laboratory testing (68.4%), hepatocellular carcinoma screening (55.1%), gastrointestinal endoscopy (87.2%) and liver biopsy (43.4%). Patient anxiety and fear (67.4%), loss of staff to COVID-19 response (49.0%) and limited availability of staff (46.4%) were responded as challenges to resume services to pre-COVID-19 level. About COVID-19 response, engagement in COVID-19 testing and vaccination were reported by 51.5% and 61.2%, respectively. For Perceived benefits of COVID-19 response were strengthening general health care system (45.9%), demonstration of hepatitis infrastructure for COVID-19 response (44.4%) and improved training of infectious disease testing and management (35.7%)



Conclusion: In Japan, a greater decrease was noticed on HBV and HCV confirmatory testing, screening than treatment initiation. However, anxiety and fear of patients, lack of staff and facilities are major challenges to overcome such situation. Perceived benefits of COVID-19 on hepatitis were strengthened health care system, demonstration of hepatitis infrastructure and improved training in infectious disease testing and management.

THU275

Knowledge, attitude and practice regarding COVID-19 vaccination among HCV infected patients in Georgia

Lasha Gulbiani[1], Tiko Kamkamidze[1], Ana Gamezardashvili[1], George Kamkamidze[2], Maia Butsashvili[1]. *[1]Health Research Union, Tbilisi, Georgia; [2]Clinic NeoLab, Tbilisi, Georgia*
Email: lashagulbiani7@gmail.com

Background and aims: COVID Vaccination coverage is low in Georgia (24.7%). There are different vaccine-related misconceptions, particularly among people with different chronic diseases, who are at greatest risk of COVID related health complications and death. The aim of this study was to assess the COVID vaccine knowledge, attitude and practice among HCV infected patients enrolled in HCV elimination program in Georgia
Method: The interviewer administered questionnaire was used to survey the random sample of patients at one of the outpatient clinics providing HCV treatment services within HCV elimination program in Tbilisi, capital of Georgia. The sample included patients at different types of visits at the clinic-having diagnostic tests before the treatment, receiving the treatment and having sustained viral load (SVR) test at 12–24 weeks after treatment. Patients with and without liver cirrhosis were enrolled in the survey.
Results: 230 patients were interviewed in total. Only 42 (18.2%) reported to receive two doses and 12 (5.2%)-1 dose of COVID vaccine. Out of 176 not vaccinated patients 45 (25.5%) declared that they do not wish to get vaccinated because of their disease (HCV infection); 32 (18.1%) plan to get the vaccine; 29 (16.4%) patients think they are not at risk of COVID related health problems, 12 (6.8%) did not get the vaccine because they had COVID in the past and consider themselves defended against the disease, 25 (14.2%) are afraid of side effects and 33 (18.7%) do not trust the vaccine. Among not vaccinated patients 38 (21.5%) had liver cirrhosis.
Conclusion: COVID vaccination coverage is very low among patients enrolled in HCV elimination program, including patients with liver cirrhosis. Targeted educational campaigns for people with chronic diseases are needed to fight vaccine misconceptions among this high-risk population.

THU276

CRIVALVIR-FOCUS: low HIV and chronic Hepatitis B and C infection prevalence among women in reproductive and sexual health services in Valencia, Spain

Miguel Garcia-Deltoro[1], Pilar Obon[1], Caterina Canapele[2], Jose Maria Mari[2], Adela Vidal[2], Maria Martinez-Roma[3], Maria Dolores Ocete[4], Concepción Gimeno Cardona[4], Moisés Diago[5], Neus Gomez-Muñoz[3], Alba Carrodeguas[6], Diogo Medina[6], Enrique Ortega González[3]. *[1]Consorcio Hospital General Universitario de Valencia, Enfermedades Infecciosas, Valencia, Spain; [2]Consorcio Hospital General Universitario de Valencia, Ginecologia y Obstetricia, València; [3]Fundacion de Investigacion HGUV, València, Spain; [4]Consorcio Hospital General Universitario de Valencia, Microbiologia, València, Spain; [5]Consorcio Hospital General Universitario de Valencia, Hepatologia, València, Spain; [6]Gilead Science, Madrid, Spain*
Email: gdeltoromiguel@gmail.com

Background and Aims: In Spain, HIV, HBV, and HCV prevalence are lower in females. A 2017–2018 Ministry of Health serosurvey in 7, 675 primary care patients found 0.35% and 0.08% chronic HCV infection in men and women. A previous opportunistic, population-based screening program in 11, 449 primary care patients seen in our

health department found 0.18% and 0.06% HIV infection prevalence, 1.11% and 0.56% chronic HBV infection prevalence, and 0.73% and 0.25% chronic HCV infection prevalence in men and women from February to December 2019.

We aimed to assess HIV, HBV, and HCV prevalence among women seeking care in our health department's 5 Sexual and Reproductive Health Units (SRHU), in the Human Reproduction Unit (HRU), and the Obstetrics and Gynecology Service (OGS).

Method: We implemented opportunistic HIV, HBV, and HCV screening from March to October 2021, despite challenges related to a fifth wave of the SARS-CoV-2 pandemic. We used existing infrastructure and staff, aided by electronic health record system modifications, to identify screening eligibility and request serologies.

Patients were eligible for testing upon verbal consent if they were between 18 and 80, and had no record of testing in the previous year, and required blood tests in their current health care visit. Follow-up or discharge was given, regardless of test results. A case manager contacted positive patients to ensure and monitor linkage to specialist medical care.

Herein we analyze data from patients aged 18 to 45 — the maximum age of patients seen in the HRU.

Results: We screened 934 women, of whom 48.1% (449) in SRHUs, 26.0% (243) in the HRU, and 25.9% (242) in the OGS (26%). Regarding age and nationality, 14.6.% (136) were aged 18 to 25, 45.5% (425) were 26 to 35, 39.9% (373) were 36 to 45, and 20.6% (192) were foreigners. We found 1 (0.1%) HIV antibody positive patient (a 45-year-old from the Dominican Republic), 1 (0.1%) HBV surface antigen positive patient (a 36-year-old from China), 1 (0.1%) HCV antibody positive patient, and no HCV RNA positive patients.

Conclusion: HIV prevalence among Valencian women in reproductive and sexual health services was similar to the general population in primary health care in the area. In contrast, chronic HBV infection prevalence was low, and chronic HCV infection was not found.

Our data suggest that opportunistic HBV and HCV screening of women aged 18 to 45 out of populations at increased risk is an inefficient public health strategy in our area.

THU277

mRNA COVID-19 vaccine effectiveness in liver transplant patients

Muhammad Khan[1], Kamran Mushtaq[1], Deema AlSoub[1], Hussam Almasri[1], Bisher Sawaf[1], Saad AlKaabi[1], Yasser Kamel[1].
[1]*Hamad Medical Corporation, Doha, Qatar*
Email: mumair86@gmail.com

Background and aims: There is poor antibody response in up to 61% of the liver transplant patients after mRNA COVID-19 vaccination, and almost 20% of liver transplant recipients have undetectable antibody levels. However, antibodies are surrogate markers of disease protection and absence of seroconversion does not mean complete susceptibility to the disease. We hypothesized that COVID-19 vaccines are effective in liver transplant patients despite low seroconversion rates.

Method: We designed a test-negative case-control study to assess the vaccine effectiveness (VE) of COVID-19 vaccination in liver transplant recipients followed at our center in Hamad Medical Corporation. All liver transplant patients who were tested for SARS-CoV-2 infection between 1st of February till 30th of July in Qatar were included in the study. Case patients were identified as patients who had positive SARS-CoV-2 test on nasopharyngeal and throat swab while control patients were identified as patients who were tested negative during the same period. Information regarding demographic and clinical characteristics, transplant history, current immunosuppressive treatment was obtained from the medical records. Also, we recorded the type of COVID-19 vaccination, number of vaccine doses (one or two), COVID-19 complications, hospitalizations, and ICU admissions.

VE was estimated by a test-negative case-control design in which symptomatic liver transplant patients who were tested negative for COVID-19 were recorded as controls, while patients who tested positive were considered cases. VE was defined as "1- OR (odds ratio)."

Results: A total of 136 liver transplant patients were included in the study. 13 (9.6%) patients were diagnosed with COVID-19 during the study period, out of which 7 (5.2%) needed hospitalization and 5 (3.7%) were admitted to the ICU. None of the patients died. The baseline characteristics, transplant history, comorbid conditions, and current immunosuppressive treatment for the participants is summarized in the table.

Among the vaccinated patients, 86 (83.5%) had received **Pfizer** vaccine, and 92 (89.3%) of the patients had received both the doses, three weeks apart.

VE of mRNA based vaccines against any COVID-19 infection, hospitalization and ICU admission is shown. In liver transplant patients VE was 84.1% (38.2%-96.2%, p = 0.002) for any documented infection. VE was 88.9% (26.4%- 98.9%, p = 0.003), and 92.8% (22.8%-99.8%, p = 0.003) for COVID-19 related hospitalizations and ICU admissions respectively.

	Overall (N=136)	Vaccinated (n=103)	Unvaccinated (n=33)	p-value
Age	55.1 ± 14.5	55.9 ± 13.9	52.5 ± 16.1	0.12
Gender, male	103 (75.7%)	74 (71.8%)	15 (45.5%)	0.006

	OR	VE (1-OR)		
Any COVID-19 Infection	0.16 (0.04 – 0.46)	84.1% (38.2% - 96.2%)		0.002
Hospitalization	0.11 (0.01 – 0.74)	88.9% (26.4%- 98.9%)		0.003
MICU Admission	0.07 (0.001 – 0.78)	92.8% (22.8% - 99.8%)		0.003

Conclusion: In liver transplant patients, two doses of mRNA based SARS-CoV-2 vaccines is effective against any documented infection. The protection is higher against hospitalization and ICU admissions. Combined analysis of cellular and humoral response is needed to identify vaccine responders

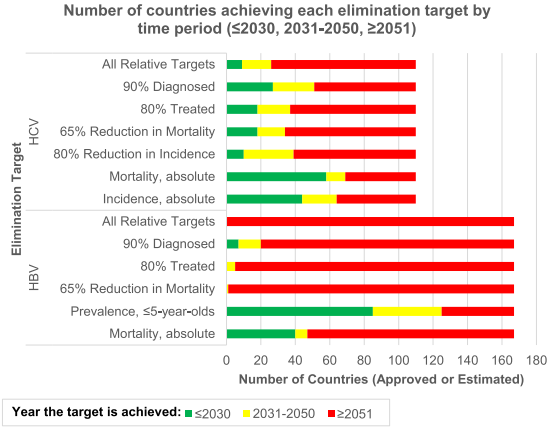
THU278

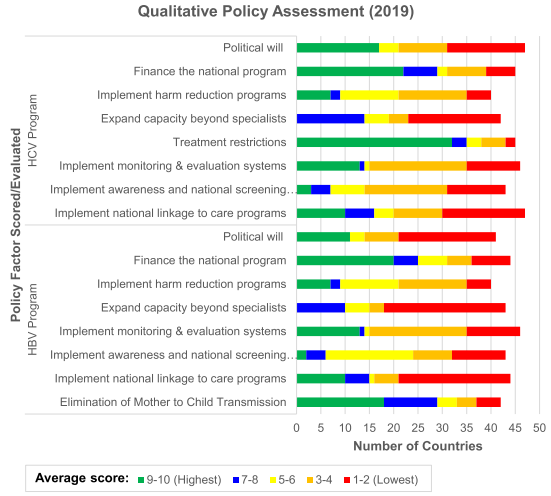
Evaluation of global progress towards HBV and HCV elimination

Sarah Blach[1], Devin Razavi-Shearer[1], Ellen Mooneyhan[1], Chris Estes[1], Kathryn Razavi-Shearer[1], Ivane Gamkrelidze[1], Homie Razavi[1]. [1]*Center for Disease Analysis Foundation, Lafayette, United States*
Email: sblach@cdafound.org

Background and aims: The Polaris Observatory maintains mathematical models for hepatitis B (HBV) and hepatitis C (HCV) viruses which are updated annually and used to monitor progress towards elimination. The outcomes of this work, including country/territory progress reports are publicly available online. The objective of this

analysis was to evaluate progress towards elimination (by elimination target) among the countries with approved or estimated models, and to report on policy assessment surveys returned by country experts.
Method: The year of elimination (by target) was extracted from 110 HCV and 167 HBV models available on the Polaris Observatory website (data from 2020). Results were summarized across countries by disease area and time period of elimination (target achieved before 2030, target achieved between 2031 and 2050, target achieved after 2050). Additionally, average country-level results from a qualitative policy assessment survey (administered in 2020 by the CDA Foundation, with responses from 47 countries) were used to score national viral hepatitis elimination policies.
Results: Based on 2020 data, no countries were on track to achieve all HBV elimination targets by 2030; however, 85 countries were expected to achieve the target for prevalence among 5-year-olds, 40 countries were on track to achieve absolute mortality targets, and 7 were on track to achieve the diagnosis target. Based on 41 survey responses, only 11 countries (26%) received the highest score of 10 for political will ("Government is fully committed to the elimination in any population who tests positive for the virus").
Nine countries were on track to achieve all relative HCV elimination targets by 2030, with 27 expected to achieve the diagnosis target and 18 expected to achieve the treatment target. When absolute targets were considered, 58 countries would achieve the mortality target and 44 would achieve the incidence target. Relative mortality and incidence targets would only be met by 18 and 10 countries, respectively. Based on 47 survey responses, 17 countries (36%) received a score of 10 for political will. Political will was found to be the strongest predictor of country achieving viral hepatitis elimination. Unfortunately, across the board, countries reported a lower political will score for HBV elimination as compared to HCV.





Conclusion: Nuanced country reports on viral hepatitis elimination progress and policies are vital feedback mechanisms for policy makers. Although most countries were not on track to achieve all HBV or HCV targets, substantial progress has been made by countries with regards to individual targets. Substantial work is needed to increase political will for HBV and HCV elimination.

THU279

The impact of vaccination on the global and regional pediatric prevalence of hepatitis B from 1985 to 2022

Devin Razavi-Shearer[1], Ivane Gamkrelidze[1], Sarah Blach[1], Chris Estes[1], Ellen Mooneyhan[1], Kathryn Razavi-Shearer[1], Homie Razavi[1]. [1]*Center for Disease Analysis Foundation, Lafayette, United States*
Email: drazavishearer@cdafound.org

Background and aims: The first vaccine to prevent the hepatitis B virus (HBV) was available in 1981. The rollout and coverage of the vaccine varied by country, but three dose coverage became widespread in 2001 when Gavi, the vaccine alliance, began to support these programs. This study aims to examine the impact of prophylaxis measures on the pediatric, under 18 years of age, prevalence of HBV between 1985 and 2022.
Method: The Polaris Observatory maintains 166 country specific PRoGReSs Models. These models consider the impact of prophylaxis measures (timely birth dose, three dose, hepatitis B immunoglobulin, and anti-viral treatment of pregnant women) and treatment on the incidence and disease burden of HBV. These models were utilized to estimate the historical and current prevalence among the pediatric population at the country and regional level. For countries in which models were not available, a regional prevalence was applied to the population of said missing country.
Results: Modeled countries represented 99.6% and 99.7% of all estimated pediatric cases in 1985 and 2022 respectively. Globally it was estimated that in 1985 the pediatric HBV prevalence was 5.23%, representing 101.9 million infections, this dropped to 1.0%, 23.8 million infections, by 2022 (Figure 1). This represents an 81% reduction in prevalence. High income and upper middle-income countries saw the largest drop, 96%, whereas lower middle- and low-income countries only saw a reduction of 74–75%. Discrepancies in regional reductions were also observed of 95% in Europe, 91% in the Americas, 88% in Asia, 77% in Oceania and 72% in Africa.

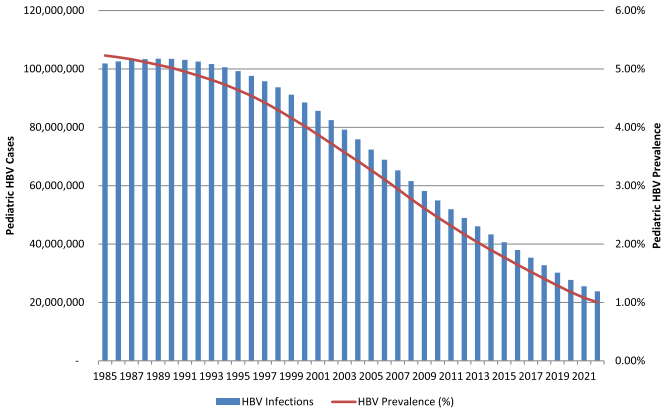


Figure 1: The Global HBV Pediatric Prevalence, 1985–2022.

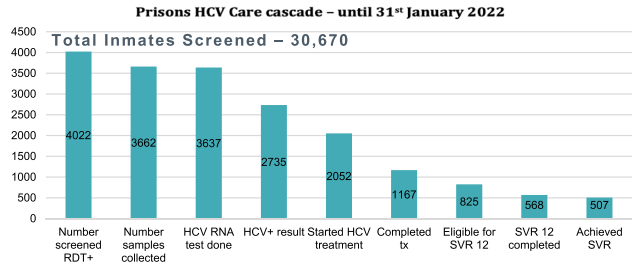
Conclusion: Countries and regions that historically provided timely birth-dose as well as additional mother to child transmission prophylaxis measures have greatly reduced the burden of HBV in their pediatric population. While all regions have reduced the pediatric prevalence, the reductions have been highly inequitable with lower-middle- and low-income countries continuing to bear the brunt of the disease. Without additional assistance to provide timely birth dose and other prevention measures these inequities will continue well into the future.

THU280

Feasibility and effectiveness of hepatitis C micro-elimination among 19 prisons of northern India

Kanudeep Kaur[1], Gagandeep Singh Grover[2], Praveen Kumar Boora[3], V K Bansal[3], Veena Singh[3], S Suman[4], Virendra Singh[5], Arka De[5], Rajashree Sen[1], Sanjay Sarin[6], Sonjelle Shilton[6]. *[1]FIND India, Public Health, Delhi, India; [2]Directorate of Health Services, Public Health, Punjab, India; [3]Directorate of Health Services, Public Health, Panchkula, India; [4]Directorate of Health Services, Public Health, Chandigarh, India; [5]Post Graduate Institute of Medical Education and Research, PGIMER-, Hepatology, Chandigarh, India; [6]FIND, Public Health, Geneva, Switzerland*
Email: kanudeep.kaur@finddx.org

Background and aims: The estimated prevalence of hepatitis C virus (HCV) infection in India is 0.32%, which comprises a considerable proportion of the global HCV burden. The incarcerated population is disproportionately affected by HCV and significant scale-up of access to testing and treatment is needed in order achieve the 2030 global targets for the elimination of HCV. The objective of this intervention was to provide early diagnosis and management of HCV and evaluate the feasibility and efficacy of a decentralised HCV micro-elimination care model in 19 prisons across states of Punjab, Haryana and Union Territory of Chandigarh in the northern part of India.
Method: Anti-HCV antibody rapid diagnostic test (RDT) was performed for the inmates at time of admission or via screening camps. Inmates with positive HCV RDT results received reflex blood draw for HCV RNA testing and pre-treatment investigations. Liver staging was determined by APRI and FIB-4 scores (non-cirrhotic is APRI <2 and FIB-4 <3.5 and cirrhotic as APRI >2 and FIB-4 >3.5). Non-cirrhotic patients were initiated on treatment by the prison medical officer trained by the health department of the respective states. The cirrhotic cases were referred to specialist care at the model treatment centers set up by the states. Test of cure (SVR12) was assessed with an HCV RNA test done 12 weeks after completion of treatment.
Results: A total of 30, 670 inmates, which represent 100% of the prison population in the 19 prisons at the time the intervention started, were screened from November 2019 to January 2022. Of the 13.11% (n = 4022) HCV antibody-positive, 90.42% (n = 3637) received a confirmatory viral load test, of which, 75.19% (n = 2735) were HCV RNA-positive, 74.04% (n = 2052) of those testing HCV RNA positive were initiated on treatment, and 56.87% (n = 1167) had completed treatment as of January 2022. Of those who completed treatment, 48.67% (n = 568) were assessed for SVR cure assessment, with SVR achieved in 89.26% (n = 507) inmates.
The median days and IQR for the turnaround time from RDT screening to viral load result completion was 6 days, IQR 4–12 days (n = 2553); between viral load results and treatment initiation was 6 days, IQR 0–15 days (n = 1622) and total median time between RDT screening and treatment initiation was 16 days with an IQR of 10–30 day (n = 1597).



Conclusion: This simple decentralised HCV testing and treatment model in prison settings has shown to be feasible, effective, and replicable in the Indian context. As this care model is fully transitioned to government partners, additional efforts are being made to re-engage individuals released from incarceration that had not completed all steps in the HCV care cascade.

THU281

The impact of treatment and health policies for Hepatitis C Virus on hospitalizations in the last decade: data analysis of records of hospital discharge (SDO) at Italian national level

Francesco Saverio Mennini[1,2], Paolo Sciattella[3], Claudia Simonelli[1], Andrea Marcellusi[1], Loreta Kondili[4]. *[1]Economic Evaluation and HTA (EEHTA-CEIS), Centre for Economic and International Studies, Faculty of Economics, University of Rome "Tor Vergata", Rome, Italy; [2]Institute of Leadership and Management in Health, Kingston Business School, Kingston University, London, United Kingdom; [3]Economic Evaluation and HTA (EEHTA-CEIS), Centre for Economic and International Studies, Faculty of Economics, University of Rome "Tor Vergata"; [4]Center for Global Health, Istituto Superiore di Sanità, Rome, Italy*
Email: claudia.simonelli1996@gmail.com

Background and aims: In the last decade, innovative treatments and health policies for Hepatitis C Virus (HCV) are leading to the reduction of the burden of HCV-related diseases. Direct-Acting Antiviral (DAA) therapy has shown a high rate of viral eradication, and there is evidence that HCV cure reduces HCV complications and is cost-saving in most western countries in the long term. The aim of this analysis is to evaluate the trend of hospitalizations in patients with HCV chronic infection and HCV-related liver complications in Italy and to discuss the impact of the introduction of DAAs in 2015.
Method: The analysis was based on records of hospital discharge (SDO) at national level from 2012 to 2019. SDO collect information related to all discharges from public and private hospitals in Italy. Data was extracted based on primary and secondary diagnosis for HCV, cirrhosis and hepatocellular carcinoma (HCC). We calculated the annual incident hospitalizations with diagnosis of HCV and HCV-related complications. Analyses were stratified by age cohort (40–59, 60–79 and 80+ years) and divided into two distinct periods: (1) 2012–2015, in which DAAs were not available or had just been approved, and (2) 2016–2019, in which DAAs were available initially with prioritized access and later with universal access. The trend of alcoholic liver complications was also evaluated with the same methodology as comparison.
Results: Annual incident hospitalizations for cirrhosis reduced from 73 new cases per 100.000 inhabitants in 2012 to 44 in 2019 (-39%). Each year, patients with age ≥80 years represent around 20% of new hospitalizations. For alcoholic liver related complications, a reduction of only 9% was observed, and patients with age ≥80 years only represent around 5% of new hospitalizations. From 2012 to 2019, incident cases of HCC also reduced from 52 to 45 per 100.000 inhabitants (-14%) and incident cases of HCV reduced from 113 to 49 per 100.000 inhabitants (-57%). For cirrhosis, HCC, and HCV the reduction was more marked in the second period (2016–2019) than in the first period (2012–2015).

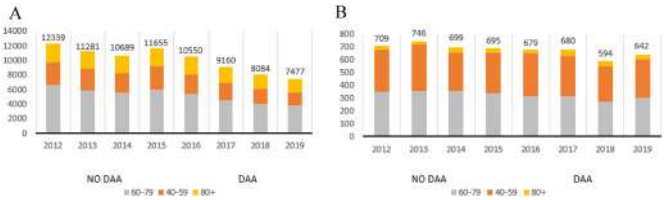


Figure: Annual incident hospitalizations for cirrhosis (A) without and (B) with mention of alcohol, by age cohort

Conclusion: From 2012 in Italy there has been a decreasing trend of hospitalizations for chronic HCV infection, cirrhosis complications and HCC. This reduction is becoming more evident in recent years. Alcoholic liver related complications are decreasing at a slower rate and affect younger patients on average. Overall, these data confirm

the clinical benefit of viral eradication by DAA and the long-term economic benefit of reduced expenses for severe liver complications.

THU282

Hepatitis B birth dose coverage remains dramatically low in The Gambia and has been disrupted by the COVID-19 pandemic

Gibril Ndow[1], Esu Ezeani[1], Cecile de Bezenac[2,3], Julien Randon-Furling[4], Umberto D'Alessandro[1], Yusuke Shimakawa[5], Maud Lemoine[6]. *[1]MRC Unit The Gambia at LSHTM, Fajara, Gambia; [2]Turing Institution, LONDON, United Kingdom; [3]The Alan Turing Institute, LONDON, United Kingdom; [4]Sorbonne University, Paris, France; [5]Pasteur Institution, Paris, France; [6]Imperial College London, Hepatology, LONDON, United Kingdom*
Email: m.lemoine@imperial.ac.uk

Background and aims: Africa has the lowest coverage of hepatitis B birth dose (HepB-BD) vaccination (11%) worldwide and lags far behind the 90% coverage target recommended by the WHO for viral hepatitis elimination by 2030. We aimed to assess i. the coverage and limiting factors of HepB-BD vaccination and ii. the impact of the COVID-19 pandemic on HepB-BD coverage in The Gambia, the first African country to introduce in 1990 hepatitis B vaccination at birth.
Method: we analysed data form the Health and Demographic Surveillance system (HDSS) in four areas in The Gambia. HepB-BD coverage was calculated at birth (0–1 day), day 7 and day 28 in children born between 2015 and 2021. We also performed multiple comparisons tests and a logistic regression to identify factors associated with lack of timely delivery.
Results: between 1 January 2015 and 31 July 2021, 77, 913 births were recorded; of them 77, 515 live births with complete information were analysed. 3, 494/77, 515 babies (4.5%) received a timely HepB-BD (D0–1). The median age at first dose was 20 days (IQR: 12–31 days). HepB-BD was administrated at D7 and D28, in 7, 308/77, 515 (9.4%) and 38, 239/77, 515 (49.3%) babies, respectively.
Whilst timely HepB-BD coverage steadily increased over time (Figure 1), a major disruption was observed between March and August 2020, corresponding to the first wave of COVID-19 outbreak in The Gambia. Between March and August 2020, the HepB-BD coverage dropped from 9% (July 2019 to Feb 2020) to 5%.

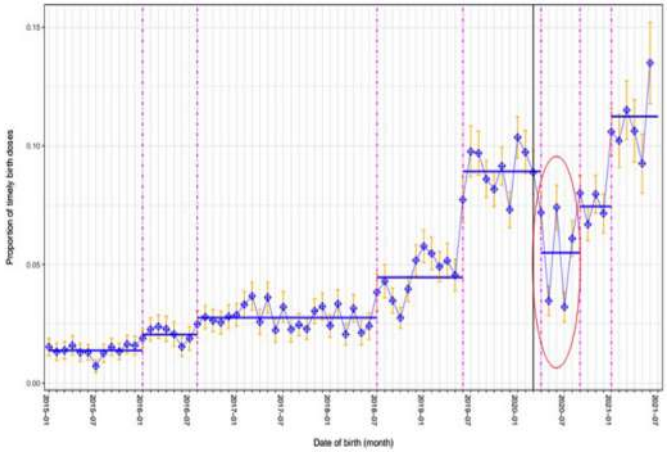

Figure: Monthly proportion of timely HepB-BD from 1st Jan. 2015 to 31st July 2021. Circled in red is the disruption observed in the immediate wake of the first CoViD 19 outbreak (the black vertical line shows the date of the 1st case, 17 March 2020). Magenta dashed vertical lines are change points detected using general fluctuations tests (Bai-Perron). Blue horizontal segments show the mean timely BD rate for each period between change points.
Factors associated with lack of timely HepB-BD were: births on Friday or Saturday (OR:3.2 (95% CI: 2.0 to 3.5), p value $<10^{-15}$), high maternal age (OR:1.5 (1.4 to 1.6), p $<10^{-12}$ for mothers older than 20 with respect to (wrt) mothers younger than 20, and OR: 1.8 (1.6 to 2.1), p $<10^{-15}$) for older than 25 wrt younger than 25), delivery outside the hospitals (OR: 4.6 (3.7 to 5.8), p $<10^{-15}$) especially home delivery (OR:2.1 (95% CI: 1.9 to 2.3), p $<10^{-15}$), born to a primiparous mother (OR: 1.8 (1.6 to 2.2), p $<10^{-12}$) and delivery during the first COVID-19 outbreak (17 March 2020–1st August 2020) (OR:1.7 (1.4 to 1.9, p $<10^{-11}$, among all babies born after June 2019).
Conclusion: more than 30 years after adoption of the HepB-BD vaccination, only minor progress has been made in HepB-BD coverage in The Gambia, putting at risk the HBV elimination goals.

THU283

Hepatitis B prevalence and the impact of vaccination in Georgia: results from a nationwide serosurvey

Nino Khetsuriani[1], Amiran Gamkrelidze[2], Shaun Shadaker[3], Maia Tsreteli[2], Maia Alkhazashvili[2], Nazibrola Chitadze[2], Irina Tskhomelidze[4], Lia Gvinjilia[5], Francisco Averhoff[6], Gavin Cloherty[6], Qian An[1], Giorgi Chakhunashvili[2], Jan Drobeniuc[3], Paata Imnadze[2], Khatuna Zakhashvili[2], Paige A Armstrong[3]. *[1]Centers for Disease Control and Prevention, Global Immunization Division, Atlanta, United States; [2]National Center for Disease Control and Public Health, Tbilisi, Georgia; [3]Centers for Disease Control and Prevention, Division of Viral Hepatitis, Atlanta, United States; [4]The Task Force for Global Health, Tbilisi, Georgia; [5]Centers for Disease Control and Prevention, Eastern Europe and Central Asia Regional Office, Tbilisi, Georgia; [6]Abbott Diagnostics, Abbott Park, United States*
Email: nck7@cdc.gov

Background and aims: Georgia introduced routine infant hepatitis B (HepB) vaccination in 2001 with >90% coverage over the last decade. In 2015, a nationwide serosurvey demonstrated an anti-hepatitis B core antibody (anti-HBc) prevalence of 25.9% and hepatitis B surface antigen (HBsAg) prevalence of 2.9% among adults ≥18 years. No prevalence data were available for children. In 2021, we assessed hepatitis B virus (HBV) infection prevalence among children and updated estimates for adults in a combined COVID-19, hepatitis C and hepatitis B serosurvey of persons aged ≥5 years.
Method: We used a stratified, multi-stage cluster design. We collected data on demographics, medical and exposure history; we tested blood samples for anti-HBc and, if positive, for HBsAg. Nationally representative weighted proportions and 95% confidence intervals (CI) for anti-HBc and HBsAg were calculated. Participants aged 5–20 years had been eligible for routine HepB vaccination as infants.
Results: Among children aged 5–17 years, 0.7% were anti-HBc+ and 0.03% were HBsAg+ (Table). Among adults ≥18 years, 21.7% were anti-HBc+ and 2.7% were HBsAg+. Anti-HBc prevalence increased with age from 1.3% among 18–23-year-olds to 28.6% among ≥60 years. HBsAg prevalence was lowest (0.2%) among 18–23-year-olds and highest (8.6%) among 35–39-year-olds. Males had higher HBsAg prevalence than females (3.6% versus 2.0%; p = 0.003). Anti-HBc prevalence was highest in Samegrelo-Zemo Svaneti, Adjara, and Imereti regions. Higher education and income were associated with lower anti-HBc, and unemployment-with higher HBsAg prevalence.

Table. National anti-HBc and HBsAg prevalence by age and sex, Georgia, 2021

Age, years/sex	No. tested	Anti-HBc+, weighted % (95% CI)	HBsAg+, weighted % (95% CI)
All ages ≥5	8, 710	17.9 (16.7-19.1)	2.2 (1.8-2.8)
Children 5-17	1, 473	0.7 (0.3-1.6)	0.03 (0-0.19)
Adults ≥18	7, 237	21.7 (20.4-23.2)	2.7 (2.2-3.4)
18-23	322	1.3 (0.6-3.1)	0.2 (0.0-1.5)
24-29	430	3.8 (2.0-7.1)	0.9 (0.2-4.8)
30-34	565	11.7 (8.2-16.5)	2.9 (1.2-7.0)
35-39	684	27.8 (23.4-32.6)	8.6 (6.1-12.1)
40-49	1, 233	27.4 (23.9-31.3)	3.0 (2.0-4.5)
50-59	1, 517	28.2 (25.0-31.7)	3.0 (1.6-5.7)
≥60	2, 476	28.6 (26.1-31.2)	1.7 (1.2-2.6)
Sex (adults)			
Male	2, 409	23.1 (20.9-25.5)	3.6 (2.8-4.7)
Female	4, 828	20.5 (19.1-22.1)	2.0 (1.4-2.7)

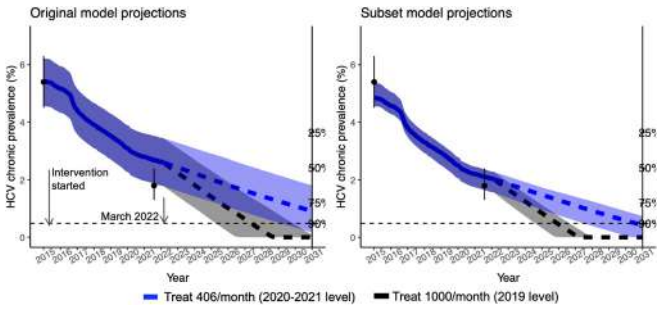
Conclusion: The impact of HepB vaccination in Georgia is demonstrated by a low HBsAg prevalence among children that is below the 0.5% European regional hepatitis B control target and meets the ≤0 .1% seroprevalence target for elimination of mother-to-child transmission of HBV. Chronic HBV infection remains a problem among adults born before routine infant HepB vaccination. Focusing efforts on screening, treatment, and preventive interventions among adults, along with sustaining high immunization coverage among children, can help Georgia achieve elimination of hepatitis B as public health threat by 2030.

THU284

Progress towards HCV elimination in the country of Georgia: insights from modelling and national survey

Josephine Walker[1], Irina Tskhomelidze[2], Shaun Shadaker[3], Maia Tsreteli[4], Senad Handanagic[3], Paige A Armstrong[3], Amiran Gamkrelidze[4], Peter Vickerman[1]. [1]*University of Bristol, Population Health Sciences, Bristol, United Kingdom;* [2]*Task Force for Global Health, Tbilisi, Georgia;* [3]*Centers for Disease Control and Prevention, Division of Viral Hepatitis, Atlanta, United States;* [4]*National Center for Disease Control and Public Health, Tbilisi, Georgia*
Email: jogwalker@gmail.com

Background and aims: A national serosurvey in 2015 found the country of Georgia had high hepatitis C virus (HCV) prevalence, with 5.4% of adults (~150, 000 people) chronically infected. In April 2015, Georgia launched a national program to eliminate HCV infection (reduce prevalence by 90%). We developed an HCV transmission model to capture current and historical dynamics of HCV infection in Georgia, and project long-term impact of the elimination program. A follow-up serosurvey in 2021 provided data which was used to validate the model and update impact projections.
Method: The original model was calibrated to the 2015 serosurvey and surveys among people who inject drugs (PWID), accounting for age, sex, PWID status, and liver disease state. We compare model projected prevalence overall and by age group, sex, and among ever injected drugs to 2021 serosurvey prevalence, and filter the original 532 parameter sets to match the serosurvey results. We used logistic regression to assess which input parameters or model characteristics affect fit. We used program data on 77, 168 persons treated May 2015-February 2022 to estimate current incidence of HCV infection, cases and deaths averted. We project the impact of reductions in treatment rates that occurred in during the COVID-19 epidemic.
Results: The original modelled adult hepatitis C prevalence for 2021 (2.7%, 1.9–3.5%) was higher than the observed serosurvey prevalence (1.8%, 1.3–2.4%); across all groups uncertainty bounds overlap. Only 14% of 532 model runs fit within the 95% confidence interval of all hepatitis C prevalence estimates; 32% fit overall, 28% fit in females, 43% fit in males, 85% fit in ever-injected drugs. Runs that fit the 2021 serosurvey data tend to have lower total population and lower general population hepatitis C incidence, suggesting the model overestimated the initial burden of infection. After filtering, modelled hepatitis C adult prevalence is slightly higher than the observed prevalence (2.1%, 1.6–2.4%). Hepatitis C incidence in March 2022 is estimated to be 0.05 (95% credible interval (CrI) 0.03–0.11) per 100 person-years in general population, and 1.14 (0.08–6.4) per 100 person-years in PWID, a 60% decrease since 2015. As of March 2022, 9, 186 (5, 396–16, 720) infections and 842 (489–1324) deaths have been averted, with benefit accumulating to 26, 154 (15, 850–47, 627) infections and 3, 971 (2, 516–5, 536) deaths averted if tracked to 2030. Treatment numbers went from 996/month in 2019 to 406/month March 2020-March 2022 during the COVID-19 pandemic, resulting in 14, 127 fewer treatments, 471 (242–817) fewer infections averted by March 2022. At 406 treatments/month, elimination can be reached in 2031.



Conclusion: HCV prevalence reduction due to treatment and prevention interventions was greater than originally projected, but treatment numbers must still increase in order to reach HCV elimination by 2030.

THU285

Measuring the alcohol related hospital burden in Ireland and the impact of Minimum Unit Pricing (MUP)

Tobias Maharaj[1,2], Olufemi Aoko[1,2], Elizabeth Gilligan[3], Siobhan MacHale[1,3], John Ryan[1,2]. [1]*Royal College of Surgeons in Ireland (RCSI), Ireland;* [2]*Beaumont Hospital, Hepatology Unit, Dublin, Ireland;* [3]*Beaumont Hospital, Liaison Psychiatry, Dublin, Ireland*
Email: maharajt@tcd.ie

Background and aims: Alcohol harms are a significant burden on healthcare services and in Ireland alcohol related hospital admissions account for approximately 7% of state health expenditure. Minimum Unit Pricing (MUP) sets a legally required floor price per alcohol unit. On 4 January 2022, MUP was introduced in Ireland at €1.00 per unit (10 grams of alcohol). Accurately determining the hospital burden of alcohol in Ireland is a challenge due to inadequate clinical documentation and hospital coding of alcohol harms. Previously published MUP studies have suggested immediate reductions in admissions for acute alcohol-related conditions. The objective of this study was to accurately determine the alcohol-related hospital burden, as well as to measure any immediate impact from the introduction of MUP.
Method: All patients presenting to the emergency department of a major hospital in Dublin city were interviewed by a research clinician from 22:00 to 04:00, over seven consecutive nights before and after the introduction of MUP (total of 84 hours). Data collection included a brief clinical history of presenting complaint, time of last alcohol consumption, AUDIT-C alcohol screening score, and type of alcoholic beverage preference. Each hospital attendance was determined to be either alcohol-related or non-alcohol-related using published ICD codes of alcohol-related conditions from MUP modelling data in Ireland. Alcohol presentations were further categorized into acute or chronic conditions, and directly related or partially related to alcohol.
Results: Excluding missing data (n = 43), there were 245 presentations to hospital: 114 pre-MUP and 131 post-MUP. The median age of attendances was 49 years old with 50% females pre-MUP and 51.2% females post-MUP. High risk alcohol consumption (AUDIT-C score ≥ 5) was similar pre-MUP (43%) and post-MUP (42.0%). Beer was the most preferred beverage pre-MUP (45.5%) and post-MUP (48.8%) compared to all other beverage types. Since the introduction of MUP, there was no immediate difference in alcohol-related hospital attendances (31.6% versus 27.5%; p = 0.48) and no difference in alcohol-related admissions (8.8% versus 7.6%; p = 0.75). Acute alcohol-related admissions signaled a 40% reduction (95% CI = 3.9%, 76.1%; p = 0.03) with MUP. Alcohol admissions for 'partially related', 'directly related', and 'chronic conditions', as well as beverage preferences did not show any significant difference with MUP (p >0.05).
Conclusion: Almost a third of all hospital attendances and almost a tenth of all hospital admissions are alcohol related, representing a

significant burden on healthcare resources. Alcohol is a modifiable risk factor and interventions such as €1.00 MUP may have an immediate impact on reducing admissions for acute alcohol conditions. Larger sample sizes and longitudinal data are awaited.

THU286
Is hepatic steatosis individually a risk factor for colorectal adenoma?

Yuvaraj Singh[1], Maya Gogtay[1], Anuroop Yekula[1], Kartikeya Tripathi[2], George Abraham[1,3,4]. *[1]Saint Vincent Hospital, Internal Medicine, Worcester, United States; [2]University of Massachusetts Medical School-, Baystate campus, Department of Gastroenterology, Springfield, United States; [3]UMass Chan Medical School, Internal Medicine, Worcester, United States; [4]American College of Physicians, Philadelphia, United States*
Email: yuvaraj.singh@stvincenthospital.com

Background and aims: Most colorectal cancers (CRC) originate from adenomatous lesions. Data suggests that obesity, insulin resistance, and metabolic syndrome are risk factors for CRC. Non-alcoholic fatty liver disease (NAFLD) is one of the manifestations of metabolic syndrome. Many studies have correlated metabolic syndrome with a risk of CRC but there is a paucity of evidence on NAFLD and its association with CRC. We aim to study the association between moderate to severe hepatic steatosis detected on vibration-controlled transient elastography (VCTE) and colorectal adenomas.
Method: This retrospective cohort study was approved by the institutional review board (IRB). We included adult patients who underwent VCTE and colonoscopy. Other causes of liver diseases, such as autoimmune hepatitis, alcohol use disorder, viral hepatitis, and primary biliary cirrhosis were excluded. Steatosis was categorized as S0-S1 (mild) and S2-S3 (moderate/severe) based on the controlled attenuation parameter (CAP) grade of VCTE. Colonoscopy findings were stratified on the biopsy results i.e., hyperplastic, adenoma, CRC, inflammatory or normal mucosa. Continuous variables were assessed using the Mann Whitney U test and categorical variables using chi-square with $p < 0.05$ considered statistically significant. A multinomial logistic regression analysis (MLRA) was done between colorectal adenoma and significant covariates.
Results: Out of the 415 patients analyzed, 206 patients met inclusion criteria. 124 had moderate/severe steatosis and 82 had no/mild steatosis. Descriptive analysis showed that BMI ($p = 0.001$), aspirin ($p = 0.011$), smoking ($p = 0.004$), and adenoma ($p = 0.02$) were significantly different between both groups. In the MLRA model; aspirin had an odds ratio (OR) = 0.39 [0.25–0.84] ($p = 0.01$), moderate/severe steatosis OR = 3.5 [2.39–10.45] ($p = 0.03$) and obesity OR = 2.9 [1.07–6.78] ($p = 0.02$) in association with colorectal adenoma.

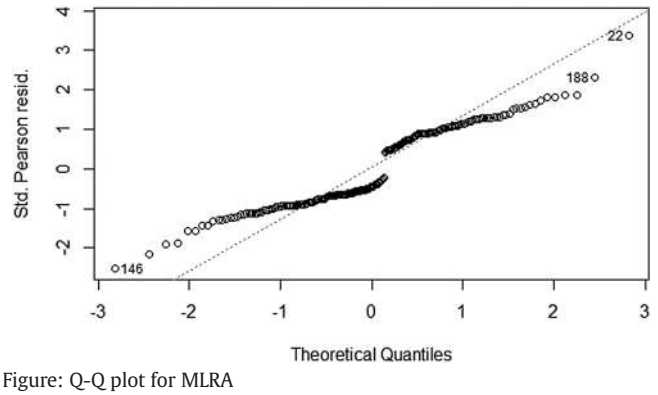


Figure: Q-Q plot for MLRA

Conclusion: Our study indicated that moderate/severe hepatic steatosis is associated with an increased risk of colorectal adenoma detection on colonoscopy. Several patients were excluded due to the non-availability of colonoscopy reports, many of whom were less than 45 years of age. Current guidelines do not recommend earlier screening for CRC after detection of hepatic steatosis for patients. We recommend prospective studies to understand this positive association better. Further studies would be needed to determine if the increase in adenoma detection lowers the risk for the detection of CRC.

No effect of HBsAg positivity on antibody response after COVID-19 vaccine

Ganbolor Jargalsaikhan[1,2], Enkhtuul Batbold[1,2], Delgersaikhan Zulkhuu[1,2], Oyungerel Lkhagva-Ochir[1,2], Uurtsaikh Baatarsuren[1,2], Myagmarjav Budeebazar[1,2], Khatanzul Ganbold[1,2], Sumiya Byambabaatar[1,2], Byambasuren Ochirsum[1,2], Munkhzaya Munkhbaatar[1,2], Purevjargal Bat-Ulzii[1,2], Bishguurmaa Renchindorj[1,2], Andreas Bungert[1,2], Naranbaatar Dashdorj[1,2], Katy Shaw-Saliba[3], Irini Sereti[3], Sally Hunsberger[3], Renee Ridzon[3], Naranjargal Dashdorj[1,2]. *[1]Onom Foundation, Ulaanbaatar, Mongolia; [2]The Liver Center, Ulaanbaatar, Mongolia; [3]National Institute of Health, Bethesda, Maryland, United States*
Email: dashdorj@onomfoundation.org

Background and aims: Immune responses to vaccines may vary based on nutritional status, underlying comorbidities and/or concomitant infections. Despite the high burden of chronic HBV infection worldwide it is not known if this affects the immune response following COVID-19 vaccination. We aimed to evaluate antibody levels in people with chronic Hepatitis B virus (HBV) infection, compared to control group among those receiving either their third or fourth COVID-19 vaccination.
Method: Samples from a subset of participants in the InVITE study (ClinicalTrials.gov Identifier: NCT05096091) were assessed for SARS-CoV-2 IgG level (MINIVIDAS 3.0, BIOMEREUX, France) and HBsAg (HISCL-5000, Sysmex, Japan). Chronic HBV infection was defined as HBsAg>0.03mIU/ml. T-tests were used to compare mean IgG levels and a regression analysis was performed to control for age, sex, history of COVID-19, number of vaccines received, obesity, and time since previous vaccine.
Results: Participants received BBIBP CorV (n = 377), ChAdOx1 nCov-19 (n = 196), BNT162b2 (23), Sputnik V (n = 17) vaccines as their initial two-dose COVID-19 vaccine regimen. Of the 613 participants included in this analysis, 104 with chronic HBV and 504 controls. Overall characteristics included: 6.5% older than 60 years, 62% female, 20% with history of COVID-19, 17% receiving a fourth dose of vaccine, 20% obese, and 48% had greater than 6 months since previous vaccine; these were well balanced between groups. The IgG levels between groups were not significantly different ($p = 0.265$), with mean (std) of control 32.3 (13.6) BAU/ml, chronic HBV, 34.0 BAU/ml (14.4). Only history of COVID-19 was significantly associated with increased antibody levels in the regression model ($p = 3.0 \times 10^{-3}$).
Conclusion: This study showed no difference in SARS-CoV-2 IgG levels between control and HBsAg positive groups. SARS-CoV-2 IgG level was higher in participants with previous COVID-19 infection than those without COVID-19 infection.

THU288
Prevalence of hepatitis B and C virus in the Uzbekistan Hepatitis Elimination Program (UHEP) patients

Erkin Musabaev[1], Chris Estes[2], Shakhlo Sadirova[3], Shokhista Bakieva[1], Krestina Brigida[1], Kathryn Razavi-Shearer[2], Bakhodir Yusupaliev[4], Homie Razavi[2]. *[1]Research Institute of Virology, Tashkent, Uzbekistan; [2]Center for Disease Analysis Foundation, Lafayette, United States; [3]Center for Disease Analysis Foundation, Tashkent, Uzbekistan; [4]Ministry of Health, Tashkent, Uzbekistan*
Email: homie.razavi@centerforda.com

Background and aims: Chronic infection with hepatitis B and C viruses (HBV and HCV) is a major contributor to liver disease and liver-related mortality in Uzbekistan. There is a need to better

quantify the number of undiagnosed cases, the characteristics of infected patients, and the risk factors associated with disease.

Method: In the capital city of Tashkent, 13 clinics were established to diagnosed and treat chronic HBV and HCV infection among the general adult population. Patients underwent testing for HBV and HCV infection, along with follow-up biochemical measures and questionnaire items. Nurses were trained to use rapid HCV and HBV tests to screen large number of people and an electronic medical system was put in place to record the test and questionnaire results. The prevalence of previously undiagnosed HBV and HCV was estimated and adjusted to the Uzbekistan population. Regression analyses quantified risk of infection based on demographic factors.

Results: HBV and HCV screening was conducted on 62, 000 people over a 12-month period that included a 6-month shutdown due to the COVID-19 pandemic. Before the shutdown, 30, 000 people were screened while another 32, 000 were screened in conjunction with COVID-19 testing. Complete dataset was available for 53, 841 HBV patients and 54, 396 HCV patients. Age-adjusted adult prevalence of previously undiagnosed chronic HBV and HCV infection were estimated at 3.23% (3.00–3.37%) and 3.02% (2.80–3.16%), respectively. Prevalence was significantly higher in males for both HBV and HCV, while increasing age was significantly associated with higher HCV prevalence. The most commonly reported risk factors among HCV+ patients were dental procedures and medical injections, and 2.5% of HCV+ patients had APRI score >2.5. Among HBV+ patients 1.2% had eFGR <30 while for HCV+ patients the portion was 3.3%.

Conclusion: This program represent the first of its kind in terms of scope (HBV and HCV testing) and size providing a detailed estimate of viral hepatitis infection. A large population of patients chronically infected with HBV and HCV remains undiagnosed in Uzbekistan. There should be further efforts to screen, diagnose and treat these patients in the general population to achieve the WHO 2030 elimination targets.

Evaluation of the clinical and economic value of sofosbuvir/velpatasvir (SOF/VEL) in patients with chronic hepatitis C in Spain during the last 5 years

Rafael Esteban[1], Raquel Domínguez-Hernández[2], Helena Cantero[3], Miguel Ángel Casado[2]. [1]*Hospital Universitari Vall d'Hebron, Barcelona, Spain;* [2]*Pharmacoeconomics and Outcomes Research Iberia (PORIB), Pozuelo de Alarcón, Spain;* [3]*Gilead Sciences, Madrid, Spain*
Email: rdominguez@porib.com

Background and aims: The introduction of direct-acting antivirals in the therapeutic arsenal for the treatment of hepatitis C virus (HCV) infection represented a paradigm shift. Sofosbuvir/velpatasvir (SOF/VEL; Epclusa®) has added value to HCV treatments, achieving high response rates that lead to a cure in most HCV chronic patients. The aim of this analysis was to evaluate the long-term impact on health and economic outcomes of patients with chronic hepatitis C treated with SOF/VEL during the first 5 years after its approval in Spain (2017–2022).

Method: A previously developed lifetime Markov model was adapted to estimate HCV morbidity and mortality comparing two treatment alternatives: SOF/VEL versus previous therapies (peginterferon and ribavirin in double/triple therapy with telaprevir or boceprevir). The target population (30, 488 patients) entered the model during the first 5 years (22% 1st year, 26% 2nd, 22% 3rd, 13% 4th, 17% 5th) and were distributed among the fibrosis states in treated or untreated. In SOF/VEL, all patients (100%) were treated regardless of fibrosis states (F0-F4) with an average weighted sustained viral rate (SVR) of 98.9% from real-world data. In previous therapies, only 49% of ≥F2 states HCV patients were treated, with 61% SVR. All parameters required for the analysis were obtained from real-world data and the literature. Only direct healthcare costs associated with disease management were included. A discount rate (3%) was applied to costs and healthcare outcomes. The results were measured as the number of cases of decompensated cirrhosis (DC), hepatocellular carcinoma (HCC), and liver transplant as well as their costs associated, in addition to liver-related deaths, comparing both alternatives. An alternative analysis was performed with a reduction in the SVR rate of SOF/VEL to 95%.

Results: In the analysis of SVR rate (98.9%), the lifetime results showed that SOF/VEL decreased liver-related mortality by 85% (4, 017 cases avoided) as well as avoided cases of liver complications: 3, 467 DC (-92%), 2, 536 HCC (-80%) and 474 LT (-87%), having the greatest impact on DC. In economic terms, the costs associated with SOF/VEL in the management of liver complications generated a total saving of 197 million euros. In the alternative analysis, a variation in the SVR rate (95%) decreased the impact on the reduction of avoided liver-related events between 75 and 86%.

Mortality and liver complications	Number of cases with each alternative treatment	
	Previous therapies	Sofosbuvir/Velpatasvir
Liver-related death	4, 727	710
Decompensated cirrhosis	3, 757	291
Hepatocellular carcinoma	3, 151	615
Liver transplant	547	73

Conclusion: SOF/VEL significantly decreases HCV morbidity and mortality adding value to the management of patients with chronic hepatitis C reducing the clinical and economic burden of the disease and contributing to the goal of disease elimination in Spain.

THU290

The value of increased HCV testing and treatment strategies in Spain to achieve elimination goals

José Luis Calleja Panero[1], Jaime Espin[2], Ankita Kaushik[3], Manuel Hernández Guerra[4], Rob Blissett[5], Adam Igloi-Nagy[5], Alon Yehoshua[3]. [1]*Universidad Autónoma de Madrid, Hospital Universitario Puerta de Hierro, Madrid, Spain;* [2]*Escuela Andaluza de Salud Pública, Granada, Spain;* [3]*Gilead Sciences, Inc., Foster City, United States;* [4]*Hospital Universitario de Canarias, Tenerife, Spain;* [5]*Maple Health Group, LLC, New York City, United States*
Email: alon.yehoshua@gilead.com

Background and aims: In 2015, Spain launched a national eradication strategy for Hepatitis C virus (HCV) through prevention, screening, diagnosis, and link-to-care, resulting in the highest HCV treatment rate of any European country and substantial reductions in HCV prevalence. To achieve the goal of HCV elimination, it is necessary to scale up the diagnosis, treatment, and management of HCV infection in the general population, migrants and people who inject drugs (PWID). Our aim was to assess the prevalence, incidence, and cost effectiveness of scaling up compared to status quo scenarios.

Method: A compartmental dynamic transmission model was developed in visual basic for applications (VBA). The model comprises two modules: the first represents the cascade of HCV care and the second represents the progression of liver disease. Direct and indirect costs, as well as utilities to estimate quality of life were considered as model inputs. Outcomes included the prevalence and incidence of HCV infection as well as the incremental cost per quality-adjusted life year (QALY) and per life year (LY). Outcomes for a hypothetical elimination strategy were compared to those expected with the status quo staying in place. Costs and effects were discounted at 3.0%; the model time horizon is until the year 2030 in the base case and extended to 2040 in scenario analysis.

Results: The base case analysis found that scaling up testing and treatment reduced both the prevalence and incidence of HCV over time resulting in incremental costs per QALY and LY of €13, 291 and €12, 285 respectively, compared to the status quo. Excluding indirect costs from the analysis brought the incremental costs per QALY and LY to €13, 761 and €12, 720, respectively. Main drivers of the cost-effectiveness results included cost of diagnosis, cost of treatment, proportion of people who are unaware, percentage of population of people who inject drugs, and various calibration parameters related to HCV infection prevalence. Scenario analyses found that reducing the screening intervals decreased the prevalence of HCV infection over time; extending screening to include migrants upon arrival in Spain also decreased the prevalence over time with the same or better cost effectiveness metrics.

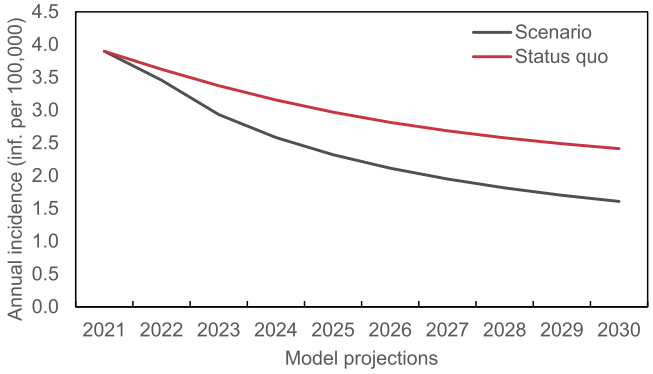

Figure 1: Annual incidence of HCV in Spain over time in the increased testing scenario compared to status quo.

Conclusion: This analysis demonstrated that scaling up testing and treatment with direct acting antivirals (DAAs) is an efficient strategy for reducing the incidence and prevalence of HCV infection among

key populations of interest in Spain. Given the global burden of HCV infection, and its associated liver-related morbidity and mortality, increasing access to testing and treatment among key populations of interest may be a successful strategy to achieve HCV elimination goals in Spain.

THU291

National hepatitis elimination profiles: progress towards HBV and HCV elimination in five European countries

Lindsey Hiebert[1], Isabelle Nassar[1], Vanessa Nunez[1], Loreta Kondili[2], Sema Mandal[3], Graham Foster[4], Francisco Javier Garcia-Samaniego Rey[5,6], Philip Bruggmann[7,8], Paolo Bonanni[9], Camila Picchio[10], Rui Marinho[11], Jeffrey Lazarus[10], John Ward[1]. *[1]Task Force for Global Health, Coalition for Global Hepatitis Elimination, Decatur, United States; [2]Istituto Superiore di Sanità, Italy; [3]UK Health Security Agency, United Kingdom; [4]Queen Mary University of London, United Kingdom; [5]Alianza para la Eliminación de las Hepatitis Víricas en España, Spain; [6]Hospital Universitario La Paz, Spain; [7]Swiss Hepatitis, Switzerland; [8]Arud Centre for Addiction Medicine, Switzerland; [9]University of Florence, Italy; [10]University of Barcelona, Institute of Global Health (ISGlobal); [11]University of Lisbon (FMUL)*
Email: lhiebert@taskforce.org

Background and aims: To achieve WHO goals for hepatitis elimination, Member States (MS) are in various stages of national planning and policy development. To track country-level progress and identify feasible next steps, CGHE is developing National Hepatitis Elimination Profiles (NHEPs). The status of hepatitis elimination in European countries are described.

Method: Together with local partners, profiles were prepared for England (EG), Italy (IT), Portugal (PT), Spain (ES) and Switzerland (CH). For comparison, key indicators include policies for prevention, testing, and treatment. Country-specific data were collected from peer-reviewed reports, ministries of health (MoH), ECDC, WHO and other credible sources. Partners in MoH, clinical practice, and civil society organizations (CSO) validated data.

Results: All MS have an HCV action plan; ES, IT, and CH have HBV action plans. EG, ES, and CH have set HBV and HCV elimination goals, while PT has goals for HCV. For CH and ES, the hepatitis AP and goals were prepared by clinical associations and CSO. All MS have >95% coverage of infant 3-dose HepB vaccination. All MS have policies for routine HBV screening of pregnant women; IT recommends maternal HCV screening. All countries recommend HepB birth dose vaccination (Hep-BD-V) for newborns of HBsAg+ mothers. PT recommends universal HepB-BD- V <24 hours of birth; PT has >50% coverage, the WHO 2020 target. The 4 countries with data distribute 27–139 needle-syringes per person who injects drugs (PWID) per year, 14%-70% of the WHO 2020 target. At least two MS have safe injection programs for persons who are incarcerated. All countries have risk-based HBV and HCV screening; IT recommends HCV testing for persons born 1969–1989. All have removed most restrictions to HCV treatment. However, some MS require HCV genotyping (CH, IT, PT) and specialty care (ES, IT, PT) (figure). Data suggest 3 countries have reduced HCV mortality rates approaching or exceeding the 2030 WHO target (≤2 /100, 000). As feasible next steps, local partners prioritize community awareness of hepatitis, expanded adult testing, and micro-elimination programs for key populations (PWID, INC).

	CH	EG	ES	IT	PT
Simplified care algorithm					
<2 visits required during treatment	Partial (Optional)	Partial *(Varies across country)*	No	No	✓
Non-specialists can prescribe treatment	✓	✓	No	No	No
No mandatory genotyping	No	✓	✓	Partial *(for key populations)*	No
No co-payments	✓	✓	✓	✓	✓
Removal of restrictions					
Based on fibrosis	✓	✓	✓	✓	✓
Based on sobriety	✓	✓	✓	✓	✓

Conclusion: NHEPs reveal advances and challenges to hepatitis prevention and care and lessons learned for overcoming barriers. With NHEPs, local coalitions (CSO, MoH, clinical) can advocate for policies expanding HBV and HCV services, accelerating progress toward hepatitis elimination.

THU292

Economic investment and strategies to eliminate hepatitis C in Mexico

Ellen Mooneyhan[1], Alethse De la Torre Rosas[2], Daniel Bernal Serrano[2], David Kershenobich[3], Maria Jesus Sanchez[4], Leandro Soares Sereno[5], Ivane Gamkrelidze[1], Sarah Blach[1], Homie Razavi[1]. *[1]Center for Disease Analysis Foundation, Lafayette, United States; [2]National Center for the Prevention and Control of HIV (CENSIDA), Mexico City, Mexico; [3]The National Institute of Health Sciences and Nutrition Salvador Zubirán (INCMNSZ), Tlalpan, Mexico; [4]Pan American Health Organization, Mexico City, Mexico; [5]Pan American Health Organization, Washington DC, United States*
Email: emooneyhan@cdafound.org

Background and aims: In July 2020, the Mexican Government initiated the National Program for Elimination of Hepatitis C (HCV) under a procurement strategy that secured universal, free access to HCV screening, diagnosis, and treatment for 2020–22. This analysis quantifies the clinical and economic burden of HCV under a continuation (or an end) to this agreement.

Method: A modeling and Delphi approach was used to evaluate the current and future disease burden (from 2020 to 30) and economic impact (from 2020 to 35) of the historical paradigm (Historical Base) compared to HCV elimination (Elimination). The elimination cost analysis was stratified assuming the agreement continues (Elimination-Agreement to 2035) or terminates (Elimination-Agreement to 2022). We also analyzed the price of HCV treatment needed to achieve net-zero cost (defined as the difference in cumulative direct costs between the scenario and the Historical Base), starting at a base price of 77, 838 MXN per person per treatment. Elimination is defined by the World Health Organization as a 90% reduction in new infections, 80% diagnosis coverage, 80% treatment coverage, and 65% reduction in mortality, by 2030.

Results: A viremic prevalence of 0.55% (0.38–0.60) was estimated in Mexico on January 1, 2021, corresponding to 745, 000 (677, 000–812, 000) viremic infections. In the Historical Base, cases of advanced liver disease and liver-related deaths are projected to rise 75%-80% and annual direct costs are projected to remain at 2.4–2.5 billion MXN, with cumulative direct costs reaching 39.7 billion MXN. Elimination could save 23, 500 lives and divert 6.5 billion MXN in healthcare costs. Under Elimination-Agreement to 2035, annual direct costs are projected to peak at 2.6 billion MXN, with cumulative direct costs

of 31.2 billion MXN. Under the Elimination- Agreement to 2022, annual direct costs would peak at 8.1 billion MXN, estimating 74.2 billion MXN in cumulative direct costs. The price of HCV treatment must decrease to 11, 000 MXN per patient to achieve net-zero cost by 2035.

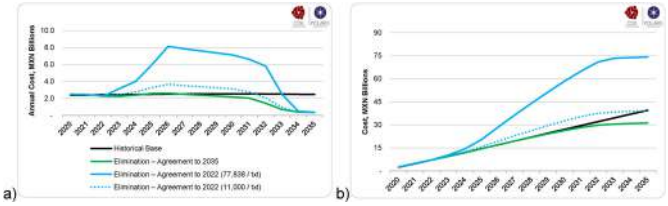

Figure: Direct Medical Costs, 2020–2035 annual direct medical costs, b) cumulative direct medical cost

Conclusion: To achieve HCV elimination at net-zero cost or below, the Mexican Government could either extend the procurement agreement through 2035 or reduce the cost of HCV treatment from 77, 838 MXN to 11, 000 MXN per person per treatment, starting in 2023. Otherwise, the Mexican Government must increase national budget allocation to the elimination program in order to achieve elimination by 2030.

THU293

Assessing the cost-effectiveness of integrated screening of viral hepatitis C, HIV, and tuberculosis

Ketevan Goginashvili[1], Ekaterine Adamia[1]. [1]*Ministry of Internally Displaced Persons from the Occupied Territories, Labour, Health and Social Affairs of Georgia, Policy Department, Tbilisi, Georgia*
Email: kgoginashvili@moh.gov.ge

Background and aims: Georgia has made significant progress in reducing the burden of communicable diseases, which is due to effective measures taken to manage these diseases. The aim of the study was to evaluate the cost-effectiveness of integrated screening for the early detection of hepatitis C, HIV/AIDS, and tuberculosis, introduced at the level of primary health care since 2018.
Method: A pre and post-intervention study focused on comparing of two different methods of hepatitis screening using the cost-effectiveness evaluation. For the purpose of the study: the costs, screening coverage, and prevalence rates were compared for two different screening methods 1) integrated screening for hepatitis C, tuberculosis, and HIV/AIDS; 2) Separate screening of all three diseases in Samegrelo region.
Method: In Samegrelo region, primary health physicians conducted an average of 0.68 integrated screenings per adult person for hepatitis C, tuberculosis, and HIV/AIDS in 2019–2020, the mean screening cost was 9.4 GEL per person and the hepatitis C prevalence rate was 6.5% (p <0.05). While in 2017–2018, Separate screening of all three diseases per adult person in the same region was 0.35, expenditure on hepatitis screening was GEL 17.4 and the prevalence rate was 6.9% (p <0.05). The Cost-effectiveness coefficient was 13.8 and 49.7 for integrated screening and for hepatitis screening respectively (p = 0.01).
Results: In Samegrelo region, primary health physicians conducted an average of 0.68 integrated screenings per adult person for hepatitis C, tuberculosis, and HIV/AIDS in 2019–2020, the mean screening cost was 9.4 GEL per person and the hepatitis C prevalence rate was 6.5% (p <0.05). While in 2017–2018, Separate screening of all three diseases per adult person in the same region was 0.35, expenditure on hepatitis screening was GEL 17.4 and the prevalence rate was 6.9% (p <0.05). The Cost-effectiveness coefficient was 13.8 and 49.7 for integrated screening and for hepatitis screening respectively (p = 0.01).

	Integrated screening of three diseases	Hepatitis C screening	P value
Screening per person	0.68	0.35	<0.05
Screening mean cost per adult person, GEL	9.4	17.4	<0.05
Hep. C prevalence rate	6.5%	6.9%	<0.05
Cost-effectiveness coefficient	13.8	49.7	0.01

Table: Clinical and economic outcomes for integrated screening of three diseases and hepatitis C screening

Conclusion: This study provides evidence that adherence to the integrated screening of Hepatitis C, HIV/AIDS, and tuberculosis is more cost-effective and increases the rate of screening coverage compared to single hepatitis C screening alone.

THU294

Eliminating chronic hepatitis B in the northern territory of Australia through a holistic care package delivered in partnership with the community

Jane Davies[1], Joshua Saul Davis[1], Kelly Hosking[2], Paula Binks[1], Catherine Gargan[2], Belinda Greenwood-Smith[2], Sarah Bukulatjpi[3], Terese Ngurruwuthun[3], Amanda Dhagapan[3], Phillip Wilson[2], Teresa De Santis[2], Karen Fuller[4], Melita McKinnon[1], Mikaela Mobsby[2], Emily Vintour-Cesar[1]. [1]*Menzies School of Health Research;* [2]*Northern Territory Government, Department of Health, Darwin City, Australia;* [3]*Miwatj Health Aboriginal Corporation;* [4]*Katherine West Health Board Aboriginal Corporation*
Email: jane.davies@menzies.edu.au

Background and aims: Hep B PAST is a partnership project developed to eliminate chronic hepatitis B (CHB) from the Aboriginal population of the Northern Territory (NT) in Australia. Preliminary results from the project demonstrate significant improvements in the cascade of care for those living with CHB. The project aims to:
Improve hepatitis B related health literacy
Improve the cascade of care for people living with CHB
Method: Aim 1: Using a participatory action approach (PAR) the "Hep B Story" educational app was designed, translated (forward and back translation) launched in pilot language Yolŋu matha, and evaluated, with the process then repeated for the seven next most widely spoken NT Aboriginal languages.
Aim 2: Reviewing existing pathology and vaccination data from electronic health record systems, individuals in consenting health services were allocated to one of six hepatitis B sero-status codes (Hep B: Fully vaccinated, Hep B: Immune by Exposure, Hep B: Infected ON Treatment, Hep B: Infected NOT ON Treatment, Hep B: Non-Immune, No data) triggering an appropriate follow-up response for all clients. To support primary care to manage recalls and follow-ups as appropriate, we delivered hepatitis B education to remote doctors, nurses, and Aboriginal Health Workers (AHWs). Using a PAR, a hepatitis B management education course for AHWs was developed, delivered, and evaluated.
Results: The Hep B Story App is now available in English and eight Aboriginal languages spoken in the NT and roll out and evaluation is underway. All client files in participating health services have been reviewed, with approximately 30, 000 Aboriginal clients allocated a hepatitis B serocode and appropriate care pathway. Hepatitis B education has been delivered to over 150 general practitioners and nurses in the NT, and to approximately 100 AHWs. The cascade of care for those living with hepatitis B in the NT has significantly improved, now exceeding National Hepatitis B Strategy Targets, with 90% allocated a serocode (national target = 80%), 61% engaged in care (national target = 50%), and 21% receiving antiviral treatment (national target = 20%)
Conclusion: This project is demonstrating the effectiveness of a partnership approach with communities, with AHWs at the centre of the care model, and creating a community led, culturally acceptable, in-language health promotion tool in improving client outcomes for CHB. The preliminary findings from the project demonstrate

improvements in clinical care whilst preserving Aboriginal languages and empowering community through increased health literacy.

THU295

Hepatitis C prevalence and elimination in Pakistan; a bottom-up approach accounting for provincial variation

Ellen Mooneyhan[1], Huma Qureshi[2], Hassan Mahmood[2], Samra Mazhar[2], Muhammad Tariq[3], Nabeel Ahmed Maqbool[3], Ambreen Khan[3], Masood Anwar[3], Sarah Blach[1], Homie Razavi[4], Sabeen Shah[5], Saeed Sadiq Hamid[6], Tanweer Hussain[3], Saira Khowaja[5], Uzma Khan[7], Syeda Zahida Sarwar[3], Khalid Mahmood[8,9], Gul Sabeen Azam Ghorezai[10], Farooq Azam[11], Ayub Rose[12], Mohammad Khalil Akhter[13], Aamir Ghafoor Khan[13], Mujahid Aslam[14], Ahmad Nawaz[13,14]. *[1]Center for Disease Analysis Foundation, United States; [2]Ministry of National Health Services, Regulations and Coordination, Islamabad, Pakistan; [3]Chemonics International, Pakistan; [4]Center for Disease Analysis Foundation, Lafayette, United States; [5]Indus Hospital and Health Network, Karachi, Pakistan; [6]Aga Khan University and Hospitals, Karachi, Pakistan; [7]IRD Pakistan, IRD Global, Karachi, Pakistan; Singapore, Singapore, Pakistan; [8]Punjab Hepatitis Control Programme, Lahore, Pakistan; [9]Punjab Hepatitis Control Program, Primary and Secondary Healthcare, Lahore, Pakistan; [10]Balochistan Hepatitis Control Programme, Quetta, Pakistan; [11]Chemonics International/USAID, Quetta, Pakistan; [12]Chemonics International/USAID, Peshwar, Pakistan; [13]Health Department Khyber Pakhtunkhwa, Peshawar, Pakistan; [14]Lady Reading Hospital, Peshwar, Pakistan*
Email: emooneyhan@cdafound.org

Background and aims: In Pakistan, substantial changes to hepatitis C virus (HCV) programming and treatment have occurred since the 2008 national serosurvey estimated a 4.8% anti-HCV prevalence. However, a recent national serosurvey is unavailable. This analysis estimates a national prevalence using a bottom-up approach to account for provincial variation, coupled with screening, treatment, and prevention targets needed to achieve elimination by 2030.
Method: Using a Delphi method, epidemiologic HCV data for the four provinces of Pakistan (accounting for 97% of the country's population) were reviewed with 21 provincial and national subject-matter experts over 10 virtual meetings. Province-level estimates were then aggregated and inputted into a mathematical model to estimate the national HCV disease burden in the absence of intervention (Base), and if the World Health Organization (WHO) elimination targets of a 90% reduction in new infections, 80% diagnosis coverage, 80% treatment coverage, and 65% reduction in mortality, are achieved by 2030 (WHO Elimination).
Results: An estimated 9, 746, 000 (7, 573, 000–10, 006, 000) Pakistanis are living with viraemic HCV as of January 1, 2021, corresponding to a viraemic prevalence of 4.3% (3.3–4.4). Under the Base, it is estimated that 21% (2, 010, 000) of the infected Pakistani population has been diagnosed with HCV and only 2% (215, 000) of those infected received treatment in 2021. WHO Elimination would require an annual average of 18.8 million people screened, 1.1 million treated, and 46, 700 new infections prevented between 2021–2030. WHO Elimination would reduce total infections by 7, 040, 000, save 152, 000 lives and prevent 104, 000 incidence cases of hepatocellular carcinoma between 2015 and 2030.
Conclusion: Recent blood surveys, programmatic data, and expert panel input from the four provinces of Pakistan uncovered a higher number of HCV infections and lower number of patients treated than has been estimated using national extrapolations, which demonstrates the benefits of a bottom-up approach. Screening and treatment must increase 20-fold and 5-fold, respectively, from current levels, to curb the HCV epidemic in Pakistan and achieve elimination by 2030.

THU296

Association between immunosuppressants and poor antibody responses to inactivated SARS-CoV-2 vaccines in patients with autoimmune liver diseases

Hu Li[1], Yuting Wang[1], Ling Ao[1], Mingxia Ke[1], Zhi-wei Chen[1], Min Chen[1], Ming-Li Peng[1], Ning Ling[1], Peng Hu[1], Dachuan Cai[1], Dazhi Zhang[1], Hong Ren[1]. *[1]Key Laboratory of Molecular Biology for Infectious Diseases (Ministry of Education), Institute for Viral Hepatitis, Department of Infectious Diseases, the Second Affiliated Hospital of Chongqing Medical University*
Email: renhong0531@vip.sina.com

Background and aims: To evaluate the safety, antibody responses and explore the impact of immunosuppressants on inactivated SARS-CoV-2 vaccines in patients with autoimmune liver diseases (AILD).
Method: In this prospective study, 76 adult patients with AILD and 136 healthy subjects were enrolled at least 21 days since the second dose of vaccines (BBIBP-CorV or CoronaVac). All adverse events (AEs) after the COVID-19 vaccination were recorded and graded. The anti-RBD-IgG and neutralizing antibodies (NAbs) were determined. In addition, SARS-CoV-2 specific B cells were also analyzed.
Results: All AEs were mild and self-limiting, and the incidence was similar between AILD patients and controls within 7 days and 30 days after COVID-19 vaccination. The anti-RBD-IgG and NAbs were detectable in 74 (97.4%, 100% in healthy controls, $p = 0.13$) and 48 (63.2%, 84.6% in healthy controls, $p < 0.001$) patients. The titers of anti-RBD-IgG ($p = 0.02$) and NAbs ($p < 0.001$) were both significantly lower in AILD patients than healthy controls. In multiple regression analysis, immunosuppressive therapy was an independent risk factor for the low-level anti-RBD-IgG responses (AOR: 4.7; 95% CI, 1.5–15.2; $p = 0.01$) and reduced probability of NAbs seropositivity (AOR, 3.0; 95% CI, 1.0–8.9; $p = 0.04$) in AILD patients. However, regardless of with or without immunosuppressants, the RBD-specific MBCs responses were comparable between patients with AILD and healthy controls.
Conclusion: The COVID-19 inactivated vaccine is safe and achieves efficient antibody responses in patients with AILD. In addition, immunosuppressants are significantly associated with poor antibody responses to the SARS-CoV-2 vaccine.

THU297

"Like what? You think I have that?"-Impact of stigma on pharmacy-based identification and treatment of hepatitis C in Victoria, British Columbia

Marion Selfridge[1,2], Tamara Barnett[1], Kellie Guarasci[1], Karen Lundgren[1], Anne Drost[1], Chris Fraser[1,3]. *[1]Cool Aid Community Health Centre, Victoria, Canada; [2]University of Victoria, Canadian Institute of Substance Use Research, Victoria, Canada; [3]University of British Columbia, Department of Family Medicine, Vancouver, Canada*
Email: mselfridge@coolaid.org

Background and aims: Canada is currently on target to reach the 2030 WHO goal of HCV elimination. Continued high rates of treatment initiation are required to meet this goal. Novel models have proven successful to engage populations who use drugs (PWUD) in HCV therapy with a simplified, task-shifted cascade of care: Tayside, Scotland pharmacy-based HCV screening and treatment has demonstrated excellent outcomes and progress towards local HCV elimination. The EPIC Study seeks to determine whether pharmacy-based treatment successes can be replicated at community pharmacies in Victoria BC.
Method: Four community pharmacies known to work with PWUD and provide opioid agonist therapy (OAT) were provided training sessions to equip staff with a standardized tool kit of resources. In fall 2020, pharmacy staff were trained to provide verbal informed consent and perform point of care HCV OraQuick antibody screening. Pharmacies were supported by a study nurse to link to HCV RNA testing when antibody positive patients were identified, with initiation of HCV treatment offered to those found to be RNA positive.

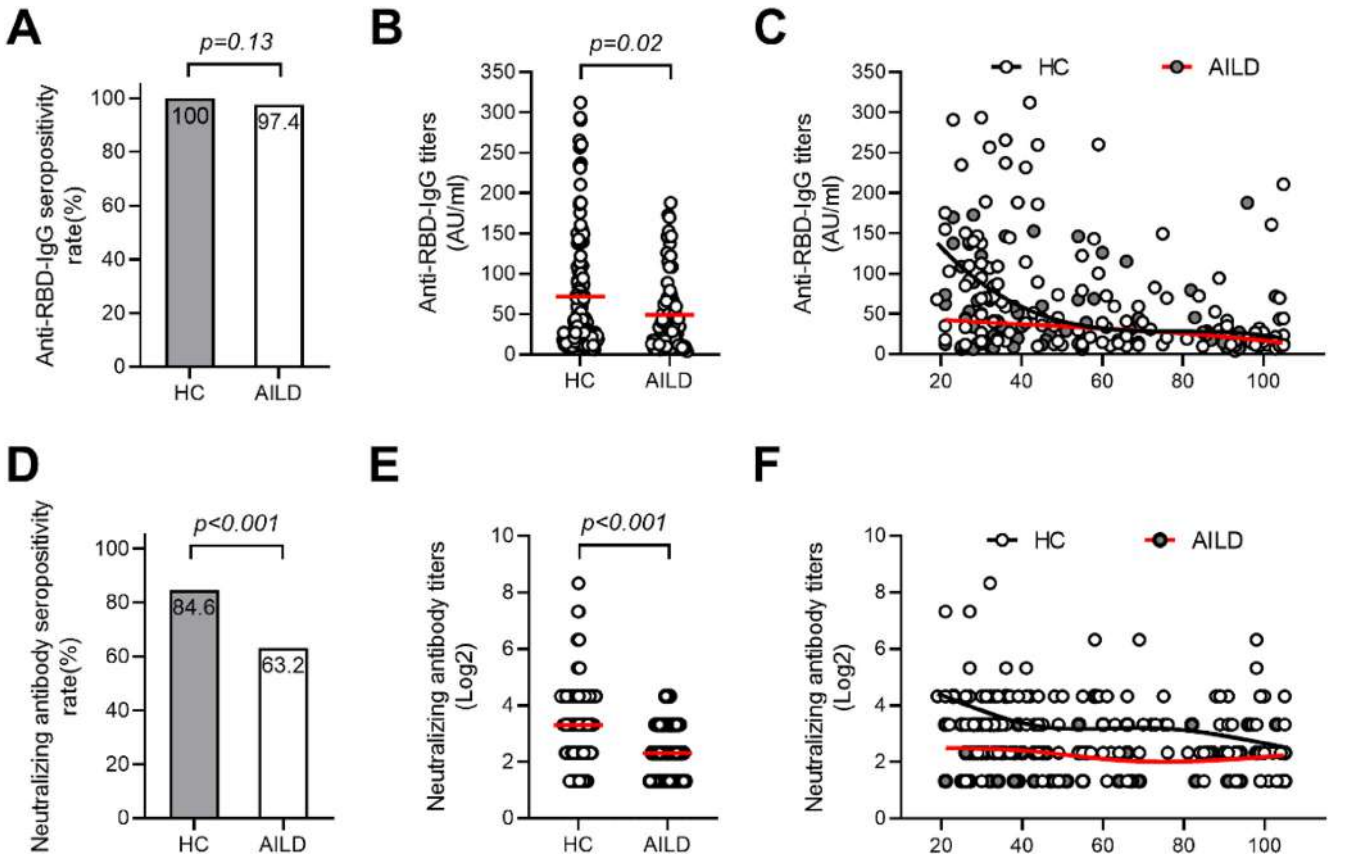

Figure: (abstract: THU296): Antibody responses after the COVID-19 vaccination in patients with AILD and healthy controls. (A-B) The seropositivity rate (A) and titers (B) of anti-RBD-IgG in patients with AILD and healthy controls. (D-E) The seropositivity rate (D) and titers (E) of NAbs in patients with AILD and healthy controls. The distribution of anti-RBD-IgG (C) and NAbs (F) antibody titers over time in patients with AILD and healthy controls. AILD, autoimmune liver disease; anti-RBD-IgG, spike receptor-binding domain IgG antibody; NAbs, neutralizing antibodies.

The study nurse worked with pharmacy staff to strategize adherence and support as needed by study subjects. Qualitative interviews have been conducted with five pharmacy staff to explore their experiences with testing and monitoring HCV treatment and the feasibility of involving pharmacists in the HCV care cascade.

Results: To date pharmacy staff completed 171 HCV OraQuick tests finding 53 tested positive for HCV antibodies: 23 people were HCV RNA negative, (20 previously treated and 2 self-cleared), 8 unk/LTF. Of the 22 RNA positive participants, 1 is pending treatment start, 21 people have started treatment, with 8 achieving SVR. While great success has been achieved in treating identified people, less than half of projected OraQuick tests have been completed. Although the onset of the Covid 19 pandemic was a fundamental barrier incorporating HCV testing at pharmacies, stigma related to HCV and illicit drug use continues to impact this process. Pharmacists described feeling hesitant about approaching participants, especially after receiving negative responses from clients about HCV testing. Some worried their relationship would change with clients as asking about HCV implied risky drug use.

Conclusion: This innovative and novel approach to HCV therapy in PWUD attempted to use a pharmacy-based approach to find people with limited connection to primary health care to test and treat HCV. Increased training of pharmacy staff related to stigma around drug use and HCV is required both before and ongoing for successful integration of pharmacy-led HCV testing and treatment in Canada.

THU298

Improved clinical and economic outcomes in an intensive care unit with a focus on hepatology through interprofessional cooperation between physicians, staff nurses, and pharmacists

Schmid Stephan[1], Schlosser Sophie[1], Karsten Guelow[1], Vlad Pavel[1], Alexander Mehrl[1], Martina Mueller-Schilling[1], Alexander Kratzer[2].
[1]University Hospital Regensburg, Department of Internal Medicine I, Gastroenterology, Hepatology, Endocrinology, Rheumatology, and Infectious Diseases, Regensburg, Germany; [2]University Hospital Regensburg, Hospital Pharmacy, Regensburg, Germany
Email: stephan.schmid@ukr.de

Background and aims: Since 2015, the medical intensive care unit (ICU) with a focus on hepatology of the Department of Internal Medicine 1 at the University Hospital Regensburg, Germany, has a particular emphasis on interprofessional collaboration with staff nurses and hospital pharmacists. The hospital pharmacists have access to the hospital information system and the electronic charting program. Consultations take place on daily basis. Furthermore, weekly joint rounds within the antibiotic stewardship program are performed. Furthermore, there is a joint training and teaching of medical, nursing and pharmacy students within the intensive care training ward Regensburg (I'M A-STAR project). The study aims to investigate to what extent the newly introduced structural changes affect clinical and economic outcomes.

Method: We examined clinical performance data and consumption figures for antibiotics and other drugs over a 10-year period from

2011 to 2021. Data from the hospital pharmacy, hospital administration, electronic charting, and hospital information systems were included in the analyses. An electronic platform was developed specifically to improve documentation. The years 2020 and 2021 were considered separately due to the COVID-19 pandemic and the care of numerous COVID-19 patients in the ICU.

Results: It could be shown that the pharmacist's recommendations regarding drug administration were mainly related to indication (43.6%), dosage (27.6%), interactions (9.4%), and side effects (4.1%). Antibiotic consumption was reduced by 12.2% from 2015 to 2019. Encouragingly, this included a 23.4% reduction in carbapenem use. Antibiotic spending was reduced by 24.9% overall.

An analysis of the intensive care G-DRGs showed that the case-mix points increased significantly by 31.6% during the period under review. Similarly, patient severity of illness as measured by the SAPS II score increased by 21.4%. The proportion of mechanically ventilated patients exceeded 50%.

In another analysis, antibiotic spending per case-mix point was calculated. While spending was EUR 60.22 per case-mix point in 2015, this could be reduced by 42.9% to EUR 34.37 per case-mix point by 2019.

Conclusion: Through close interprofessional collaboration between physicians, staff nurses, and pharmacists, the consumption of antibiotics and other drugs (e.g., albumin) was significantly reduced, thus improving patient care. There was also a positive economic effect-with a simultaneous increase in case-mix points, expenditure on antibiotics was significantly reduced.

Responsible use of resources and high-performance medicine are not contradictory. In our view, a close interprofessional collaboration between physicians, staff nurses, and pharmacists will be of outstanding importance in the future, particularly in intensive care medicine.

THU299

Need to implement the screening strategy to advance HCV elimination in Italy: a cost-consequences analysis

Andrea Marcellusi[1], Kristi Tata[2], Francesco Mennini[1], Massimo Andreoni[3], Loreta Kondili[4]. *[1]Tor Vergata University, CEIS, Rome, Italy; [2]University Hospital Center of Tirana, Tirana, Albania; [3]Tor Vergata University, Rome, Italy; [4]Istituto Superiore di Sanità, Center for Global Health, Rome, Italy*
Email: loreta.kondili@iss.it

Background and aims: In Italy, the HCV disease burden is the highest of western Europe. A graduated screening strategy that covers the birth cohort population from 1948-to 1988 is cost-effective to achieve HCV elimination in Italy. A dedicated fund for HCV screening could permit free of charge testing of the population from 1969-to 1989, but if the screening is not implemented to other birth cohorts the HCV elimination targets could not be achieved. Based on the HCV infection burden, by a cohort of age and fibrosis stage previously estimated, we evaluated the cost-consequences of a delay of HCV diagnosis in the next 5 years in Italy.

Method: We used a previously designed and validated probabilistic model to estimate the clinical, and economic outcomes of different screening coverage uptakes, considering the HCV disease costs by the fibrosis stage as reported by the PITER cohort real-life data. The model starts with a decision probabilistic tree that simulates 5 years of HCV testing in the general population cohort born between the years 1948–1967 (15, 485, 565 individuals to be tested) with different coverage rates lower in the lack of active screening and higher in case of screening implementation. The first part of the model identified and categorized HCV chronic patients by the fibrosis stage. A Markov model was considered for 10 years horizon time. The simulations consider two alternative coverage rates and timing during the five years simulated scenarios: 1) Incremental approach (coverage rates equal to 10%, 20%, 25%, 30% respectively at years 1, 2, 3, and 4) and 2) Fast approach (50% of the target population each year at years 1, 2, 3 and 4).

Results: The overall estimated number of HCV active infections to be diagnosed in the target population was 106, 200. The incremental approach scenario estimated 62% of the target population diagnosed vs 94% diagnosed in the fast approach scenario. An increase in overall costs was observed in the fast approach scenario up to year 5, but at year 6 the cost starts to decrease due to a higher number of diagnosed patients versus the incremental approach in which the disease costs continue to increase. (Figure 1). At ten years' time-horizon, the model estimated a cumulative not mutually exclusive reduction of 5, 406 persons living in the HCC health state, 4, 614 in decompensated cirrhosis and 11, 081 liver-related deaths. A cost reduction of € 74 million was estimated if a fast approach was adopted versus the incremental one.

Conclusion: A delay in HCV diagnosis in the general population from 1968-to 1948, yet not addressed for the HCV free of charge screening, will have important clinical and economic consequences in Italy.

THU300

Evaluation of access to treatment for hepatitis C: a large retrospective cohort from a tertiary care hospital in Turkey

Merve Eren Durmuş[1,2], Gökhan Köker[3], Yeşim Çekin[4], Serkan Ocal[5], Ayhan Çekin[5]. *[1]Antalya Education and Research Hospital, Gastroenterology, Antalya, Turkey; [2]Antalya Education and Research Hospital, Gastroenterology, Turkey; [3]Antalya Education and Research Hospital, Internal Medicine, Antalya, Turkey; [4]Antalya Education and Research Hospital, Medical Microbiology, Turkey; [5]Antalya Education and Research Hospital, Gastroenterology, Turkey*
Email: drmerveeren@gmail.com

Background and aims: Hepatitis C virus (HCV) infection is a major public health issue. According to 2015 data, approximately 71 million people have chronic HCV viremia in the world. It is one of the leading causes of liver-related morbidity and mortality globally. The seroprevalence of anti-HCV in our country has been detected 0.5–1%. Due to its silent progress many patients may be unaware of the situation. In our study, we aimed to determine the rate of the anti-HCV positive patients who were able to access to treatment.

Method: Subjects who had anti-HCV positivity between 2014–2019 have been reviewed retrospectively. The data of the patients were recorded and patients referred for further evaluation and accessed to treatment were identified.

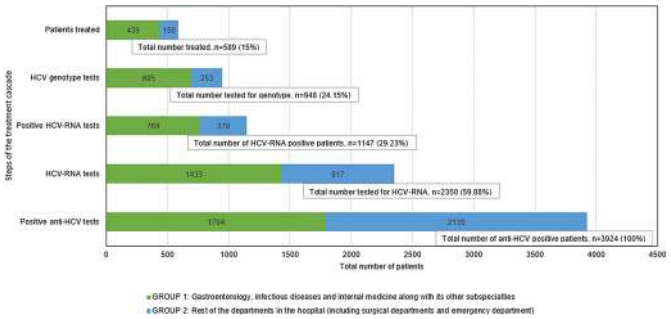

Figure: Disparity between the number of anti-HCV positive individuals, those who were tested for HCV-RNA viremia, HCV genotypes and the ones who could access to the treatment and comparison of two groups contributions on each stage.

Results: The clinics that requested anti-HCV tests were divided in to two groups. Group 1 included gastroenterology, infectious diseases and internal medicine along with its other subspecialties; and the rest of the clinics are defined as Group 2. There were 3924 anti-HCV positive patients in 5-years period. 2350 of them were tested for HCV viremia (%59.9). HCV-RNA were positive in 1147 of them (%29.2), corresponding to %48.8 of the patients who have been tested. Among the patients with HCV-RNA positivity, 948 of them were tested for

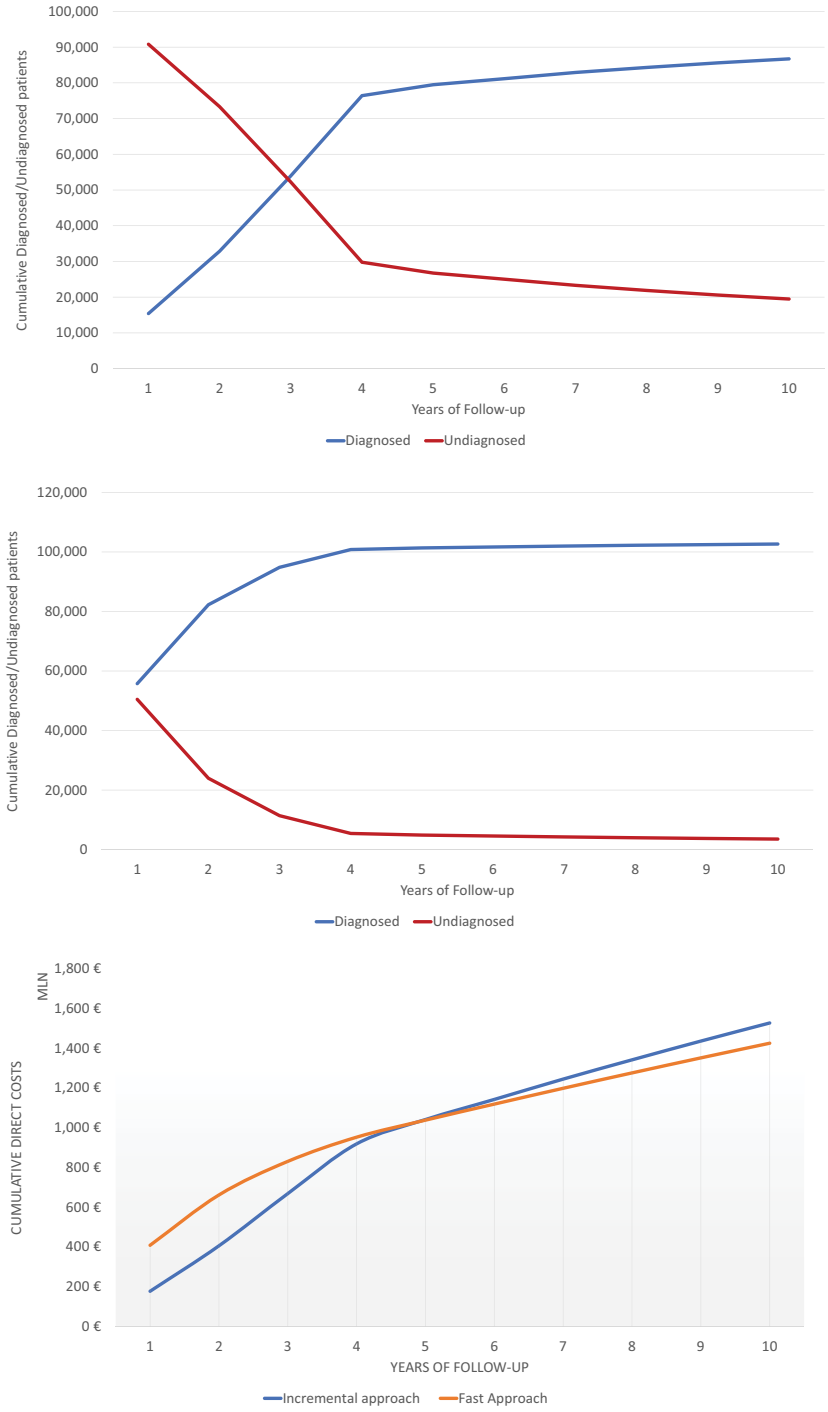

Figure: (abstract: THU299) Cumulative diagnosed patients at each year of simulation- Incremental Scenario (Panel A) Fast Scenario (Panel B) and the respective Costs (Panel C)

HCV genotype (%24.1). Of these patients, 251 were genotype 1A, 438 were genotype 1B, 26 were genotype 2, 193 were genotype 3, 39 were genotype 4 and one patient was genotype 5. Only 589 of them could access to treatment (%15). Numbers of patients in each step of the treatment cascade are presented in Figure 1. Although the departments in Group 2 detected more anti-HCV positivity, the number of the ones that could access treatment were lower.

Conclusion: World Health Organization has been set international targets for the elimination of HCV infection by 2030, which is a public health threat. According to our study, there are significant deficiencies in several stages of the treatment cascade, which is consistent with world data. The rate HCV- RNA testing was low among all clinics. However, Group 2 has lower referral rates according to Group 1 indicating a lower level of awareness. Knowledge of all physicians should be improved to prevent losses and delays in the diagnosis and treatment of HCV infection independent of their departments.

Hepatitis E Virus Capsid Antigen (HEV-Ag): a practical diagnostic biomarker in the HEV outbreak scenerio

Simon Lytton[1], Rakibul Hassan Bulbul[2], Mamunur Rashid[2].
[1]*SeraDiaLogistics;* [2]*Bangladesh Institute Of Tropical And Infectious Diseases Hospital, Chittagong, Bangladesh*
Email: simon.lytton@t-online.de

Background and aims: The increased global incidence of hepatitis E virus (HEV) infections, warrants accurate and affordable diagnostics across different geographical regions. The soluble and highly conserved HEV open reading frame 2 (ORF2) capsid antigen (HEV-Ag) is detectable in self-limited acute enteric hepatitis by HEV-Ag ELISA which is a promising serological assay in settings where HEV-RNA testing is not feasible. Our aim was to assess the HEV-Ag biomarker in an HEV outbreak in a low income country.
Method: A prospective single center longitudinal study during HEV outbreaks in the Chittagong, Bangladesh region between October 2018 and October 2019 was conducted based on recruitment of acute jaundice cases with clinical signs and symptoms of suspect HEV infections. Acute HEV infection was defined as a positive test result for anti-HEV IgM antibodies.
Results: Forty four of the 51 enrolled enteric hepatitis cases (86%) were confirmed HEV by anti-HEV IgM ELISA at day 0 hospital entry. The anti-HEV-IgM and IgG were positive in all patients and did not reveal significant differences; neither between the time points day 0 and follow-up hospitalization on day 2–6 or day 7–10 nor between RNA-positive (n = 36) versus RNAnegative (n = 8) HEV groups. The HEV-Ag positivity was higher in viral RNA-positive (29/36, 81%) than the viral RNA-negative (1/8, 12%) group, p <0.001 and the HEV-Ag levels positively correlated with viremia, r = 0.77, p <0.0001. All non-HEV cases; n = 7 tested negative anti-HEV IgM and HEV-Ag and 5 of 7 (71%) tested anti-HAV IgM positive.
Conclusion: The HEV-Ag ELISA is a reliable and practical diagnostic tool in this acute HEV outbreak.

Bulevirtide is broadly active against all HDV genotypes expressing envelopes from HBV genotypes A-H and a large panel of clinical isolates

Savrina Manhas[1], Bin Han[1], Simin Xu[1], Lindsey May[1], Dong Han[1], Tahmineh Yazdi[1], Silvia Chang[1], Thomas Aeschbacher[1], Rishi Aryal[1], Ross Martin[1], Yang Liu[1], Roberto Mateo[1], Vithika Suri[1], Dmitry Manuilov[1], John F. Flaherty[1], Julius Hollnberger[2,3], Stephan Urban[4], Tomas Cihlar[1], Evguenia S Svarovskaia[1], Hongmei Mo[1]. Background and aims: Bulevirtide (BLV) is a 47-amino acid lipopeptide derived from the HBV large envelope protein (LHBsAg). BLV binds to the HDV/HBV host entry receptor sodium taurocholate cotransporting polypeptide and acts as a potent HDV entry inhibitor. BLV has been approved for treatment of HDV in the European Union and is under late stage clinical evaluation in the United States. Based on sequence divergence, there are eight HDV genotypes (HDV-1 to HDV-8) and eight HBV genotypes (GTA to GTH). To determine the activity of BLV against diverse HDV/HBV variants sequences, the antiviral activity of BLV against HDV-1 to HDV-8 enveloped with HBV GTA-H and against 137 clinical isolates from study participants with HDV infection was assessed.
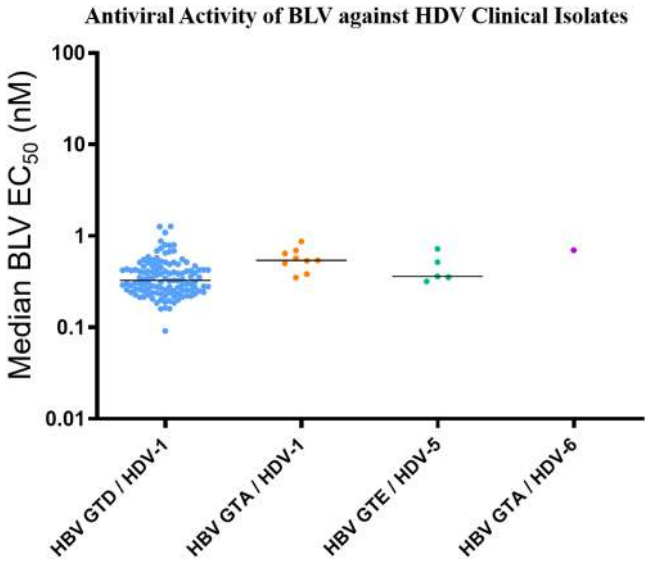
Method: HDV viruses were produced by co-transfection of Huh7 cells with HDV genome and HBV envelope plasmids. Subsequently, virus containing supernatant was collected, titered and used to infect primary human hepatocytes (PHHs). For the HDV phenotyping assay, PHHs were pre-treated with BLV and then infected with clinical plasma or a lab strain of HDV. After five days, immunofluorescence staining was performed to determine cells that were positive for HDV antigen (HDAg). The concentration of BLV decreasing the HDV HDAg positive cells by 50% was expressed as a mean EC_{50} value from at least two independent experiments.
Results: For HDV lab strains, the median EC_{50} of BLV against HDV-1 to HDV-8 pseudotyped with HBV GTA-D envelopes ranged from 0.35 nM to 0.64 nM. Similarly, for HDV-1 to HDV-8 lab strains pseudotyped with HBV GTE-H envelopes, the median EC_{50} of BLV ranged from 0.21 nM to 0.61 nM. Across HDV-1 to HDV-8 lab strains enveloped with HBV GTA-H envelopes, the median EC_{50} of BLV ranged from 0.26 nM to 0.64 nM. Additionally, the median EC_{50} of BLV against HDV-1 with envelopes carrying common polymorphisms in the LHBsAg PreS1 region that corresponds to the BLV sequence region for HBV GTA, GTB, GTC and GTD were 0.57, 0.59, 0.43 and 0.33 nM, respectively. The activity of BLV was also evaluated against 165 clinical isolates with a total of 137 out of 165 clinical isolates having sufficient infectivity to be tested for BLV activity. Most clinical isolates tested (n = 122) belonged to HBV genotype D/HDV genotype 1 (D/1) and had a median EC_{50} value of 0.33 nM. Similarly, the median EC_{50} values for clinical isolates of A/1 (n = 9), E/5 (n = 5) and A/6 (n = 1) were 0.54, 0.36, and 0.70 nM, respectively (Figure).



Conclusion: BLV demonstrated potent broad spectrum antiviral activity against HDV-1 to HDV-8 enveloped with HBV GTA to GTH and against a larger panel of HDV clinical isolates showing similar EC_{50} values across different HBV/HDV genotypes irrespective of the presence of polymorphisms. These results support that BLV has broad genotype coverage potential for the treatment of patients with chronic HDV infection.

THU303

A persistent HBV infection features spontaneous cccDNA loss and new rounds of infection

Bai-Hua Zhang[1], Yuanping Zhou[2], Stephen Horrigan[3], Fabien Zoulim[4], David Baltimore[5], Yong-Yuan Zhang[1]. *[1]HBVtech, Virology, Frederick, United States; [2]Nanfang Hospital, Southern Medical University, Dept. of Gastroenterology and Hepatology Unit, Guangzhou, China; [3]Noble Life Sciences, Preclinical Studies, Sykesville, United States; [4]Cancer Research Center of Lyon, Hepatology, Lyon, France; [5]California Institute of Technology, Biology, Pasadena, United States*
Email: yongyuanzhang50@gmail.com

Background and aims: Clinical evidence shows frequent replacement of serum wild type viral population with mutants in chronic HBV infection, which indicates cccDNA turnover and new rounds of infection. We hypothesized that HBV infection is maintained by new rounds of infection. This hypothesis can be tested in HBV infected uPA/SCID chimeric mice by blocking new rounds of infection using anti-HBs antibody. Since anti-HBs Ab mainly functions extracellularly, its administration in HBV infected chimeric mice is expected to have a therapeutic impact on HBV infection level only if it is sustained with new rounds of infection.

Method: An optimized AAV vector that carries human anti-HBs Ab genes was used to express sustained high level of anti-HBs antibody. HBV infected uPA/SCID chimeric mice were treated with AAV vector expressing malaria antibody or anti-HBs antibody day 49 post infection. Serum HBV DNA and HBsAg level were monitored until day 183 and liver HBV DNA was determined through 20 random samplings of each autopsied liver.

Results: Two key findings were observed: I. Dynamic cccDNA status and spontaneous cccDNA loss: average cccDNA level ≤1 copy/cell was detected in 260 (46%) of 566 cccDNA samplings of 18 HBV infected human livers from chimeric mice, suggesting cccDNA was already lost spontaneously in a fraction of infected cells. II. Anti-HBs treatment profoundly impacts HBV infection level: i) Viremia was significantly lowered by up to >100-fold; ii). Intrahepatic rcDNA level was significantly lowered by 4, 000 to 10, 000 copies/cell; iii). The number of cccDNA samplings with cccDNA level ≤1 copy/cell was significantly expanded (50.2%, 244/486) in anti-HBs treated animals compared to malaria antibody animals (20%, 16/80); and iv) HBV functional cure with nearly complete cccDNA elimination was achieved in one animal with baseline viremia of 4.6E HBV DNA copies/ml (Figure 1).

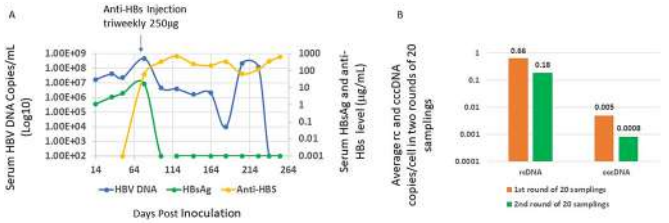


Figure 1. HBV functional cure in animal 970. A. Showing both viremia and serum HBsAg became undetectable after starting anti-HBs treatment. Kinetic anti-HBs level is also plotted. The lately surged viremia reflects reaching peak infection in a fraction of infected cells that experienced long incubation period. Undetectable serum HBsAg implies all HBsAg –containing particles were likely complexed with anti-HBs antibody while the complexed virions became detectable through releasing HBV DNA from complexes with proteinase K digestion. The lower limit of detection for serum HBV DNA is 100 copies/ml and 1ng/ml for HBsAg and anti-HBs antibody. **B.** Two rounds of samplings of the harvested liver were performed, and each round comprising 20 randomly samplings. Average intrahepatic rcDNA and cccDNA level expressed as copies/cell from each round of 20 liver samplings.

Conclusion: cccDNA level is dynamic with spontaneous cccDNA loss, which mediates spontaneous HBV clearance and but can be replenished by new rounds of infection in infected human livers of chimeric mice. New rounds of infection prolong HBV persistent infection. Therapeutic blocking of new rounds of infection profoundly impacts both rcDNA and cccDNA level including a nearly complete cccDNA elimination in one animal with HBV functional cure. Our study identifies an opportunity to durably terminate persistent HBV infection through blocking new rounds of infection.

Functionnal and mitochondrial dynamics alterations in patients with chronic hepatitis B and advanced fibrosis

Dimitri Loureiro[1,2], Issam Tout[1,2], Cheikh Mohemed Bed[1,2], Morganer Roinard[1,2], Ahmad Sleiman[1,2], Boyer Nathalie[1,2], Stephanie Narguet[1,2], Nathalie Pons-Kerjean[2,3], Corinne Castelnau[1,2], Nathalie Giuly[1,2], Vassili Soumelis[4], Jamel El Benna[2], Patrick Soussan[5], Richard Moreau[2], Valérie Paradis[1,2], Abdel Mansouri[1,2], Tarik Asselah[1,2]. *[1]Hospital Beaujon AP-HP, Hepatology, Clichy, France; [2]Center Recherche Sur l'Inflammation, U1149, Paris, France; [3]Hospital Beaujon AP-HP, Pharmacy, Clichy, France; [4]Hospital Saint-Louis, Laboratoire d'Immunologie et Histocompatibilit, Paris, France; [5]Paris Diderot University, U1135, Paris, France*
Email: dimitri.loureiro@inserm.fr

Background and aims: Patients with chronic hepatitis B (CHB) have an increased risk of advanced fibrosis and hepatocellular carcinoma (HCC). In experimental models, hepatitis B virus (HBV) infection causes oxidative stress and alters hepatic mitochondria. The aim of the study is to investigate the role of mitochondrial stress in the progression of fibrosis in CHB.

Method: 132 treatment-naïve CHB mono-infected patients with available liver biopsies specimen were included in this study. Patient demographics and laboratory parameters were recorded at the time of the biopsy. Liver mitochondrial DNA (mtDNA) damage was screened by long PCR and sequencing and levels by Slot blot. The expression of the main genes of cytochrome c oxidase subunits, mitophagy, mitochondrial peptidases and chaperonins, TNFα and IL6, inducible NO synthase and MnSOD were investigated by RT-qPCR and Western-blotting. Patients with CHB and advanced fibrosis (F3-F4 Metavir score;n = 43) were compared to patients with no-mild-moderate fibrosis (F0-F2;n = 89). In vitro, HBV and HBx were transiently expressed in HepG2 cells and the superoxide anion formation, peroxynitrite, nitration of mitochondrial chain complexes, iNOS, MnSOD protein levels and mtDNA depletion were assessed.

Results: Whereas 100% of patients with F3-F4 exhibited multiple mtDNA deletions, 50% of those with F0-F2 ($\kappa c2 = 6.8$;$p < .001$) carried a single mtDNA deletion. Significant decreases were observed in patients with F3-F4 compared to those with F0-F2 for the mRNAs of MT-CO1 (0.55 ± 0.36 and 1.20 ± 0.75, $p < .001$), HSPA9 (0.70 ± 0.28 and 1.06 ± 0.37, $p < .001$), HSPD1 (0.83 ± 0.36 and 1.10 ± 0.44, $p < .05$), Lon Peptidase 1, LONP1 (0.83 ± 0.22 and 1.06 ± 0.33, $p < .05$), PRKN (0.45 ± 0.26 and 1.12 ± 0.57, $p < .0001$), PINK1 (0.59 ± 0.17 and 1.06 ± 0.26, $p < .0001$), Liver TNFα (1.72 ± 0.2 and 0.99 ± 0.2;$p < .05$), IL6 (7.82 ± 0.90 and 1.14 ± 0.26; $p < .05$). Protein levels significantly decreased in F3-F4 for MT-CO1 (2.55 ± 0.88 and 3.44 ± 0.80, $p < .01$), LONP1 (0.67 ± 0.31 and 0.87 ± 0.51, $p < .05$), HSPA9 (0.67 ± 0.31 and 1.20 ± 0.77, $p < .05$) MT-ATP8 (0.14 ± 0.03 and 0.30 ± 0.06, $p < .05$). iNOS and MnSOD proteins are significantly increased in patients with F3-F4 with MnSOD activity decreased in these patients ($p < .05$).

In HepG2 cells, HBV or HBx expression increase mitochondrial superoxide formation at 24 and 48 h ($p < .05$), increase iNOS protein levels, but only HBV increase MnSOD protein expression by 2-fold ($p < .05$). Then, an increase of peroxynitrite as well as mtDNA depletion ($p < .01$) and nitration of the mitochondrial respiratory chain complexes were observed.

Table: Patients characteristics

	Patients
Number (n)	**132**
Sex (M/F)	84/48
Age (ans) (mean ± SEM)	44 ± 3.47
BMI (Kg/m²) (mean ± SEM)	24.55 ± 3.34
ALT (UI/L) (mean ± SEM)	109.22 ± 12.79
AST (UI/L) (mean ± SEM)	70.86 ± 13.72
γ-GT (UI/L) (mean ± SEM)	78.51 ± 18.53
Cholesterol (mmol/L)	4.38 (2.9-6.5)
Triglycerides (mmole/L)	1.13 (0.38-3.69)
Glucose (mmole/L)	5.05 ± 0.56
HBeAg positive, n (%)	41 (37.48)
HBsAg (log_{10} IU/mL) (moyenne)	3.72
HBV DNA (log_{10} IU/mL)	5.12 (2.17-8.04)
Hepatic histology	
Metavir	
Activity A0	33
A1	65
A2	24
A3	10
Fibrosis (Metavir)	
F0-F2 (n=89)	
F0	26
F1	32
F2	31
F3-F4 (n=43)	
F3	27
F4	16

Conclusion: Diverse mtDNA damages and alterations of mitochondrial function and dynamic seems to be involved in the progression of fibrosis in patients with CHB. Our results emphasized the importance on modulating mitochondrial function, and therefore could be an attractive therapeutic strategy to block the progression of fibrosis in CHB.

THU305

Dual antiviral activity of farnesyl transferase inhibitor on hepatitis D virus infection revealed by RT-ddPCR

Eloi Verrier[1], Anna Salvetti[2], Caroline Pons[2], Michelet Maud[3], Thomas Baumert[1,4], David Durantel[2], Julie Lucifora[2]. *[1]Université de Strasbourg, Inserm, Institut de Recherche sur les Maladies Virales et Hepatiques UMR_S1110, Strasbourg, France; [2]CIRI-Centre International de Recherche en Infectiologie, Univ Lyon, Université Claude Bernard Lyon 1, Inserm, U1111, CNRS, UMR5308, ENS Lyon, Lyon, France; [3]Inserm, U1052, Cancer Research Center of Lyon (CRCL), Université de Lyon (UCBL1), CNRS UMR5286, Centre Léon Bérard, Lyon, France; [4]Institut Hospitalo-Universitaire, Pôle Hépato-digestif, Nouvel Hôpital Civil, Strasbourg, France*
Email: e.verrier@unistra.fr

Background and aims: Chronic hepatitis D is the most severe form of chronic viral hepatitis and to date, efficient therapeutic approaches against hepatitis D virus (HDV) are absent. Among the antiviral molecules currently tested in clinical trials, the farnesyl transferase inhibitor (FTI) Lonafarnib inhibits the prenylation of the large delta antigen (L-HDAg), blocking virus assembly. Given the importance of L-HDAg in the virus life cycle,
We hypothesized that Lonafarnib treatment may have side effects on virus replication.
Method: Here, we setup an innovative method based on reverse transcription digital droplet PCR (RT-ddPCR) for the quantification of HDV RNA allowing the independent quantification of edited and non-edited versions of the HDV genome upon infection.
Results: We demonstrated that FTI treatment of HBV-HDV co-infected cells leads to an accumulation of intracellular HDV RNAs and a marked increase in the levels of edited HDV RNAs not only within the infected cells but also in the viral particles that are secreted. Interestingly, these viral particles were less infectious, probably due to an enrichment in edited genomes that are packaged, leading to unproductive infection given the absence of S-HDAg synthesis after viral entry.
Conclusion: Taken together, we setup an innovative quantification method allowing the investigation of HDV RNAs editing during HDV infection in a simple, fast, clinically-relevant assay and demonstrated for the first time the dual antiviral activity of FTI on HDV infection.

Characterization of circulating hepatitis B Virus RNAs in vitro and chronic hepatitis B patients

Doohyun Kim[1], Delphine Bousquet[1,2], Marie-Laure Plissonnier[1], Hyoseon Tak[1], Xavier Grand[1], Chloe Goldsmith[3], Françoise Berby[1], Bordes Isabelle[1], Alexia Paturel[1,2], Aaron Hamilton[4], Marintha Heil[4], Massimo Levrero[1,2,5], Barbara Testoni[1], Fabien Zoulim[1,2,6]. *[1]Cancer Research Center of Lyon, Chronic Viral Hepatitis: virus/host interactions, pathogenesis and novel antiviral strategies, Lyon, France; [2]Université de Lyon, Lyon, France; [3]University of Canberra, Bruce, Australia; [4]Roche Diagnostics, Pleasanton, United States; [5]Sapienza University of Rome, Roma, Italy; [6]La Croix-Rousse Hospital, Lyon, France*
Email: fabien.zoulim@inserm.fr

Background and aims: Circulating HBV RNA (CirB-RNA) is a promising non-invasive biomarker for cccDNA transcriptional activity. However, the molecular characteristics and circulating particles containing cirB-RNA in vitro and in vivo remain to be fully defined.
Method: Supernatants from cultured hepatocytes infected by HBV and treated or not with lamivudine, and sera from 9 untreated [4 HBeAg (+) and 5 HBeAg (-)] and 1 HBeAg (+) ETV-treated chronic hepatitis B (CHB) patients were subjected to Iodixanol/Sucrose ultracentrifugation for buoyant density. Each density fraction was analyzed for HBV DNA/RNA by specific qPCR and droplet digital (dd) PCR. Viral and extracellular vesicles (EVs)-associated proteins were detected by ELISA and Western Blotting. 5′ RACE PCR followed by ONT MinION sequencing was used to identify CirB-RNA species. Longitudinal serum samples before and at two time points after NUC therapy initiation were obtained from two additional patients [HBeAg (+) TDF-treated CHB and HBeAg (-) ETV-treated CHB].
Results: After ultracentrifugation, CirB-RNA was mainly detected in core-associated virion-like particles, in 2 log10 less amount than HBV DNA. However, CirB-RNA was the predominant species in lighter density fractions (1.17–1.18 g/ml) deprived of viral proteins, both in cell supernatant and in serum. The enrichment for EVs in these fractions was confirmed by detection of CD9 and CD81 by Western Blotting, immunoprecipitation assay, Nanoparticle tracking analysis and Transmission Electron Microscopy. Distribution of CirB-RNA did not differ significantly according to HBeAg status, while in a patient with low HBsAg level, CirB-RNA was mainly detected in the EVs-enriched fractions. Lastly, CirB-RNA profiling by 5′ RACE and ONT MinION sequencing identified different proportions of pgRNA-derived transcripts according to HBeAg status and HBsAg level.
Conclusion: Our results indicate that EVs-enriched compartment also contributes to the circulation of HBV-RNAs. Moreover, different HBV-RNA transcripts in addition to pgRNA can be detected *in vivo*. Altogether, these data could significantly contribute to the characterization of cirB-RNAs as new viral biomarker.

THU307

Identification of shuttle protein hnRNPA1 as a modulating factor of circulating hepatitis B Virus RNAs release in chronic hepatitis B patients

Hyoseon Tak[1], Doohyun Kim[1], Delphine Bousquet[1,2], Marie-Laure Plissonnier[1], Françoise Berby[1], Bordes Isabelle[1], Aaron Hamilton[3], Marintha Heil[3], Massimo Levrero[1,2,4], Barbara Testoni[1], Fabien Zoulim[1,2,5]. [1]*Cancer Research Center of Lyon, Lyon, France;* [2]*Université de Lyon, Lyon, France;* [3]*Roche Diagnostics, Plesanton, United States;* [4]*Sapienza University of Rome, Roma, Italy;* [5]*Croix Rousse hospital, Lyon, France*
Email: fabien.zoulim@inserm.fr

Background and aims: Circulating HBV RNA (CirB-RNA) reflects the transcriptional activity of the intrahepatic cccDNA, thus representing a promising non-invasive serum biomarker for the reduction or inactivation of cccDNA pool. Although several studies have suggested that cellular releasing pathways may determine the fate of these RNAs, the specific regulators of the shuttle machinery involved remain largely unknown.
Method: Expression of candidate shuttle proteins were analyzed by Western Blotting and RT-qPCR in cell lysate and supernatant from HBV-infected HepG2-NTCP cells and Primary human hepatocytes (PHHs). Shuttle protein interaction with CirB-RNAs was investigated by RNP-IP (Ribonucleoprotein-Immunoprecipitation) and Biotin pull down assay. Adapted Iodixanol/Sucrose density ultracentrifugation allowed to isolate exosome-enriched fractions from sera of 5 untreated [2 HBeAg (+) and 3 HBeAg (-)], 2 HBeAg (-) chronic infection and 2 NUC-treated chronic hepatitis B (CHB) patients.
Results: Among the RNA-binding proteins analyzed, heterogeneous nuclear ribonucleoprotein A1 (hnRNPA1) expression was increased in both cell lysates and supernatants of HepG2-NTCP cells and PHHs upon HBV infection. hnRNPA1 was also detected in the serum of CHB patients and, after density ultracentrifugation of serum samples, hnRNAP1 was mostly detected in the exosome-enriched fractions. Loss-of-function studies in HepG2-NTCP cells indicated that hnRNAP1 downregulation was associated to reduced expression of exosome markers CD9 and CD81 in cell supernatant, as well as a decreased secretion of CirB-RNA in exosome fractions. Anti-CD81 IP confirmed the association between hnRNAP1 and exosomes. RNP-IP experiments revealed that hnRNPA1 was able to bind to 5′ region of 3.5Kb RNA and to the 3′ region common to all HBV transcripts. Specific binding sites for hnRNAP1 on HBV RNAs were mapped by Biotin pull-down assays.
Conclusion: Altogether, our data suggest that hnRNPA1 directly binds to HBV RNAs and can function as a novel shuttling mechanism for the export of HBV RNAs in vivo.

Long-read sequencing of HCC samples reveals complete architecture of HBV integrations and chimeric mRNA isoforms associated with oncogenes

Cameron Soulette[1], Lindsey May[1], Atefeh Khakpoor[2], Dong Han[1], Ricardo Ramirez[1], Narmada Balakrishnan[3], Nicholas Van Buuren[1], Ramanuj Dasgupta[3], Vithika Suri[1], Li Li[1], Hongmei Mo[1], Becket Feierbach[1], Jeffrey Wallin[1], Seng Gee Lim[2]. [1]*Gilead Sciences, Inc., Foster City, United States;* [2]*Yong Loo Lin School of Medicine, Singapore, Singapore;* [3]*Genome Institute of Singapore (GIS), Singapore, Singapore*
Email: cameron.soulette@gilead.com

Background and aims: Hepatitis B virus (HBV) integrations are associated with large-scale genomic rearrangements that dysregulate gene expression and are implicated in hepatocellular carcinoma (HCC). Our work is aimed towards understanding the development of oncogenesis mediated by HBV integrations by characterizing integrations in HCC patients. We use a long-read DNA and mRNA sequencing approach to characterize complete HBV integrations and their expression from paired tumor and adjacent tissue.
Method: HCC liver resections were collected from 20 patients, 15% were HBeAg-, 10% were treatment naïve, and 75% on nucleos (tide) analogue treatment. DNA and RNA were sequenced from tumor/tumor adjacent tissue. We enriched for HBV sequences using a pan-genotypic panel of biotinylated oligos from sheared genomic DNA (~7 kb) and polyA+ reverse transcribed cDNA. Samples were sequenced on the PacBio long-read platform and analyzed with a bioinformatic method for identification of VirAL Integrations ANd Translocations (VALIANT). cDNA was also sequenced using standard Illumina RNA-Seq. We used Catalogue of Somatic Mutations in Cancer (COSMIC) to identify integrations near cancer-associated genes.
Results: We found that nearly all HBV DNA reads (avg. ~95%) from tumor and adjacent tissue were derived from integrated HBV. We found integration sites common to paired tumor and adjacent tissue in nearly half of samples. We found >20 COSMIC genes with nearby integrations, including *HLF, LRP1B, ERBB4*, and *TERT*. Moreover, we found numerous HBV-associated translocations, including a chromosome 1 to 3 translocation in *NAALADL2*, a known HBV integration hotspot. We further quantified the frequency of translocations and insertions in our HCC cohort and a cohort of chronic hepatitis B patients and found a higher translocation frequency in HCC samples (~30% vs 15%). Finally, our long-read RNA-seq data captured HBV transcripts chimeric with various genes, including HBV-TERT isoforms which coincided with elevated TERT expression measured by short-read RNA-seq.
Conclusion: We find a substantial amount of HBV integrations in tumors. Increased translocation frequency in tumors supports the hypothesis that HBV integrations may promote oncogenesis through genomic instability and highlights the importance of treatments that prevent HBV integration. Moreover, our observation of HBV-TERT chimeric isoforms and TERT upregulation strengthens the view that HBV integrations are a direct driver of HCC.

THU309

Polymorphic analysis of bulevirtide sequence in PreS1 of large HBsAg across HBV genotypes A-H

Roberto Mateo[1], Thomas Aeschbacher[1], Yang Liu[1], Simin Xu[1], Bin Han[1], Tahmineh Yazdi[1], Savrina Manhas[1], Lindsey May[1], Dong Han[1], Silvia Chang[1], Rishi Aryal[1], Ross Martin[1], Evguenia S Svarovskaia[1], Hongmei Mo[1]. [1]*Gilead Sciences, Inc., Foster City, United States*
Email: roberto.mateo@gilead.com

Background and aims: Bulevirtide (BLV) is a novel 47-amino acid, N-terminally myristoylated lipopeptide that binds specifically to the sodium taurocholate cotransporting polypeptide (NTCP) and acts as a potent, highly selective entry inhibitor of HDV into hepatocytes. The BLV sequence was designed based on the consensus sequence of the preS1 domain of the large HBsAg (LHBsAg) of eight different genotypes of HBV (A-H). The aim of this study was to investigate the impact of polymorphisms found in the LHBsAg PreS1 region from HBV clinical isolates of eight HBV genotypes on susceptibility to BLV.
Method: The polymorphic residues in BLV sequence region of Pre-S1 were identified using an alignment of 7427 PreS1 sequences of HBV genotypes A-H obtained from clinical isolates and public databases. HDV genotype 1 viruses containing these polymorphisms were generated by transient transfection and analyzed phenotypically for their susceptibility to BLV in an infectious assay using primary human hepatocytes.
Results: Polymorphic analyses of HBV sequences from genotypes A-H revealed a high degree of conservation of the 47aa long peptide, with a remarkable conservation of the sequence from positions 9-NPGLFFP-15, which is crucial for binding. Only one amino acid residue was found to be variable with a frequency above 5% for genotype A; genotypes B, C and D had 2, 5 and 2 amino acids above the 5% cut-off value, respectively. Within representative sequences for the most common genotypes A-D, genotype C was the closest to the BLV sequence with only one amino acid change (K57Q).

Genotypes A and B had 4 to 6 amino acid changes, respectively, and genotype D had 8. Despite their sequence differences, HDV genotype 1 viruses containing HBV genotype A-H preS1 representative sequences and the most prevalent HBV genotype A-D polymorphisms were fully susceptible to BLV with EC_{50} values that ranged from 0.28 nM to 0.85 nM.

Conclusion: BLV demonstrated potent activity against HDV harboring the polymorphisms in the PreS1 region corresponding to the BLV sequence across HBV genotypes A-D, indicating the broad-spectrum antiviral activity of BLV for the treatment of patients infected with HDV viruses.

Email: ggasegui@unav.es

Background and aims: Hepatitis delta virus (HDV) infection represents the most severe form of viral hepatitis; however, the molecular mechanisms involved in the severity of the disease remain unknown. The absence of mouse models in which HDV-induced liver damage occurs has prevented the study of this important aspect of the disease. We developed an adeno-associated virus (AAV)-mediated HDV/HBV co-infection model in which, for the first time, liver damage associated with HDV was detected in mice that was, at least partially, associated with TNF-α production. The aim of the present study is to elucidate the mechanisms involve in HDV-mediated liver damage.

Method: Replication competent HBV and HDV genomes were delivered to mouse hepatocytes using AAVs as shuttle vector to stablish an active replication of both viruses. Using blocking agents, KO mice, and CRISPR Cas9 system to delete the expression of key molecules we evaluate the role of different players involve in hepatocytes death.

Results: Here, we report that TNF-α was mainly produced by liver macrophages and that the death of HDV-hepatocytes occurs predominantly by caspase-8 induced-apoptosis.

Upon AAV-HBV/HDV co-injection, RIPK1-edited mice presented with a significantly higher liver damage than mice receiving control CRISPR/Cas9, reflected by higher transaminase serum levels and an increased percentage of apoptotic hepatocytes, indicating that RIPK1 plays a significant role in hepatocytes survival in an HDV infected liver. The elimination of both caspase 8 and RIPK1 from hepatocytes resulted in the almost complete absence of hepatocytes death after AAV-HBV/HDV injection, which further corroborated caspase 8-induced apoptosis as the main cell death mechanism in RIPK1-edited mice. Surprisingly, the absence of TNF-α or the depletion of macrophages had no effect on the exacerbation of liver disease associated with the RIPK1 downregulation in hepatocytes. Interestingly depletion of macrophages had a significant detrimental effect, indicating that these cells play a protective role.

Conclusion: Our investigations demonstrate the protective role of RIPK1 in HDV-induced liver pathology and strongly suggest that the RIPK1-caspase-8 axis influences the pathogenesis of HDV infection. More experiments are needed for a better understating of the mechanism involved.

Limited value of HBV-RNA levels for the prediction of relapse after discontinuation of nucleos(t)ide analogue therapy in HBe antigen negative chronic hepatitis B patients

Valerie Ohlendorf[1], Maximilian Wübbolding[1], Christoph Hoener zu Siederdissen[1], Birgit Bremer[1], Katja Deterding[1], Heiner Wedemeyer[1], Markus Cornberg[1], Benjamin Maasoumy[1]. [1]*Hannover Medical School, Clinic of Gastroenterology, Hepatology and Endocrinology, Hannover, Germany*
Email: ohlendorf.valerie@mh-hannover.de

Background and aims: EASL guidelines suggest that treatment with nucleos(t)ide analogue (NA) can be stopped in HBeAg negative patients after three years of viral suppression. Recently, the combination of HBsAg and HBV-RNA level at the time of NA cessation has been linked to a better prediction of off-treatment response compared to HBsAg alone in mixed cohorts of HBeAg negative and positive patients. In this study we investigated the association of relapse after NA cessation with baseline serum HBV-RNA level in a large cohort of HBeAg negative patients.

Method: Serum level of HBV-RNA, HBsAg and HBcrAg were determined in 154 HBeAg negative patients, participating in a prospective, multicenter therapeutic vaccination trial (ABX-203, NCT02249988) or in an observational register trial (Terminator 2), before stop of NA therapy. Importantly, vaccination showed no impact on relapse. HBV DNA >2, 000 IU/ml 24 weeks after NA cessation was defined as virological relapse, while clinical relapse comprised attendant ALT levels ≥2 × ULN. The lower limit for the quantification of HBV-RNA was 10 copies/ml. For the comparison of continuous and categorical variables the Mann-Whitney U and the Fisher's exact test were used. Kaplan-Meyer analysis with the log-rank test was used for the calculation of cumulative relapse rates.

Results: The majority of patients were male (n = 115/154; 75%) with a median age of 53 years. Two thirds of patients were treated with entecavir (n = 94/154; 61%), while the rest received tenofovir. Median HBV-RNA, HBsAg and HBcrAg BL level was 0 copies/ml, 950 IU/ml and 1585 kU/ml, respectively. No significant correlation was found between HBV-RNA and HBsAg (r = – 0.253, p = 0.055) or HBV-RNA and HBcrAg (r = 0.044, p = 0.73), respectively. Virological relapse occurred in 53% of patients (N = 82/154), including 8 patients (10%) developing an ALT flare. BL HBV-RNA level did not differ significantly between relapsers and off-treatment responders (p = 0.86) or between virological relapsers and clinical relapsers (p = 0.36), respectively. Further, no significant difference occurred in proportions of detectable HBV-RNA BL level between off-treatment responders (N = 10/72; 14%) and relapsers (N = 13/82;16%) (p = 0.68). Relapse prediction could not be improved by combining predefined HBsAg cut-offs (100 IU/ml, p = 0.0016) or HBcrAg cut-offs (3 log U/ml, p = 0.07) with a HBV-RNA cut-off of ≤10 copies/ml (p = 0.0031) (figure).

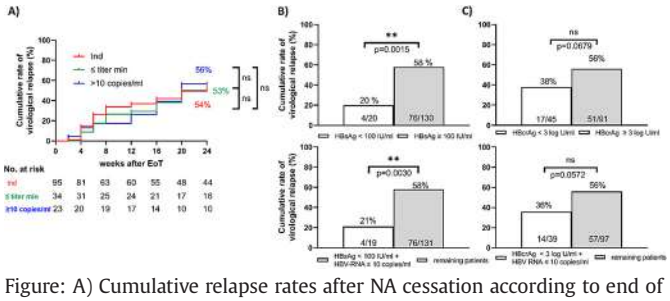

Figure: A) Cumulative relapse rates after NA cessation according to end of treatment (EoT) grouped by serum RNA baseline levels and proportion of patients with virological relapse grouped by B) BL HBsAg level ± HBV-RNA level or C) BL HBcrAg level ± HBV-RNA level.

Conclusion: In a cohort of exclusively HBeAg negative patients no improvement in relapse prediction was achieved by considering HBV-RNA BL levels.

THU312

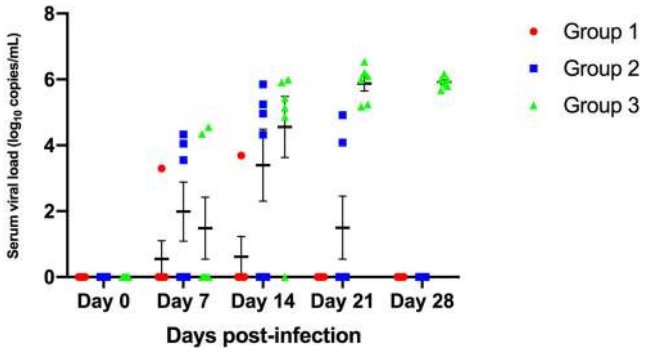
A versatile small animal immunocompromised model for chronic hepatitis E

Siddharth Sridhar[1], Shusheng Wu[2], Jianwen Situ[2]. [1]*The University of Hong Kong, Microbiology;* [2]*The University of Hong Kong, Microbiology*
Email: sid8998@hku.hk

Background and aims: Hepatitis E virus (HEV) is an important cause of chronic hepatitis in immunocompromised persons. We aimed to develop a small animal model of chronic hepatitis E using immunocompromised rats infected with *Orthohepevirus* species C (HEV-C; rat hepatitis E virus), which is an emerging cause of human hepatitis.

Method: Female 6–8 week old Sprague-Dawley rats were divided into 3 groups (6 rats per group): immunocompetent (group 1), low-dose immunosuppressed (group 2) and high-dose immunosuppressed (group 3). Rats in groups 2 and 3 were immunosuppressed using a combination of tacrolimus (5 mg/kg vs 7.5 mg/kg respectively), mycophenolate mofetil (25 mg/kg vs 30 mg/kg respectively), and prednisolone (10 mg/kg vs 4 mg/kg respectively). Drugs were administered 10 days prior to infection and continued thereafter. Filtered stool supernatants containing 2.5×10^5 copies/ml of HEV-C were administered to rats intravenously. Stool supernatants were either from infected humans (3 rats per group) or rats (3 rats per group). Stool and serum viral loads in infected rats were monitored. Antibody responses and liver tissue histology were assessed. Ethics approval was obtained.

Results: HEV-C infections in group 1 rats were fleeting with transient viremia (figure). Group 2 and 3 rats developed higher viral loads in both stool and serum (figure). No differences in viral loads between human or rat-derived HEV-C strains were observed. Most group 1 and 2 rats cleared virus from stool or serum by day 28, but group 3 rats maintained high viral loads in stool and serum throughout. Mean viral loads in liver tissue at day 28 were markedly higher in group 3 (8.89 $\log_{10}$ copies/ml) compared to group 1 (3.76 $\log_{10}$ copies/ml) and 2 (4.35 $\log_{10}$ copies/ml) rats; this was reflected by strongly positive immunohistochemical staining in liver tissue of group 3 rats. Western blot antibody responses to HEV-C were weaker in group 3 rats than group 1 rats. Alanine aminotransferase was similar in all 3 groups. The immunosuppressive regimen was tolerated well by rats in groups 2 and 3. A couple of rats in group 3 were monitored beyond day 28 and they supported viral infection for up to 3 months without any drop in viral loads.



Conclusion: We designed a versatile gradable immunocompromised rat model of chronic hepatitis E infection using immunosuppressants commonly taken by transplant recipients. This model will enable convenient investigation of pathogenicity and antivirals for HEV infections. This work establishes capacity to perform chronic HEV research without using large animal models or genetically modified rats. Further evaluation of this model for studying antivirals is required.

Acquisition of positively charged amino acids in HBsAg C-terminus correlates with HBV-induced liver cancer, hampers HBsAg stability and secretion and promotes cell survival

Lorenzo Piermatteo[1], Luca Carioti[1], Gianluca Leoni[1], Leonardo Duca[1], Patrizia Saccomandi[1], Daniele Stella[1], Eleonora Andreassi[1], Ada Bertoli[1,2], Giuseppina Cappiello[3], Hervé Fleury[4], Pascale Trimoulet[4], Simona Francioso[5], Ilaria Lenci[5], Massimo Andreoni[5], Mario Angelico[6], Sandro Grelli[1,2], Antonella Minutolo[1], Loredana Sarmati[6], Claudia Matteucci[1], Francesca Ceccherini Silberstein[1], Valentina Svicher[1,7], Romina Salpini[1]. [1]*University of Rome "Tor Vergata", Experimental medicine, Rome, Italy;* [2]*Tor Vergata University Hospital, Microbiology and Virology Unit, Rome, Italy;* [3]*"Sandro Pertini" Hospital, Microbiology and Virology Unit, Rome, Italy;* [4]*Hôpital Pellegrin tripode, Laboratoire de Virologie, Bordeaux, France;* [5]*Tor Vergata University Hospital, Hepatology Unit, Rome, Italy;* [6]*Tor Vergata University Hospital, Infectious Disesases Unit, Rome, Italy;* [7]*University of Rome "Tor Vergata", Biology, Rome, Italy*
Email: lorenzo.piermatteo@uniroma2.it

Background and aims: HBsAg C-terminus is a hydrophobic transmembrane domain, crucial for HBsAg secretion. Gain of charged amino acids (aa) in this domain can alter HBsAg folding, and in turn its secretion, a mechanism known to favor HBV-induced hepatocellular carcinoma (HCC). Here, we assess the role of HBsAg C-terminus mutations, associated with gain of charged aa, on HCC onset.

Method: We analyze HBsAg sequences from 807 CHB patients: 28 with HCC (78.6%D; 21.4%A) and 779 without HCC (79.8%D; 20.2%A). Impact of mutations on HBsAg-secretion is analyzed by transfecting Huh7 cells with plasmids encoding wt- and mutated-HBsAg. Extra- and intra-cellular HBsAg is quantified by Liaison immunoassay (DiaSorin) and used to define HBsAg secretion factor (extracellular/intracellular HBsAg). Cell viability after treatment with etoposide (a cell death inducer) was evaluated by MTS assay. HBsAg structure and stability was assessed by I-Tasser ($\Delta\Delta$G[wt-mutated]<0 indicates decreased stability vs wt, Quan, 2016).

Results: The acquisition of ≥1 positively charged aa at HBsAg C-terminus positions 204, 207 and 210 strongly correlates with HCC (71.4% with HCC vs 30.2% without HCC, $P < 0.001$). Result confirmed by multivariable analysis (OR[95%CI]:6.3[2.6–15.3], $P < 0.001$). These positively charged aa derive from S204R, S207R and S210R, found in 14.3%, 28.6% and 28.6% of HCCs, respectively.

In vitro, all these mutations determine a significant decrease in extracellular HBsAg compared to wt (42% for S204R, 39% for S207R and 32% for S210R, $P < 0.0001$ for all). Moreover, S204R and S210R cause a 58% and 28% reduction in HBsAg secretion factor respect to wt ($p < 0.0001$ and $P = 0.009$), reinforcing their detrimental role in HBsAg release.

Notably, despite etoposide treatment at 25 and 50 µM, S204R determines a 50% and 30% increase in cell viability respect to wt ($p < 0.001$ for both), supporting its ability to promote cell survival.

Finally, in silico, S204R, S207R and S210R decrease HBsAg stability ($\Delta\Delta$G[S204R-wt] = −0.27; $\Delta\Delta$G[S207R-wt] = −0.11; $\Delta\Delta$G[S210R-wt] = −0.14) and determine a shortening of transmembrane motif (predicted length: aa209–224 for S204R, S207R and S210R vs 205–225 for wt).

Conclusion: Gain of positively charged aa in HBsAg C-terminus tightly correlates with HCC, hampers HBsAg release and promotes cell survival, thus potentially predisposing to HBV-related HCC. The detection of these mutations may help identifying patients at higher HCC-risk, deserving more intense liver monitoring.

THU314

PAGE-B and FIB-4 predict the occurence of hepatocellular carcinoma in HBV patients: a french nationwide cohort study

Gautier Boillet[1], Mathieu Chalouni[2], Clovis Lusivka-Nzinga[3], François Teoule[3], Helene Fontaine[4], Pierre Nahon[5], Marc Bourliere[6], Fabrice Carrat[3], Stanislas Pol[4], Victor de Lédinghen[1], Linda Wittkop[2]. *[1]Maison Du Haut-Lévêque-Haut-Lévêque Hospital Group Sud-Chu De Bordeaux, Pessac, France; [2]ISPED, Bordeaux, France; [3]Hospital Saint-Antoine Ap-Hp, UMR-S 1136, Paris, France; [4]Gh Cochin-St Vincent De Paul, Hepatology, Paris, France; [5]Hospital Jean-Verdier, UMR-1162, Bondy, France; [6]Hôpital Saint Joseph, Hepatology, Marseille, France*
Email: boillet.gautier@yahoo.fr

Background and aims: Hepatocellular Carcinoma (HCC) is the first cause of death among chronic hepatitis B (CHB) patients. PAGE-B and FIB-4 may predict the occurrence of HCC among all CHB patients. We aimed to compare the predictive capacity of PAGE-B and FIB-4 for the occurrence of HCC in CHB patients at 1, 3 and 5 years of follow-up in the ANRS CO22 HEPATHER cohort.
Method: CHB patients included in the ANRS CO22 HEPATHER cohort between August 6, 2012 and December 31, 2015 were eligible. Exclusion criteria were chronic HCV, HDV co-infection, liver-transplantation, or history of HCC. Primary outcome was the time between inclusion and occurrence of HCC. Predictive performances were compared by the AUROC at year 1, 3 and 5. Two cutoffs were determined for each score, maximizing respectively sensitivity then specificity, to establish three different risk groups.
Results: Among 5, 214 patients, with a median follow-up of 5.6 years (IQR: 4.3–6.9), 69 experienced HCC. Median scores values were of 10 (IQR: 6–14) for PAGE-B and 1.0 (IQR: 0.7–1.5) for FIB-4. Corrected AUROCs of PAGE-B and FIB-4 at year 1, 3 and 5, were 0.91 (0.8–0.97), 0.85 (0.81–0.97) and 0.81 (0.76–0.86) and 0.85 (0.70–0.97), 0, 83 (0.77–0.89) and 0.80 (0.75–0.86), respectively. No significant difference between the AUROCs of the two scores was estimated at any time. Best cut-offs to identify patients at lower and higher risk of HCC were 10 and 18 for PAGE-B score, and 1.0 and 2.2 for FIB-4, respectively. Cumulative probability of HCC according to these new risk groups are depicted on the figure above.

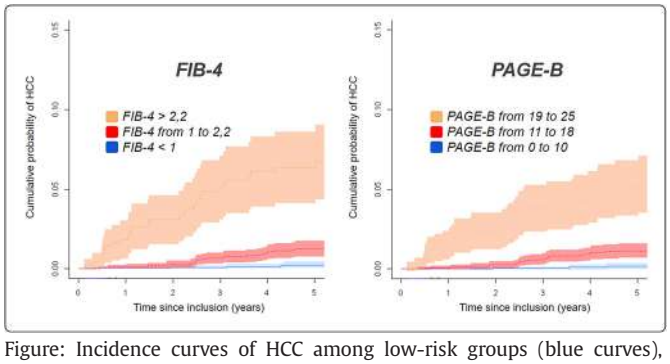

Figure: Incidence curves of HCC among low-risk groups (blue curves), intermediate risk groups (red curves) and high risk groups (orange curves) for PAGE-B and FIB-4, according to the new thresholds founded in the study.

Conclusion: PAGE-B and FIB-4 scores showed good and equivalent predictive performances for HCC in chronic hepatitis B patients in a French nationwide cohort, and could be used in clinical practice.

Email: behrendt.patrick@mh-hannover.de

Background and aims: The Hepatitis E virus (HEV) is the most common cause of acute viral hepatitis worldwide and mainly transmitted via the fecal-oral route or consumption of contaminated food products. Due to the lack of efficient cell culture systems for the propagation of HEV, limited data regarding HEV sensitivity to chemical disinfectants are available. Consequently, preventive and evidence-based hygienic guidelines on HEV disinfection are lacking. In this study we evaluated different principal components of hand disinfectants as well as commercial hand disinfectants for their virucidal activity against HEV using a recently described high titer cell culture HEV model.
Method: We used a robust HEV genotype 3 cell culture model which allows quantification of viral infection of quasi-enveloped and naked HEV particles. For HEV genotype 1 infections the primary isolate Sar55 in a faecal suspension was applied. Standardized quantitative suspension tests using end point dilution and large-volume-plating were performed for the determination of virucidal activity of alcohols (1-propanol, 2- propanol, ethanol), WHO disinfectant formulations and five different commercial hand disinfectants against HEV. Iodixanol gradients were conducted to elucidate the influence of ethanol on quasi-enveloped viral particles.
Results: Naked and quasi-enveloped HEV was resistant to alcohols as well as alcohol-based formulations recommended by WHO. Of the tested commercial hand disinfectants only one product displayed a virucidal activity against HEV. This activity could be linked to phosphoric acid as essential ingredient. Finally, we observed that ethanol and possibly non-active alcohol-based disinfectants disrupted the quasi-envelope structure of HEV particles, while leaving the highly transmissible and infectious naked virions 2 intact.
Conclusion: Different alcohols and alcohol-based hand disinfectants were insufficient to eliminate HEV infectivity with the exception of one commercially ethanol-based product which including phosphoric acid. These findings have strong implications for the efficient prevention measures to reduce viral transmission in clinical practice.

Email: m.schmidt@blutspende.de

Background and aims: This study evaluated the diagnostic accuracy of the Elecsys® HCV Duo immunoassay on the cobas e 801 analyser (Roche Diagnostics International Ltd) for the detection of hepatitis C virus (HCV) infection vs commercially available comparators.
Method: This international, multicentre study was conducted at seven sites (August 2020-March 2021). Blood donor samples and clinical laboratory samples (from routine diagnostic testing, pregnant women and patients on haemodialysis) were used for specificity analyses, while confirmed HCV-positive samples and seroconversion panels were used for sensitivity analyses. All samples were pseudonymised or fully anonymised residual serum or ethylenediaminetetraacetic acid-plasma. The Elecsys HCV Duo immunoassay was compared with two registered antigen-antibody (Ag-Ab) combination assays: the Monolisa HCV Ag-Ab ULTRA V2 and Murex HCV Ag/Ab Combination. The Elecsys HCV Duo immunoassay provides parallel, but separate, read-out of HCV Ag and Ab results (while other combination assays show a combined result only). We compared the HCV Ab (anti-HCV) module with the Elecsys Anti-HCV II and Alinity s Anti-HCV assays; no neutralisation method was available to test the HCV Ag module singularly.
Results: In all blood donor samples (n = 20634), the specificity of the Elecsys HCV Duo immunoassay was 99.94% (95% confidence interval [CI], 99.89–99.97). In all clinical laboratory samples (n = 2531), the specificity of both the Elecsys HCV Duo immunoassay and the Elecsys HCV Duo anti-HCV module was 99.92% (95% CI, 99.71–99.99), vs 99.84% (95% CI, 99.59–99.96) for the Monolisa HCV Ag-Ab ULTRA V2 and 99.76% (95% CI, 99.48–99.91) for the Elecsys Anti-HCV II assays, respectively. The sensitivity of the Elecsys HCV Duo immunoassay in confirmed HCV-positive samples (n = 257) was 99.6% vs 96.1% for the Monolisa HCV Ag-Ab ULTRA V2 assay. The Murex HCV Ag/Ab Combination assay could not detect 19% of the seroconversion panels and the Elecsys Anti-HCV II assay could not detect 20%. The former found HCV infections 2 days later (58 panels; 11 undetected) and the latter 18 days later (40 panels; 8 undetected) vs the Elecsys HCV Duo immunoassay.
Conclusion: The Elecsys HCV Duo immunoassay had comparable specificity and better sensitivity vs the comparator assays, including anti-HCV tests. The Elecsys HCV Duo immunoassay may be an alternative diagnostic tool in countries where nucleic acid testing is not possible.

Intrahepatic transcriptional profiling demonstrates preclinical models of chronic hepatitis B resemble different stages of natural history in humans

Ricardo Ramirez[1], Anastasia Hyrina[2], Rudolf Beran[2], Stephane Daffis[2], Sarah Gilmore[2], Don Kang[2], Noé Axel Montanari[3], Nicholas Van Buuren[2], Li Li[2], Dara Burdette[2], Becket Feierbach[2], Andre Boonstra[3], Simon Fletcher[2]. [1]*Gilead Sciences, Inc., Foster City, United States;* [2]*Gilead Sciences, Inc., Foster City, United States;* [3]*Erasmus MC, Rotterdam, Netherlands*
Email: ricardo.ramirez@gilead.com

Background and aims: The woodchuck and adeno-associated virus HBV (AAV-HBV) models are commonly used to evaluate novel agents for the treatment of chronic hepatitis B (CHB). However, the translational relevance of these models is not well understood. In this study, we compared the intrahepatic transcriptional profiles of the woodchuck and AAV-HBV models with a diverse group of CHB patients to determine which stage (s) of natural history they most closely resemble.
Method: Whole transcriptome profiling (RNA-Seq) was performed on liver biopsies from mice transduced with AAV-HBV (n = 8) or empty AAV (n = 8), as well as from woodchucks chronically infected with WHV (woodchuck hepatitis virus, n = 49) and from uninfected woodchucks (n = 9). These data was compared to a collection of human liver biopsies from healthy (n = 9), immune tolerant (IT, n = 15), immune active (IA, n = 15), inactive carrier (IC, n = 23), and HBeAg negative (ENEG, n = 16) donors. Pathway analysis was performed using gene set variation analysis (GSVA). Cell type deconvolution was performed using EPIC. Mouse livers were also analyzed by immunohistochemistry (IHC).
Results: Like most IT patients, AAV-HBV transduction only modestly altered the liver transcriptome, despite high intrahepatic expression of HBV RNAs. IHC confirmed there was little-to-no intrahepatic $CD3^+$ T cell infiltration in this model. Consistent with previous studies, chronic WHV infection was associated with up-regulation of intrahepatic B cell, T cell and neutrophil gene signatures in woodchucks, as well as interferon and inflammatory response pathways. Globally, the intrahepatic transcriptional signature of chronically infected woodchucks was similar to IA and ENEG patients, although there were some important differences. Most notably, an intrahepatic neutrophil signature was present in chronically infected woodchucks but neither IA or ENEG patients.
Conclusion: Comparative intrahepatic transcriptional analysis revealed that the woodchuck and AAV-HBV models of CHB most closely resemble the IA/ENEG and IT stages of human disease, respectively. These fundamental differences in intrahepatic immune environment may impact the response to immune modulatory therapies.

THU318

Hepatitis B virus splice variants are associated with reduced likelihood of functional cure and differ across phases of chronic hepatitis B infection

Olivia Maslac[1], Josef Wagner[2], Vitina Sozzi[2], Hugh Mason[2], Evguenia S Svarovskaia[3], Susanna Tan[3], Anuj Gaggar[3], Stephen Locarnini[2], Lilly Yuen[1], Margaret Littlejohn[1], Peter Revill[1].
[1]*The Peter Doherty Institute for Infection and Immunity, Victorian Infectious Diseases Reference Laboratory, Australia;* [2]*The Peter Doherty Institute for Infection and Immunity, Victorian Infectious Diseases Reference Laboratory;* [3]*Gilead Sciences, Inc., Foster City, United States*
Email: peter.revill@mh.org.au

Background and aims: Chronic hepatitis B (CHB) is characterized by progression through different phases of hepatitis B virus (HBV) infection and disease. Although not necessary for HBV replication, there is increasing evidence that HBV splice variants are associated with liver disease progression and pathogenesis.
Method: Next generation sequencing data from 404 patient samples of HBV genotype A, B, C, or D in Phase I, Phase II or Phase IV of CHB was analysed for HBV splice variants. Sp1 may include minor splice variants Sp2 and Sp4 = Sp1*, Sp13 may include minor splice variants Sp7 and Sp8 = Sp13*, and Sp9 may include minor splice variants Sp 10 and Sp12 = Sp9*.
Results: HBV splice variants differed in frequency and type by genotype and phase of natural history. Splice variant Sp1 was the most frequently detected (206/404 51% of patients), followed by Sp13 (151/404 37% of patients). These splice variants were detected in all HBV genotypes, in all three CHB phases except in phase I for genotype A in contrast to Sp5 and Sp9*, which were detected only in genotypes B and C. The diversity of splice variants was greatest amongst genotypes B and C, with all splice variants identified, and lowest in

genotype D with only 2 splice variants identified (Sp1* and Sp13*). The frequency of variants was generally highest in Phase II (123/165 75% of patients), a phase typically associated with enhanced immune activation, followed by Phase I (69/99 70% of patients). In Phase II there was significantly higher number of patients with splice variants across all genotypes A to D compare to the number of patients without splice variants (p = 0.0004). Splice variants were associated with reduced hepatitis B e antigen (HBeAg) levels and statistically reduced likelihood of achieving HBsAg loss (functional cure) in Phase II patients for Sp1 and Sp13 (p = 0.0014 and 0.0156, respectively, Figure 1 A and B).

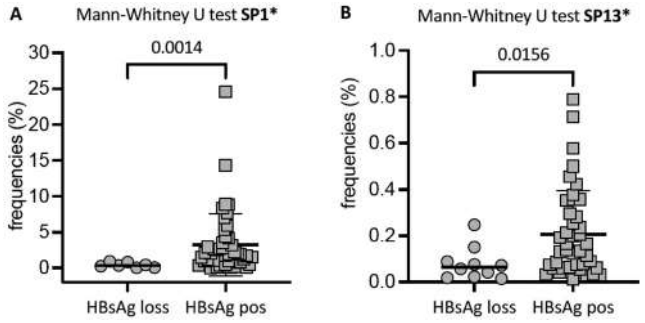

Figure 1: Sp1* and Sp13* found at statistically lower frequencies in HBsAg loss patients

Conclusion: HBV splice variants detected in patient serum are not merely a by-product of HBV replication, differing markedly by HBV genotype and phase of CHB natural history. Their frequency was generally highest in Phase II, the "immune clearance" phase of CHB natural history, suggesting an immune escape phenotype. The contribution of splice variants to the likelihood of achieving functional cure on therapy requires further investigation.

Understanding acute HCV infection kinetics in humanized mice via an agent-based modeling approach

Zhenzhen Shi[1], Yuji Ishida[2,3], Nicholson Collier[4,5], Michio Imamura[3,6], Chise Tateno[2,6], Jonathan Ozik[4,5], Jordan Feld[7], Harel Dahari[1], Kazuaki Chayama[3,8,9]. *[1]Program for Experimental and Theoretical Modeling, Division of Hepatology, Department of Medicine, Stritch School of Medicine, Loyola University Chicago, Maywood, United States; [2]PhoenixBio Co., Ltd., Higashi-Hiroshima, Japan; [3]Research Center for Hepatology and Gastroenterology, Graduate School of Biomedical and Health Sciences, Hiroshima University, Hiroshima, Japan; [4]Consortium for Advanced Science and Engineering, University of Chicago, Chicago, United States; [5]Decision and Infrastructure Sciences, Argonne National Laboratory, Aragonne, United States; [6]Department of Gastroenterology and Metabolism, Applied Life Sciences, Institute of Biomedical and Health Sciences, Hiroshima University, Hiroshima, Japan; [7]Toronto Centre for Liver Disease, Toronto, Canada; [8]Collaborative Research Laboratory of Medical Innovation, Graduate School of Biomedical and Health Sciences, Hiroshima University, Hiroshima, Japan; [9]RIKEN Center for Integrative Medical Sciences, Yokohoma, Japan*
Email: harel.dahari@gmail.com

Background and aims: uPA-SCID chimeric mice with humanized livers (SCID-MhL) are a useful tool for studying HCV infection in the absence of an adaptive immune response. Here we sought to analyse and model the HCV kinetics from inoculation to steady state in the uPA-SCID mouse model, using an agent-based modelling (ABM) approach.

Method: Ten male mice (5 PXB SCID-MhL with hepatocyte donor: JFC [1 year, male Caucasian] and human albumin >9 mg/ml, and 5 SCID mice without humanized livers, SCID-M) were inoculated intravenously with HCV (genotype 1a)-infected serum of 1×10^6 copies/animal. Viral levels were frequently measured from blood samples up to 35 days post infection (p.i.). HCV RNA was measured using quantitative real-time PCR (qRT-PCR) as previously reported (BBRC. 2006; 346 (1):67–73). We developed an ABM that accounts for two types of agents: hepatocytes and virus in the blood, attempting to recapitulate the stochastic process of HCV infection of hepatocytes in mice. The ABM simulates a series of infection stages including initial infection of uninfected cells, infected cells in a non-productive viral eclipse phase, and infected cells in a productive infection phase releasing HCV virion, which then proceed to infect additional hepatocytes. Several model parameters (e.g., virion production cycle) were calculated based on the in vivo experimental design. Model parameter fitting was done using a Genetic Algorithm (GA) with the EMEWS framework on the Midway2 high-performance computing cluster at the University of Chicago.

Results: While in SCID-M HCV was rapidly cleared (Fig. 1a, dashed lines), a productive infection was established in SCID-MhL (Fig. 1a, solid lines). After an initial viral decline, the virus resurged, followed by a transient decline (in 4 mice) that eventually stabilized at high steady state levels (Fig. 1). To account for a transient decline, a decrease in viral production was assumed reminiscent of our previous observation of such transient HCV decline seen in chimpanzees (Gastroenterology.;128 (4):1056–66). The ABM quantitatively reproduces the multi-phasic HCV kinetic patterns observed (Fig. 1b and c). The ABM predicts that: (1) the viral eclipse phase lasts between 1 and 20 h; (2) Once the infected cell passes the eclipse phase, the viral production rate is not constant, but rather increases over time. Initially all mice started with a long production cycle of 1 virion per 9–15 h but gradually reaching 1 virion per hour after 12 hr; (3) Within 5 days, the virion production reaches a steady state production rate of 1–3 virions per hour in each infected cell; and (4) a viral production drop of 83%-98% starting between 2–5 days p.i. in 4 mice.

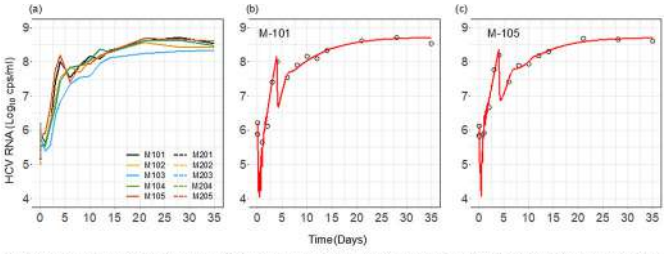

Fig 1: Kinetic and modeling of acute HCV infection in SCID mice. **(a)** HCV kinetics in SCID-M (dashed lines and SCID-MhL (solid lines). **(b and c)** ABM calibration using GA approach (solid lines) with measured HCV kinetics (circles) in two representative SCID-MhL mice.

Conclusion: The ABM provides novel insights into the HCV life cycle in vivo. The model suggests a partial block of virion production possibly due to an early stage of innate immune response.

THU320

Presence of sodium taurocholate co-transporting polypeptide and hepatitis B replication markers on placenta: another home for the virus?

Garima Garg[1], Meenu Mn[1], Kajal Patel[1,2], Shashank Purwar[1], Sramana Mukhopadhyay[3], Nitu Mishra[4], Sumit Rawat[5], Shashwati Nema[2], Debasis Biswas[1], Anirudh Kumar Singh[1], Ashish Kumar Vyas[1]. *[1]All India Institute of Medical Sciences Bhopal, Microbiology, India; [2]All India Institute of Medical Sciences Bhopal, Pathology, India; [3]All India Institute of Medical Sciences Bhopal, Pathology; [4]Gandhi Medical College Bhopal, India; [5]Bundelkhand Medical College Sagar, India*
Email: a88_ashish@yahoo.co.in

Background and aims: The role of sodium taurocholate co-transporting polypeptide (NTCP), in facilitating the binding of the virus on surface of hepatocytes is well documented. Expression of NTCP in extra hepatic cells may make these cells susceptible to HBV

infection and support cellular proliferation akin to hepatocytes. *Placental replication of HBV is not well explored/studied.* In this study we have assessed the expression of NTCP and HBV replication markers (HBeAg, HBcAg, and HBV DNA) in placental cells, to investigate if these cells act as host/reservoir for HBV.

Method: Twenty HBsAg+ve pregnant women along with 10 healthy controls were enrolled after obtaining informed consent. The HBV DNA in placenta was detected by qPCR using primers for X and core ORF. Expression of NTCP in placenta was analyzed by qRT-PCR and was further investigated by immunohistochemistry (IHC) along with HBV replication biomarkers, HBsAg, HBeAg, and HBcAg.

Results: HBV infected females showed increased expression of NTCP in trophoblasts of placenta compared to control group (3.62 ± 0.96 Vs 1.44 ± 0.81). Furthermore, significant difference in NTCP expression was also observed between HVL and LVL group (3.62 ± 0.96 Vs 2.06 ± 1.3) and it was correlated with the maternal HBV DNA load. Membranous and/or Cytoplasmic immunostaining of NTCP, and cytoplasmic staining of HBeAg and HBcAg in trophoblasts along with presence of HBV DNA indicated that trophoblasts are not only susceptible to HBV infection but may also be a probable site for viral replication.

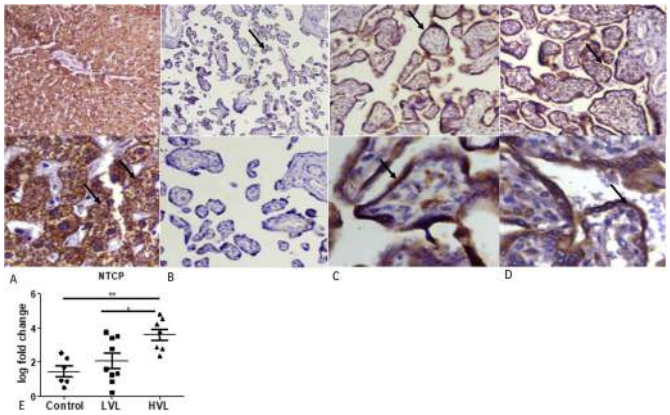

Figure: Fig. (A-D) NTCP Expression at 100X and 400X. A. NTCP expression in liver. B. NTCP expression in placenta of control. C. NTCP expression in placenta of Group B. D. NTCP expression in placenta of Group A. E. NTCP mRNA fold change among groups.

Conclusion: This is the pioneer study, which demonstrates expression of NTCP on placenta which may facilitate the entry of HBV. Furthermore, the study establishes the presence of HBeAg in trophoblasts indicating these cells may act as replication host/reservoir. Correlation of NTCP expression with maternal viral load and presence of HBeAg in placenta indicates its probable role in vertical transmission of HBV. Our preliminary finding suggest that NTCP blocking strategy may be used for therapeutic intervention of vertical transmission.

Disclosure-Conflict of interest: There are no conflict of interest among the authors.

Exploring dynamic changes in HBcrAg and HBV RNA in e-Antigen negative HBV/HIV patients on antiretroviral therapy: still evidence of integrated activity after 5 years of treatment

Ruth Byrne[1], Mark Anderson[2], Gavin Cloherty[2], Kate Childs[3], Ivana Carey[3], Mark Nelson[1], Kosh Agarwal[3]. *[1]Chelsea and Westminster Hospital, London, United Kingdom; [2]Abbott Diagnostics, Department of Infectious Diseases, Chicago, United States; [3]Kings College Hospital, Institute of Liver Studies, London, United Kingdom*
Email: ruthbyrne@nhs.net

Background and aims: Hepatitis B core-related antigen (HBcrAg) and pre-genomic (pg) HBV RNA are surrogates of covalently closed circular (ccc) DNA and have emerged as new HBV biomarkers. There is growing evidence for their role in predicting treatment durability and successful cessation of nucleos(t)ide analogue therapy in chronic HBV. Limited data exist on their utility predicting outcomes in HBV/HIV co-infection. We aimed to evaluate the value of longitudinal measurement of HBcrAg and HBV RNA in two cohorts of HBV/HIV co-infected patients.

Method: Two cohorts of e-antigen negative HBV/HIV co-infected patients were retrospectively studied. Patients were classified into 2 groups: those who started tenofovir (TDF) based antiretroviral therapy (ART) at baseline (Cohort A, n = 30) and those already established on TDF based ART with suppressed HBV DNA for 5 years at baseline (Cohort B, n = 37). HBcrAg and HBV RNA were tested at baseline, year 3 and year 5. HBcrAg was measured by automated CLEIA-method (Lumipulse G 1200 HBcrAg, Fujirebio). HBV RNA was measured by real-time PCR research assay Abbott Diagnostic with LLQ 1.65 $\log_{10}$ U/ml.

Results: Cohort A: at baseline 11 patients (37%) had undetectable HBcrAg and 10 (33%) had HBV RNA below the limit of detection. After 3 years of ART all patients had completely suppressed HBV DNA, 40% still had detectable HBcrAg and 43% had detectable HBV RNA. After 5 years of therapy there were still 10 patients (33%) with detectable HBcrAg (median 4.4 $\log_{10}$ U/ml; range 3.3–4.1) and 10 patients (33%) with detectable HBV RNA (median 1.96 ($\log_{10}$ U/ml; range 1.78–3.6). Cohort B: at baseline all patients had been on TDF based ART for 5 years and had undetectable HBV DNA, 17 patients (46%) had undetectable HBcrAg and 20 (54%) had HBV RNA below the limit of detection. After 3 years 45% still had detectable HBcrAg and 32% had detectable HBV RNA. After 5 years, there were still 15 patients (41%) with detectable HBcrAg (median 3.7 $\log_{10}$ U/ml; range 3.0–5.4) and 11 (30%) with detectable HBV RNA (median 2.19 ($\log_{10}$ U/ml; range 1.78–3.6). The impact of HBV genotype, pre therapy HIV viral load and nadir CD4 count on HBV markers in both cohorts was analysed and no significant effect found.

Conclusion: HBcrAg and HBV RNA are sensitive biomarkers for continued transcription of cccDNA in HBeAg negative HBV/HIV co-infected patients despite long term suppression of HBV DNA by TDF based ART. TDF withdrawal studies are needed in HBV/HIV cohorts but as ART moves into a new era of TDF-sparing two drug regimens, these biomarkers may have clinical utility identifying those who can stop TDF safely with minimal risk of HBV reactivation.

THU322

Next-generation sequencing of Swiss HEV isolates allows for reconstitution of functional clones

Jérôme Gouttenoire[1], Roland Sahli[2], Daniela Müllhaupt[1], Montserrat Fraga Christinet[1], Darius Moradpour[1]. *[1]Lausanne University Hospital (CHUV) and University of Lausanne, Division of Gastroenterology and Hepatology, Lausanne, Switzerlan; [2]Lausanne University Hospital (CHUV) and University of Lausanne, Institute of Microbiology, Lausanne, Switzerland*
Email: jerome.gouttenoire@chuv.ch

Background and aims: Hepatitis E acquired in Switzerland is caused primarily by a specific hepatitis E virus (HEV) subtype which has been provisionally designated as 3 s and recently assigned as a distinct group to 3 h (3 s[p]/h). Here, we analyzed HEV from patients with severe outcomes of hepatitis E by a newly developed next-generation sequencing (NGS) protocol and assembled subgenomic replicons as well as full-length clones.

Method: Illumina RNA sequencing coupled with HEV-specific sequence enrichment was carried out on plasma samples from 24 patients with hepatitis E acquired in Switzerland and severe outcomes (severe acute hepatitis, acute-on-chronic liver failure and neurologic complications). Viral genomes reconstituted by DNA synthesis and molecular cloning were functionally characterized in cell culture.

Results: The entire HEV genomes from plasma of 24 patients could be sequenced successfully, confirming the predominance of subtype 3 s

(p)/h in Switzerland. The number of reads at each nucleotide position and overall coverage allowed to establish a consensus sequence for 17 genomes. Subgenomic replicons and full-length genomes derived from some of these replicated in hepatoma cell lines. Functional clones are being further characterized, in particular for their ability to produce infectious virus. In addition, selectable replicons are currently being investigated with the aim to identify cell culture-adaptive changes.

Conclusion: A newly developed NGS protocol and DNA synthesis allowed to successfully reconstitute functional clones of Swiss HEV isolates. These represent a rare resource and should facilitate further studies on the molecular virology and pathogenesis of hepatitis E.

THU323

HEC96719, a novel FXR agonist, inhibits HBV infection in vitro and in vivo

Pu Wang[1], Qingying Lai[1], Xinye Yang[1], Jing Li[1], Yunfu Chen[1]. [1]*Sunshine Lake Pharma Co., Ltd, Department of Pharmacology and Toxicology, Dongguan, China*
Email: chenyunfu@hec.cn

Background and aims: Current treatment for hepatitis B virus (HBV) infection, including nucleos (t)ide analogues and Interferon, can reduce disease progression but have limited effect on achieving HBV functional cure. Therefore, new drugs with differentiated mechanisms of action, by targeting HBsAg and cccDNA, are required to significanlty enhancing the rate of functional cure.

Method: The *in vitro* anti-HBV activities of a novel FXR agonist HEC96719 were evaluated in HBV-infected primary human hepatocytes (PHH) model while the *in vivo* antiviral activities and modulation of FXR pathway were studied in the AAV/HBV mouse model.

Results: HEC96719 had significantly enchanced antiviral activities (Table 1) in HBV-infected PHH with mean EC_{50} values against HBV DNA, HBeAg, HBsAg and HBV RNA of <0.001μM, 0.001μM, 0.003 μM and <0.001μM, respectively, while 0.338 μM, 0.122 μM, 0.509 μM and 0.456 μM for GW4064, respectively. Southern blot analysis revealed that HEC96719 has no siginificant impact on cccDNA level, indicative of transcriptional inhibition on cccDNA. CC_{50} of HEC96719 were greater than the maximum detected concentration (10μM). In AAV/HBV mouse model, HEC96719 (0.5 mg/Kg and 2 mg/Kg) demonstrated dose dependent inhibition on viral parameters. Compared to vehicle control, mean decline of serum HBV DNA, HBeAg and HBsAg at 56 days post treatment were – 0.51 ± 0.09 log, – 0.30 ± 0.06 log, and – 0.26 ± 0.06 log respectively for the 0.5 mg/Kg dose group, while – 1.34 ± 0.33 log, – 0.50 ± 0.08log, and – 0.61 ± 0.18 log respectively for the 2 mg/Kg dose group. Furthermore, HBV DNA and 3.5 kb RNA were also significantly reduced in the liver. Metabolic regulation related indicators, *FXRα* were significantly decreased, while *SHP* and *BSEP* were significantly increased in the liver. Treatment were well tolerated with no occurance of ALT flares.

PHH cell					
CPD	EC_{50}				CC_{50}
	HBV DNA	HBsAg	HBeAg	HBV RNA	
GW4064(μM)	0.338	0.509	0.122	0.456	>10
HEC96719(μM)	<0.001	0.003	0.001	<0.001	>10
ETV(nM)	0.007	>0.500	>0.500	>0.500	> 0.5

AAV-HBV mice			
CPD	Mean decline at Day56 (Relative to vehicle)		
	HBV DNA	HBsAg	HBeAg
HEC96719(0.5mpk)	-0.51±0.09log(copy/μL), P=0.023	-0.26±0.06log(IU/ml), P=0.039	-0.30±0.06log(PEIU/ml), P=0.007
HEC96719(2.0mpk)	-1.34±0.33log(copy/μL), P=0.007	-0.61±0.18log(IU/ml), P=0.017	-0.50±0.08log(PEIU/ml), P=0.002

Table 1: Antiviral activity of HEC96719 *in viro* and in vivo

Conclusion: The *novel* FXR agonist HEC96719 has strong inhibitory effect against HBV replication in PHH cells and AAV/HBV mice, thus represent a promising agent for HBV cure.

THU324

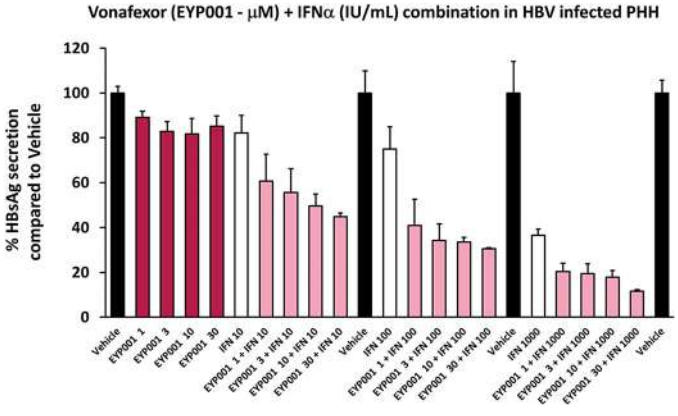
Combined effect of Vonafexor and Interferon-alpha on HBV replication in primary human hepatocytes

Romain Barnault[1], Raphaël Darteil[2], Pietro Scalfaro[2], Jacky Vonderscher[2], David Durantel[1]. [1]*INSERM U1111-CIRI, HepVir team, Lyon, France;* [2]*ENYO pharma SA, Bioserra 1, Lyon, France*
Email: david.durantel@inserm.fr

Background and aims: Despite its adverse safety and tolerance profile, as well as a limited effect in inducing a HBsAg-loss, pegylated interferon-alpha (peg-IFNα) continues to be used as first line therapy for chronic hepatitis B (CHB) patients. It is hypothesized that an immune-stimulator will be a necessary component of future combination therapies for curing CHB, therefore, it is essential to either use alternative compounds to peg-IFNα, or to introduce a second compound which may increase its efficacy and lead to lowering its dosing, which may reduce associated side effects. Several FXR agonists were shown to have some anti-HBV properties *in vitro*. Moreover, the combination of peg-IFNα2a with Vonafexor, a synthetic non-steroidal, non bile-acid and highly selective FXR agonist, has been shown in an on-going open-label phase II trial (NCT04365933) to significantly reduce HBsAg levels in HBe-negative patients after only 16 weeks of treatment (Poster 2844, EASL 2021). The aim of this work was to further evaluate the underlying mechanism of action by determining whether an increased anti-HBV effect of this combination could be recapitulated in cell culture models.

Method: We used experimentally HBV-infected differentiated HepaRG cells and primary human hepatocytes (PHH), as well as standard molecular and cellular virologic methods to study the combination of Vonafexor and peg-IFNα, and compare the combination to respective monotherapies. The cytotoxicity of the combination was also evaluated to exclude its contribution to the improved antiviral effects.

Results: The combination of Vonafexor and peg-IFNα led to an improved anti-HBV effect on all parameters analyzed in both dHepaRG and PHH cells, including intracellular decrease in HBV RNAs, viremia and HBsAg secretion. The effect was more pronounced on HBsAg secretion where a synergy between Vonafexor and peg-IFNα was observed (see figure below). At therapeutically relevant concentrations of the combination Vonafexor and peg-IFNα, no toxicity was observed using 4 different assays (Cell titer Glo, Neutral red, Sulforhodamine stainings, and LDH release), thus ruling out potential toxicity as an alternative explanation for improved anti-HBV effects. Interestingly, similar improved anti-HBV activities were also observed with other FXR agonists, thus demonstrating the class effect of those observations.



Conclusion: We were able to recapitulate, in cell culture models, the improved anti-HBV effect of combining Vonafexor and peg-IFNα. We also observed that the effect is achieved without inducing toxicity. This study provides support for the existence of a mechanism of action underlying the antiviral activity in combining Vonafexor and peg-IFNα, details of which should be explored further to eventually assist in identifying efficacy predictive factors in clinical trials.

THU325

Hepatitis Delta virus quasispecies conservation and variability in ribozyme region

Beatriz Pacín Ruiz[1,2,3], Maria Francesca Cortese[1,2,3], Sara Sopena Santisteve[3], Josep Gregori[1], Selene Garcia-Garcia[1,2,3], David Tabernero[2,3], Rosario Casillas[1,3], Marta Vila[1,3], Ariadna Rando-Segura[3], Adriana Palom[4], Mar Riveiro Barciela[4], Francisco Rodríguez-Frías[1,2,3], Maria Buti[4]. *[1]Vall D'hebron Research Institute, Barcelona, Spain, Liver Unit, Barcelona, Spain; [2]InstitutoDe Salud Carlos III, Madrid, Spain, Centro De Investigación Biomédica En Red, Enfermedades Hepáticas y Digestvas (CIBERehd), Madrid, Spain; [3]Vall D'hebron University Hospital, Biochemistry and Microbiology/Liver Pathology Unit, Barcelona, Spain; [4]Vall D'hebron University Hospital, Liver Unit, Internal Medicine Department., Barcelona, Spain*
Email: beatriz.pacin@vhir.org

Background and aims: Around the 5% of hepatitis B virus (HBV) infected patients are co-infected with Hepatitis D virus (HDV). HDV genome is characterized by an 85 nucleotides-length domain with autocatalytic activity called ribozyme, which covers a key role in HDV replication. Of note, HDV presents a high rate of evolution and circulates as a mixture of variants forming a quasispecies (QS). Here, we analyzed by Next Generation sequencing (NGS) the ribozyme QS in longitudinal samples to study its conservation and identify possible mutations that could potentially affect HDV replication.
Method: Thirty-two patients with chronic hepatitis delta (CHD) were selected and two serum samples were collected per patient with a mean follow-up of 2.25 years. Viral genotype was determined by analyzing HDV delta antigen sequence. The HDV RNA region between nt 663 and 899, corresponding to ribozyme, was analyzed by NGS (*MiSeq Illumina*, San Diego, USA). Conservation was studied by calculating QS information content. Nucleotide substitutions were identified by aligning sample QS with its genotype consensus sequence.
Results: All patients were infected by genotype 1 HDV. A median of 5040 reads/sample was obtained. The ribozyme was overall highly conserved. A hyper-conserved region was identified between nt 715–745, whereas the more variable portion was between nt 739–769, although more the 90% of nt showed a maximum of conservation. When looking QS evolution between the two follow-up samples, limited distance was observed. Eleven mutations were observed. Of them, 3 mutations (T23C, T64del, and T69C) presented a high frequency (respectively 5.51, 98.60, and 8.20%) in viral QS and were selected in the two patients' sample.

Conclusion: As expected and considering its role in viral replication, the ribozyme QS was highly conserved without changes between the two samples. The mutations observed interested domains involved in ribozyme excision activity (L3) and structural stabilization (P4), and they could potentially interfere with viral replication. Thanks to its high rate of conservation, the ribozyme could be a valuable target of gene therapy. Further *in vitro* studies are required to evaluate the effects of the mutations in HDV expression. Funding: Instituto de Salud Carlos III (grant PI17/02233), co-financed by the European Regional Development Fund (ERDF).

THU326

Exosomal cargo as a key player of the immune response after direct-acting antiviral treatment in chronic hepatitis C patients

Eirini Karamichali[1], Pelagia Foka[1], Vaia Valiakou[1], Petros Eiliadis[2], Domniki Loukaki-Gkountara[1], Konstantina Andresaki[1], Georgia Papadopoulou[1], Urania Georgopoulou[1], Ioannis-Georgios Koskinas[3]. *[1]Hellenic Pasteur Institute, Molecular Virology, Athens, Greece; [2]Hellenic Pasteur Institute, Laboratory of Molecular Biology and Immunobiotechnology, Athens, Greece; [3]Medical School of Athens, Greece, 2nd Department of Internal Medicine, Hippokration General Hospital, Athens, Greece*
Email: koskinasj@yahoo.gr

Background and aims: HCV infection causes severe liver disease. Direct-acting antivirals (DAAs) eradicate HCV but host immunity fails to fully recover. Exosomes are extracellular vesicles secreted by all cell types. They are masters of intercellular communication in health and disease. It has been demonstrated that HCV infection can be transmitted by exosomes between hepatocyte-like cells establishing a productive infection. Viruses exploit exosomes to establish persistent infection and escape the immune response. Exosomal cargo promotes disease progression possibly by "dampening down" host immune responses.
We aimed to elucidate the role of exosomes in the immune response of chronic HCV patients at various stages of liver fibrosis, before and after DAAs treatment.
Method: Whole blood from 40 chronic HCV patients with characterized fibrosis was collected before and after DAAs administration and used for isolation of exosomes and peripheral blood mononuclear cells. The existence of specific T-cell subpopulations was assessed by FACS. Exosomal cargo was analyzed for immunosuppressive factors by immunoblotting, FACS and ELISA.
Results: The (%)-ratio of cytotoxic (CTL) over total T-lymphocytes (CD3/CD8) remained unaffected by DAAs treatment and fibrosis stage. Conversely, the Tregs (CD4/CD25/FOXP3) subpopulation post-DAAs treatment was statistically decreased in mild fibrosis (stages F0-F1-F2), but remained stable in advanced fibrosis and cirrhosis

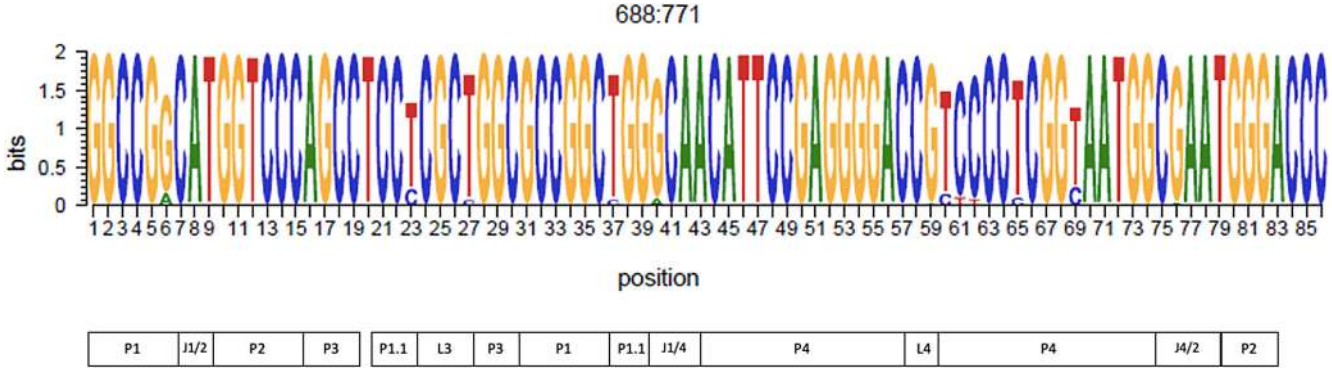


Figure: (abstract: THU325): Logo representation of the nucleotide sequence corresponding to the ribozyme region in the genomic sense (nt 688-771). At the bottom are indicated the different regions of the ribozyme and to which of them each nucleotide group corresponds

(stages F3-F4). Importantly, the active form of the immunosuppressive cytokine TGF-β was detected in the exosomal cargo and matching serum, albeit varying between fibrosis stages. We observed that the TGF-β levels of both sera and exosomes before DAAs treatment were statically increased in advanced fibrosis (F3). Treatment with DAAs statistically reduced serum TGF-β levels by 50% in the advanced stages of fibrosis and cirrhosis, whereas it did not alter TGF-β levels in exosomes in the different stages of fibrosis. Finally, we confirmed the presence of the immunosuppressive PD-L1 molecule in exosomes isolated from the same samples both before and after treatment.
Conclusion: HCV-manipulated exosomes may confer continuing immune suppression in the otherwise cured HCV patients bearing advanced liver disease. Despite DAA-mediated HCV eradication, the presence of immunosuppressive factors in the exosomal cargo supports the notion of a remaining "viral fingerprint" that could promote liver disease in susceptible individuals.

THU327

Therapeutic suppression of HBV transcripts promotes reappearance of the SMC5/6 complex and cccDNA silencing in vivo without affecting posttranslational modifications of cccDNA-bound histones

Lena Allweiss[1,2], Moritz Calaminus[1], Katja Giersch[3], Tassilo Volz[1], Andrea Pirosu[4], Marc Luetgehetmann[2,3], Maura Dandri[1,2]. *[1]University Medical Center Hamburg-Eppendorf, I. Department of Internal Medicine, Hamburg, Germany; [2]German Center for Infection Research (DZIF), Hamburg-Lübeck-Borstel-Riems, Germany; [3]University Medical Center Hamburg-Eppendorf, Department of Medical Microbiology, Virology and Hygiene, Germany; [4]Leibniz Institute for Experimental Virology, Department of Viral Immunology, Hamburg, Germany*
Email: l.allweiss@uke.de

Background and aims: There is a strong need to explore interventions able to suppress the hepatitis B virus (HBV) reservoir, the cccDNA, since its silencing may promote a functional cure of chronic hepatitis B (CHB). We previously showed that treatments with siRNA targeting all HBV transcripts or pegylated interferon α (peg-IFNα) strongly reduce all HBV markers, including HBx, thus enabling reappearance of the host restriction factor "structural maintenance of chromosome 5/6" (SMC5/6) complex and cccDNA suppression in vivo (*Allweiss/Giersch, Gut 2021*). The aim of this study was to investigate the epigenetic landscape of cccDNA-bound histones in HBV-infected humanized mice after siRNA or peg-IFNα treatment.
Method: HBV-infected human liver chimeric mice received siRNA or peg-IFNα for 4 or 6 weeks, respectively, or were left untreated. RNA in situ hybridisation demonstrated suppression of HBV transcripts in human hepatocytes. Active and repressive posttranslational modifications (PTMs) of cccDNA-bound histones and SMC5/6 occupancy were analysed by chromatin immunoprecipitation-qPCR (ChIP-qPCR) and compared with PTMs on host genes.
Results: In untreated mice with high HBV replicative activity, canonical transcriptionally active PTMs (H3K27ac, H3K4me3) were highly enriched on the cccDNA minichromosome while the repressive mark H3K27me3 was undetectable. This pattern was consistent with active transcription and similar to the active host gene promotor GAPDH. Remarkably, neither siRNA nor peg-IFNα provoked significant PTM changes on the cccDNA despite strong reduction of HBV transcription. Consistent with previous results, only NSE4 occupancy, a subunit of the SMC5/6 complex, became detectable on the cccDNA after siRNA and peg-IFNα treatment.
Conclusion: Despite shutting down cccDNA transcription in a great proportion of human hepatocytes, siRNA or peg-IFNα treatment did not alter the pattern of the analysed cccDNA-bound histone PTMs. In line with the function of SMC5/6 as a DNA micro-compaction machine (*Serrano, Molecular Cell 2020*), the data suggest that SMC5/6 could mediate silencing through physical cccDNA compaction rather than through epigenetic changes.

THU328

Updated national prevalence estimates of chronic hepatitis B virus infection in countries within the European (EU) and European Economic Area (EEA): a systematic review

Sandra Bivegete[1,2], Adam Trickey[1], Zak Thornton[1], Becky Scanlan[1], Anna McNaughton[1], Aaron G. Lim[1], Lina Nerlander[3], Hannah Fraser[1], Josephine Walker[1], Matthew Hickman[1,2], Peter Vickerman[1,2], Helen Johnson[3], Erika Duffell[3], Ellen Brooks-Pollock[1], Hannah Christensen[1]. *[1]University of Bristol, Population Health Science, Bristol Medical School, Bristol, United Kingdom; [2]University of Bristol, NIHR HPRU in Behavioural Science and Evaluation, Bristol, United Kingdom; [3]European Centre for Disease Control, Stockholm, Sweden*
Email: hannah.christensen@bristol.ac.uk

Background and aims: Hepatitis B virus (HBV) is a leading public health problem globally. In Europe, the burden of HBV disproportionately affects at-risk groups, including men who have sex with men (MSM), migrants and prisoners. There are no recent population-level estimates of HBV prevalence in Europe.
Method: We undertook a systematic review to update estimates of chronic HBV (CHB) prevalence for the EU/EEA and UK in key sentinel and at-risk population groups. Databases were searched for original research articles in English published between 1/1/2018 to 24/2/2021. Titles and abstracts were screened to identify articles containing relevant information on CHB prevalence in Europe as measured by HBsAg status, with full text screening undertaken to confirm inclusion. Sentinel groups included first-time blood donors (FTB), general population (GP) and pregnant women; at-risk groups included MSM, migrants and prisoners. The updated estimates were incorporated into an existing HBV prevalence database (spanning 2005–2017) developed by the European Centre for Disease Control using the same inclusion/exclusion criteria. External grey literature data were obtained from country experts.
Results: A total of 5678 articles were title and abstract screened, of which 307 were full-text screened. A total of 41 published studies were included in the review, consisting of studies in GP (n = 12), migrants (n = 17), pregnant women (n = 5), MSM (n = 3) and prisoners (n = 4). Additional estimates from grey literature were also included (n = 109), comprising of GP (n = 11), migrants (n = 7), pregnant women (n = 16), MSM (n = 6), prisoners (n = 8) and FTB (n = 61).
Weighted CHB prevalence estimates from the existing and updated database indicated a low HBV prevalence (≤2%) among sentinel populations in all regions with exceptions in Romania, Bulgaria, Italy and Greece (reported prevalences 3.4–7.6%). Prevalence among prisoners varied considerably across all regions (range 2.1–25.2%) and 56% countries lacked data. Studies among migrants recorded some of the highest HBV prevalences, and estimates in this subpopulation were typically higher in Southern European regions (range 5.0–12.2%). Reported HBV prevalence among MSM was low (≤2%), except in Belgium and Estonia (range 2.3–3.4%). Studies on MSM and migrants were absent in Eastern Europe.

Figure: Updated HBsAg prevalence estimates in high-risk groups in the EU/EEA and UK. Maps show the weighted average prevalence in each country.

Conclusion: This review builds on previous estimates in the EU/EEA and UK, providing an additional 150 prevalence estimates across the region (updated total; n = 582). HBV prevalence was higher in Southern and south-Eastern Europe compared to other regions. Furthermore, CHB prevalence remains high among high-risk groups,

indicating that further interventions targeting these groups are required to reduce the burden of HBV in Europe.

THU329

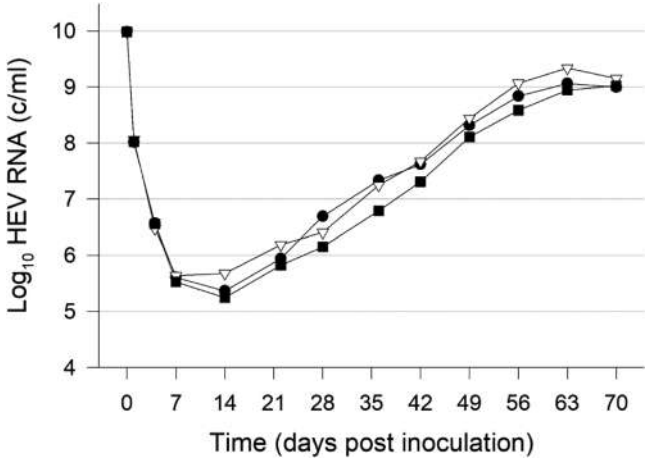
Relevance of HEV detection in ejaculate of chronically infected patients

Mathias Schemmerer[1], Marc Luetgehetmann[2], Hans Bock[3], Jörn Schattenberg[4], Samuel Huber[5], Susanne Polywka[2], M Mader[5], Ansgar Lohse[5], Daniel Todt[6,7], Eike Steinmann[6], Jürgen Wenzel[1], Thomas Horvatits[5], Sven Pischke[5]. *[1]University Medical Center Regensburg, Institute of Clinical Microbiology and Hygiene, National Consultant Laboratory for HAV and HEV, Regensburg, Germany; [2]University Hospital Hamburg-Eppendorf, Microbiology, Germany; [3]University Hospital Düsseldorf, Gastroenterology, Germany; [4]University Medical Center Mainz, Gastroenterology, Germany; [5]University Medical Center Hamburg-Eppendorf, Department of Medicine, Germany; [6]Ruhr-University Bochum, Department of Molecular and Medical Virology, Germany; [7]European Virus Bioinformatics Center (EVBC), Jena, Germany*
Email: mathias.schemmerer@ukr.de

Background and aims: Recently, HEV particles have been detected in the ejaculate of 2 out of 3 chronically infected patients. HEV RNA in the ejaculate can be significantly higher than in serum or plasma. However, it was unclear whether these viral particles in the ejaculate are infectious, and how often HEV generally occurs in the ejaculate of chronically infected individuals.

Method: After a previous cell culture model failed to demonstrate the infectivity of HEV particles from the ejaculate of two chronically infected patients (Horvatits et al. Journal of Hepatology 2021), we now used an alternative cell culture model based on overconfluent PLC/PRF/5 cells (Schemmerer et al. Viruses 2019) to study these particles for infectivity. Furthermore, we monitored HEV viral load in blood, urine, stool and ejaculate in 9 chronically HEV infected patients.

Results: For the first time, HEV particles from ejaculate were shown to be infectious in overconfluent PLC/PRF/5 cells (figure). HEV replicated to high viral loads of 10e9 HEV RNA copies per ml. Moreover, HEV was detected in the ejaculate of 7 out of 9 chronically infected patients (age 36–67 years, median 56 years). In 5 of the patients the viral loads were significantly higher (more than 2 log) compared to their serum, while in 2 patients, viral loads were lower than in their serum (more than 1 log).



Conclusion: In the context of chronic HEV infection, HEV particles can be detected in the ejaculate of 78% (7/9) of infected men, usually with significantly higher viral loads than in serum. In this regard, it should be noted that the gap between high viral load in ejaculate compared to viral load in blood may even be much higher than previously suspected. After the infectivity of HEV particles from ejaculate could not be demonstrated so far, it could now be shown that they are infectious in PLC/PRF/5 cells. While there is probably no danger from this ejaculate for immunocompetent sexual partners, safer sex practice should be followed if the sexual partners are immunocompromised.

THU330

HDV-mediated inhibition of HBV in superinfection mouse model: the role of type I Interferon

Beatriz Pacín Ruiz[1,2,3], Gracián Camps[4], Maria Francesca Cortese[1,2,3], Josep Gregori[1,2], David Tabernero[1,3], Selene Garcia-Garcia[1,2,3], África Vales Aranguren[4], Cristina Olague Micheltorena[4], Ariadna Rando-Segura[1], Josep Quer[2,3], Rafael Esteban[3,5], Mar Riveiro Barciela[3,5], Maria Buti[3,5], Gloria González-Aseguinolaza[4], Francisco Rodríguez-Frías[1,2,3]. *[1]Vall D´hebron University Hospital, Biochemistry and Microbiology/Liver Pathology Unit, Barcelona, Spain; [2]Vall D´Hebron Research Institute, Liver Unit, Barcelona, Spain; [3]Instituto De Salud Carlos III, Centro De Investigación Biomédica En Red, Enfermedades Hepáticas Digestvas (CIBERehd), Madrid, Spain; [4]University of Navarra, Center for Applied Medical Research (CIMA), Pamplona, Spain; [5]Vall D´Hebron University Hospital, Liver Unit, Department of Internal Medicine, Barcelona, Spain*
Email: beatriz.pacin@vhir.org

Background and aims: While Hepatitis B virus (HBV) replication does not significantly activate the innate immune response, it has been observed that in the presence of Hepatitis Delta virus (HDV) there is an increased type I interferon (INF) response. The aim of this study is to analyze the potential role of the IFN response on the HBV inhibition upon HDV super-infection in a novel HBV-expressing transgenic (HBVtg) mouse model knock out for the IFN alpha-receptor (IFNαR KO).

Method: Wild type (WT) and IFNαR KO HBVtg mice were intravenously administered with 5×10^{10} viral genomes of adeno-associated vector (AAV) expressing luciferase (LUC) or HDV. While Hepatitis B viremia was weekly monitored during the experiment, liver HBcAg expression and HBV-DNA levels were analyzed at 21 days after AAV injection. At this timepoint, the complexity of the HBV quasispecies (QS) at the 5′ (nt 1255–1611) and 3′ (nt 1596–1912) ends of the X gene of intrahepatic RNA was analyzed by next-generation sequencing (NGS) (*MiSeq Illumina*, San Diego, USA). Nucleotide substitutions were identified by aligning sample QS with its genotype master sequence and QS complexity was calculated using Rare Haplotype Load (RHL) index (threshold 1%).

Results: Both liver HBcAg expression and viremia was higher in HBVtg × IFNαR KO than in WT HBVtg mice under steady state conditions. AAV-HDV injection induced the decrease of hepatic HBcAg expression and HBV-DNA levels in HBVtg mice. This effect disappeared in HBVtg × IFNαR KO mice. Likewise, viremia was reduced from day 7, reaching the lowest levels at day 21 after vector administration in HBVtg mice, while HBV serum levels in HBVtg × IFNαR KO animals remained constant until the end of the experiment. Similar ALT serum levels presented by HBVtg and HBVtg × IFNαR KO mice excluded differential liver damage as the reason for the HBV repression observed in HBVtg animals. An overage higher number of changes was observed in 5′*HBX* region than in 3′ *HBX* region (42.72 *vs.* 15.61). In 5′*HBX* the RHL index was higher in presence of HDV. This index was even more pronounced in wt HBVtg than IFNαR KO.

Conclusion: The limited inhibition of HBV expression in presence of HDV in IFNαR KO mice suggested that IFN type I is essential for HDV-mediated HBV inhibition. The higher QS variability in presence of HDV might contribute to the inhibition of HBV replication. This variability is more pronounced in wt mice, thus suggesting a possible role of IFN-dependent activation of mutagenic enzymes. Further studies are required to better characterize the molecular mechanisms involved in HBV inhibition and variability, and to identify novel therapeutic strategies for HDV-infected patients. Assessment of Myrcludex or heparin antiviral activity on HBV infection using a 3-dimensional primary human hepatocyte culture system

Juliette Besombes[1], Charlotte Pronier[1], Jeremy Bomo[1], Philippe Gripon[1], Vincent Thibault[1]. [1]*CHU Rennes-Pontchaillou Hospital, Virology, Rennes, France*
Email: vincent.thibault@chu-rennes.fr

Background and aims: Despite effective vaccination, Hepatitis B Virus (HBV) infection remains responsible for significant morbidity and mortality worldwide. Robust *in vitro* models mimicking the complex liver architecture are still lacking and culture of differentiated primary human hepatocytes (PHH) remains fastidious. Three dimensional (3D) culture models of PHH have been developed offering a microenvironment closer to *in vivo* conditions. Here, we describe the characterization of a 3D cell culture model based on the formation of PHH spheroids supporting HBV infection. We focus on the effect of Heparin and Myrcludex B (MyrB) on HBV infection.
Method: PHH (freshly collected or cryopreserved) were first incubated overnight in ultra-low-attachment plates to make them aggregate in spheroids before being embedded in a collagen matrix. HBV infection was performed 2 days after seeding using a 50-fold concentrated culture supernatant of HepG.2.2.15 cells or HBV purified from chronically infected patients' plasmas using different multiplicity of infection (MOI). Susceptibility to infection was monitored by HBe antigen (HBeAg) secretion in the supernatant. HBV infection under different concentrations of Heparin (4 and 133 µg/ml) or MyrB (50 to 800 nM) was evaluated.
Results: After defining the optimal MOI of 400 HBV genome equivalents (GE)/cell, long-term HBV infections for at least 38 days were obtained with this model. The dose-response study showed that infections at a low MOI of 10 GE/cell, similar to the one used *in vivo* in animal models, were possible even though HBeAg secretion remains weak. We confirmed that high concentration of heparin (133 µg/ml) blocked HBV infection leading to 85% inhibition of HBeAg secretion ($p < 0.05$) at 14 days post infection (dpi). Conversely, heparin at therapeutic concentration (4 µg/ml) in the culture medium promoted infection with a 130% increase in HBeAg secretion ($p < 0.05$). In this model, 50 nM MyrB efficiently blocked HBV infection with an average inhibition of HBeAg secretion of 63%, at 7 dpi. An increase of MyrB concentration from 50 to 800 nM did not improve the inhibition of infection. The level of HBeAg secretion was comparable when MyrB (100nM) was present only at the time of infection or maintained throughout the culture duration with an inhibition of HBeAg secretion of 84% at 14 dpi, whatever the condition. Adjunction of MyrB in the culture medium at 4 and 8 dpi resulted in a decrease in HBeAg secretion of 61% and 25%, respectively, at 14 dpi ($p < 0.05$ compared to without MyrB).
Conclusion: This 3D PHH culture system supports long-term HBV infection. Activity of MyrB even when added at distance from infection suggests late or secondary infections. Heparin activity on HBV infection depended on its concentration in the medium, yet the mechanism underlying this effect remains partially unexplained. Optimization and characterization of this model are warranted.

Email: gibril.ndow@lshtm.ac.uk

Background and aims: The new Xpert hepatitis B virus (HBV) viral load test (Cepheid, USA) provides an opportunity to scale up and decentralise hepatitis B diagnosis, treatment and monitoring in resource-limited settings where HBV is endemic and molecular diagnostics to quantify HBV DNA are scarce. We assessed the concordance between the new Xpert HBV viral load test and the conventional quantitative PCR (Abbott, USA) in quantifying HBV viremia using stored plasma and dried blood spot (DBS) samples.
Method: Paired plasma and DBS (Whatman 903 Protein Saver cards) samples were collected from adults with chronic HBV infection followed up in the PROLIFICA (Prevention of Liver Fibrosis and Cancer in Africa) programme in The Gambia. Samples were stored in – 80C for at least 12 months before analysis.
For each plasma sample, HBV DNA was quantified using both realtime qPCR (Abbott, detection limit 26 IU/ml in plasma) and Xpert (detection limit 3.2 IU/ml in plasma). For DBS, HBV DNA was quantified using Xpert.
Concordance of the Xpert HBV test and the conventional qPCR in detecting and quantifying HBV viremia in plasma was assessed by kappa statistics, and the agreement between the two assays was assessed using the Bland-Altman plot. The concordance of HBV viremia between paired plasma and DBS samples was also assessed by kappa statistics.
Results: We analysed 266 stored plasma samples from patients at various hepatitis B disease stages. Of these, HBV viral load results were concordant between the Xpert and the conventional qPCR: 130 (48.9%) and 63 (23.7%) were detectable and undetectable by both assays, respectively. The results were discordant in 71 (26.7%) samples that were detectable by Xpert but not qPCR, and 2 (0.8%) samples that were detectable by qPCR but not Xpert. In 110 samples with quantified viral load results from both assays, the mean difference between the two assays was 0.316 log IU/ml (95% limits of agreement – 1.189, 1.820) with only 6/110 results (5.45%) being outside the limits of agreement (figure 1), indicating good agreement.
From 91 paired plasma and DBS samples analysed by Xpert assay, the mean bias between plasma and DBS was statistically significant at +1.831 log IU/ml (95% limits of agreement: 0.660–3.001). Bias was smaller at lower viral loads. The kappa statistic was 0.10 indicating very poor agreement between results. After excluding samples with error or invalid result by either sample type ($n = 40$), kappa statistic was 0.34 indicating a poor agreement.

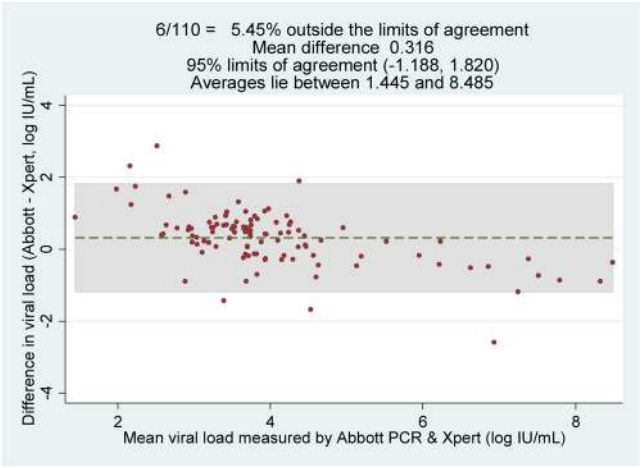

Figure 1: Bland-Altmann plot of Xpert HBV minus Abbott qPCR (vertical axis) against mean of Xpert HBV and Abbott qPCR (horizontal axis) for samples with detectable viral load (n = 110).

Conclusion: The Xpert HBV DNA test provides a reliable alternative for detecting and quantifying HBV DNA viral load using stored plasma samples. However, the assay is not reliable for detecting viremia from DBS samples.

THU333

A high-throughput viral integration sequencing method reveals that mitochondrial DNA is frequently targeted by HBV integration

Domenico Giosa[1], Daniele Lombardo[1], Cristina Musolino[2], Valeria Chines[1], Giuseppina Raffa[1], Deborah D'aliberti[3], Francesca Casuscelli di Tocco[1], Carlo Saitta[1], Riccardo Aiese Cigliano[4], Orazio Romeo[5], Angela Alibrandi[6], Giuseppe Navarra[2], Giovanni Raimondo[1], Teresa Pollicino[2]. *[1]University Hospital of Messina, Clinical and Experimental Medicine, Messina, Italy; [2]University Hospital of Messina, Human Pathology, Messina, Italy; [3]University of Milano Bicocca, DIPARTIMENTO DI MEDICINA E CHIRURGIA (SCHOOL OF MEDICINE AND SURGERY), Milan, Italy; [4]Sequentia Biotech SL, Barcelona; [5]University of Messina, Dipartimento di Scienze chimiche, biologiche, farmaceutiche e ambientali, Messina, Italy; [6]University of Messina, Dipartimento di Economia, Messina, Italy*
Email: tpollicino@unime.it

Background and aims: Although research on HBV DNA integration has made relevant progress, important aspects remain unclear. Development of new integration detection methods may help in improving knowledge in the field and in better understanding HBV-related tumorigenesis. Our aim was to conduct a high-throughput integration detection on tumor (T) and non-tumor tissues (NT) from HBsAg-positive patients using a highly sensitive method for assaying HBV integration.
Method: We studied T from 7 patients with HBV-related HCC and paired NT from 6 of the 7 cases. HBV integration sites were recovered by semi-nested ligation-mediated PCR from host DNA (fragmented by sonication and ligated to asymmetric DNA linkers) and the use of forward or reverse HBV-specific primers. Targeted sequences were further enriched by nested-PCR with forward or reverse MiSeq HBV primers and forward or reverse MiSeq plinkers. PCR products were subjected to paired-end sequencing, and reads were aligned to a hybrid genome including human genome (GRCh38.p10) and HBV genome (NC_003977).
Results: A total of 3, 339 unique HBV integration sites were detected in the 7 patients: 2, 913 integrations in T and 426 in NT. The average number of integration sites in T and NT was 416 and 71, respectively. All patients had HBV integrations, with an average of 256.8 integrations per individual patients. The detected integration sites were randomly distributed across the whole genome and no hotspot was detected. Compared to individual chromosomes, a significant enrichment of virus integration sites was observed in mitochondrial DNA (mtDNA) both in T (p <0.0001) and NT (p <0.0001), after normalization of the number of integrations to chromosome length. We found a total of 20 unique HBV integrations in mtDNA from the tissue samples obtained from 4/7 patients (17 breakpoints in T from 4/4 patients and 3 breakpoints in NT from 2/4 patients). HBV integration in mtDNA was associated with HBV DNA (p = 0.01) and pgRNA amounts (p = 0.02). In mtDNA, the integration breakpoints were preferentially located in mitochondrial genes in T (17/17 vs 0/3; P < 0.0001) and in the *D-loop* region in NT (2/17 vs 3/3; P = 0.001). *RNR2, ATP6, ND4*, and *ND5* mitochondrial genes were identified as recurrent sites of integration in T. Moreover, in T of individual patients, HBV integrations were detected in *CYTB, COX1, ND1*, and *ND2* genes. Furthermore, we found that HBV RNAs are imported into mitochondria.
Conclusion: The new HBV integration sequencing method importantly increased the detection efficiency of HBV integration breakpoints. We detected a significant enrichment of virus integrations in mtDMA from both T and NT. HBV integrations in mtDNA preferentially involved OXPHOS mitochondrial genes in T, suggesting that there is selection for mitochondria harboring HBV integration in these genes or for cells containing these mitochondria during hepatocarcinogenesis.

Enhanced T cell responses in patients and mouse model of hepatitis B and comorbid non-alcoholic fatty liver disease

Nishi Patel[1], Dan Boghici[2], Micol Rava[3], Matteo Iannacone[3], Konstantin Koro[4], Craig Jenne[2], Carla Osiowy[5], Carla Coffin[2]. *[1]University of Calgary, Cumming School of Medicine, Calgary, Canada; [2]University of Calgary, Cumming School of Medicine, Calgary, Canada; [3]San Raffaele Hospital, Division of Immunology, Transplantation and Infectious Diseases, Milano, Italy; [4]Alberta Precision Laboratories, Calgary, Canada; [5]Public Health Agency of Canada, National Microbiology Laboratory, Winnipeg, Canada*
Email: nishi.patel@ucalgary.ca

Background and aims: Individuals living with hepatitis B and comorbid non-alcoholic fatty liver disease (NAFLD) are at an increased risk for hepatocellular carcinoma. Large cohort studies show a positive association between hepatic steatosis and reduced hepatitis B virus (HBV) replication. The objective of this study is to determine the viral and immune factors and mechanisms that contribute towards lower HBV replication in patients and mouse model of hepatitis B and NAFLD.
Method: 55 patients with hepatitis B and NAFLD were recruited from 3 Canadian liver clinics. Plasma, sera, and peripheral blood mononuclear cells (PBMCs) were isolated from blood. A parallel mouse model study of HBV and NAFLD was performed using 1.3.32DH transgenic mice that included healthy, NAFLD, and HBV control groups (N = 10/group). The mice were followed for 8 weeks and then sacrificed to obtain plasma, sera, PBMCs, and liver tissue (for histopathological scoring and viral antigen staining). HBV biomarkers were quantified using in-house and/or standard clinic assays in both patient and mice samples. Next-generation sequencing of HBV surface and core genes was performed using the Illumina MiSeq platform. A panel of 13 pro-and-anti-inflammatory cytokines was measured using multiplex Luminex assay. PBMCs phenotypic profile and *ex vivo* HBV-specific T cell responses were characterized through flow cytometry and IFN-gamma ELISPOT, respectively.
Results: In 55 patients with hepatitis B and NAFLD (35% female, mean age of 45 ± 10.6 years), 52 (95%) were HBeAg negative. The mean HBV DNA, qHBsAg, and HBV pgRNA levels were 3.2 ± 1.8 $\log_{10}$ IU/ml, 2.9 ± 1.2 $\log_{10}$ pg/ml, and 2.1 ± 1.3 $\log_{10}$ copies/ml, respectively. Hepatitis B patients with NAFLD clinical factors (i.e., dyslipidemia, hypertension, and metabolic syndrome) had lower levels of qHBsAg (p <0.001). Similarly, mice with HBV and NAFLD had lower levels of HBV DNA (p = 0.022) and nucleic acid related antigen (p = 0.044) at 8 weeks. Greater frequency of immune escape mutations in HBV surface gene

(i.e., 1277L/T, M133L/I/T, and E164D/G) was detected in hepatitis B patients with severe steatosis ($p < 0.05$). Elevated levels of Th1 cytokines like IL-8 ($p = 0.002$), TNF-alpha ($p = 0.004$), IFN-gamma ($p = 0.021$), and IL-10 ($p = 0.007$) were observed in hepatitis B patients with NAFLD clinical factors (figure 1). Hepatitis B and NAFLD patients with mild steatosis had higher levels of IL-2 ($p = 0.031$). In mice with HBV and NAFLD, IL-2 levels declined with HBV DNA at 8 weeks ($p = 0.04$). Increased frequency of functional HBV-specific T cells was observed in hepatitis B and NAFLD patients compared to control groups ($p < 0.05$).

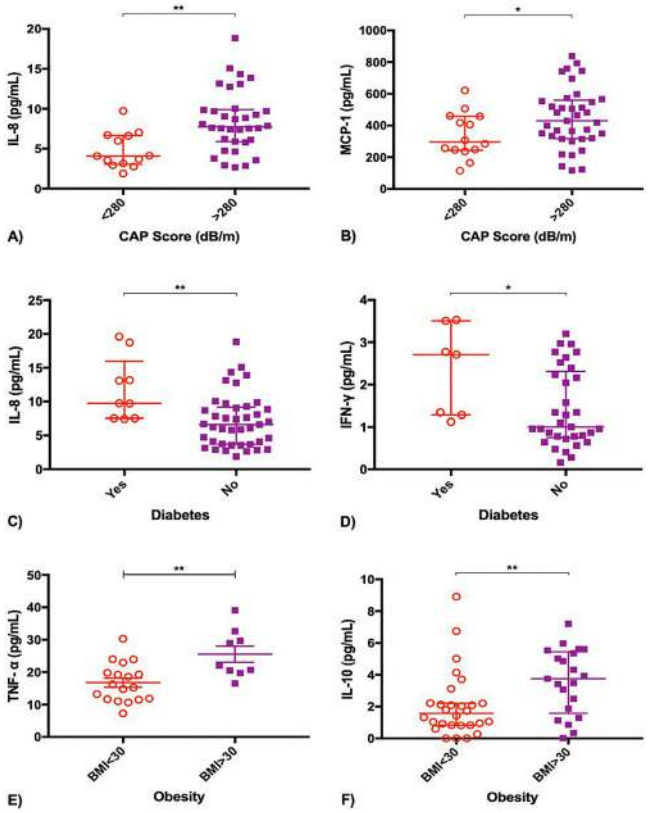

Figure 1: Cytokine levels based on NAFLD clinical factors in hepatitis B patients (Mann-Whitney U test). *p < 0.05. **p < 0.01.

Conclusion: Heightened T cell responses observed in patients and mouse model of hepatitis B and NAFLD contribute towards suppression of HBV replication.

THU335

Hepatitis B virus sero-prevalence and genotype distribution among pregnant women in Siem Reap, Cambodia

Bunthen E[1,2], Ko Ko[1], Shintaro Nagashima[1], Serge Ouoba[1,3], Kanon Abe[1], Aya Sugiyama[1], Kazuki Takahashi[1], Rattana Kim[4], Vichit Ork[5], Md. Shafiqul Hossain[6], Junko Tanaka[1]. Email: jun-tanaka@hiroshima-u.ac.jp

Background and aims: The latest report hepatitis B virus (HBV) infection prevalence in Cambodia was 4.4% among mothers and 0.56% among their 5–7 years old. High infection prevalence in women of childbearing age showed potential of vertical transmission, threatening WHO target of eliminating hepatitis virus infection by 2030.This study aimed to estimate HBsAg prevalence among pregnant women, and then to examine their genomic structure and the mutation pattern.
Method: Hospital based cross-sectional study was performed in a total of 1565 pregnant women who visited three hospitals in Siem Reap for their antenatal care from Feb-Sep 2020. The sero-markers such as HBsAg, HBsAb, HBcAb, HBeAg and HBeAb were detected from their blood samples using chemiluminescent enzyme linked. Viral titer was measured by real-time PCR. Full HBV genomes were amplified by direct sequencing. The study has been approved by ethical committees of Hiroshima University and Cambodia.
Results: The age of pregnant women participated in this study ranged from 15 to 47 years old with the mean age of 28.3 ± 5.6 years old. The prevalence of HBsAg, HBsAb, and HBcAb were 4.28%, 38.53%, 23.13%, respectively. Among the HBsAg positives, the prevalence of HBeAg and HBeAb were 41.79% and 55.22%, respectively. The overall mean viral titer was 2.22 × 106 copies/ml, where 5.30 × 106 copy/ml for HBeAg+ and 5.58 x103 copy/ml for HBeAb+. Thirty-seven samples were able to perform full-genome sequencing. HBV genotype C1 was predominant (70.27%), followed by B4 (16.22%) and B2 (13.51%). All HBV genotype B were found to be recombinant B/C. By full genome analysis on 37 HBV isolates, mutation at a determinant region of surface protein was 24.32%. Additionally, the combination mutation was found in 2.70% and double mutation in 29.73% and V149I mutation at core region in 2.70%, all of which were highly associated to hepatocellular carcinoma occurrence.

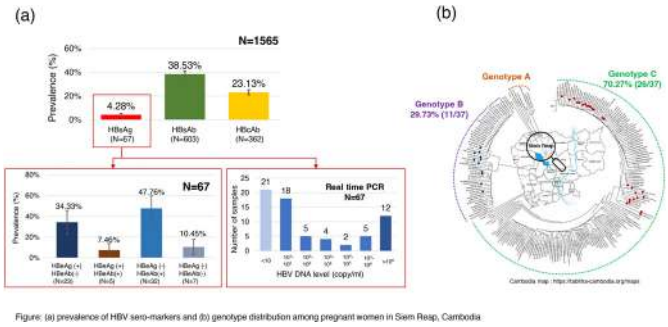

Figure: (a) prevalence of HBV sero-markers and (b) genotype distribution among pregnant women in Siem Reap, Cambodia

Conclusion: The findings from our study demonstrated the intermediate level of HBV infection endemicity, genotype distribution and mutation pattern among pregnant women in Siem Reap. These findings contribute to the establishment of HBV screening program and the management of HBsAg positive for pregnant women in Cambodia.

THU336

Genotype distribution and mutations associated with hepatocellular carcinoma risk among hepatitis B carriers in Goto Islands, Japan

Serge Ouoba[1,2], Ko Ko[1], Shintaro Nagashima[1], Bunthen E[1,3], Kazumi Yamasaki[4], Kazuki Takahashi[1], Junko Tanaka[1]. [1]*Hiroshima University, Department of Epidemiology, Infectious Disease Control and Prevention, Graduate School of Biomedical and Health Sciences, Hiroshima, Japan;* [2]*Institut de Recherche en Science de la Santé (IRSS), Unité de Recherche Clinique de Nanoro (URCN), Nanoro, Burkina Faso;* [3]*Ministry of Health, Payment Certification Agency (PCA), Phnom Penh, Cambodia;* [4]*National Hospital Organization Nagasaki Medical Center, Clinical Research Center, Nagasaki, Japan*
Email: jun-tanaka@hiroshima-u.ac.jp

Background and aims: Hepatitis B virus (HBV) genotype and specific mutations are associated with the risk of hepatocellular carcinoma (HCC). Using stored serum of a cohort of HBsAg-positive patients in

Goto Islands, we studied the genotype distribution and the mutations related to the progression of liver disease.

Method: A total of 910 samples from a cohort of Hepatitis B surface Antigen-positive patients between 1980 and 2017 underwent genomic analyses. Partial and full HBV genomes were amplified by direct sequencing using an in-house developed primer set to identify HBV genotype and mutations related to HCC risk. Phylogenetic tree was performed by the neighbor-joining method.

Results: Men represented 57.4% of the cohort and the mean age at the start of the cohort was 45.5 ± 17.3 years. The median follow-up duration was 14.6 years. At entry, 61% were asymptomatic carriers but a 172% increment of hepatocellular carcinoma was found at the end of follow-up. The mean viral load was 2.0 × 104 copies/ml, and the prevalence of HBeAg and HBeAb were 26.5% and 71.2%, respectively. The predominant circulating genotype was genotype C2 (96.2%), followed by genotype B (3.4%) and A (0.6%). Three main clusters of cases were found having 95.61%-99% homology and were closely related to HBV isolates from China and Japan. A total of 92 isolates underwent full genome analysis and mutations related to HCC occurrence were observed. Double mutation (A1762T/G1764A) was found in 73.5%, combination mutation (C1653 T and A1762T/G1764A or T1753C and A1762T/G1764A) in 29.4%, and V149I mutation in the core region in 26.9% of the isolates.

Conclusion: Genotype C, which is known to be associated with HCC risk, is the predominant circulating genotype in Goto islands, suggesting a large influence from East Asia. Mutations related to hepatocellular carcinoma occurrence were also found. In addition to the improvement of countermeasures against HBV infection in Goto Islands, genomic surveillance of HBV is essential to reduce the burden of the infection.

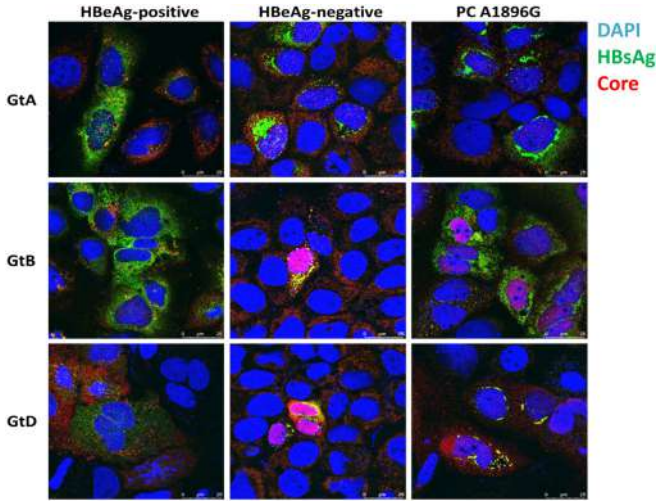
THU337

Comprehensive analysis of the different phases of chronic hepatitis B virus infection

Michael Basic[1,2], Qingyan Wu[2], Anja Schollmeier[2], Christoph Sarrazin[1,3], Stefan Zeuzem[1], Eberhard Hildt[2,4], Kai-Henrik Peiffer[1,2]. [1]*University Hospital Frankfurt, Frankfurt am Main, Germany;* [2]*Paul Ehrlich Institute, Langen (Hessen), Germany;* [3]*St. Joseph's Hospital in Wiesbaden, Wiesbaden, Germany;* [4]*German Center for Infection Research, Braunschweig*
Email: basic.michael@gmail.com

Background and aims: Chronic Hepatitis B virus (HBV) infection was classified into four active phases by the EASL: 1. HBeAg-positive chronic infection, 2. HBeAg-positive chronic hepatitis, 3. HBeAg-negative chronic infection and 4. HBeAg-negative chronic hepatitis. Recently, it was observed that released HBsAg amounts, ratios of L-, M- and S-proteins and morphology of subviral particles varied by viral genotype (Gt). Further, HBsAg composition was described to be distinct during the different phases of infection. Here, we characterized different phases of chronic HBV infection regarding HBsAg, core and particle assembly *in vivo* and *in vitro*.
Method: Sera of patients infected with GtA or GtD of different disease phases according to the EASL classification were analyzed by HBsAg-specific Western Blot (WB) and density gradient centrifugation. For *in vitro* studies, HBV genomes of GtA, GtB, and GtD of patients with HBeAg-negative chronic infection and presence of precore mutation G1896A were cloned into pUC-18 and expressed in Hepatoma cells. Corresponding HBeAg-positive wildtype genomes were used for comparison. Expression and localization of HBsAg and core protein, replication, particle morphology and infectivity as well as subcellular localization were analyzed.
Results: In the sera of patients, the ratio of HBsAg proteins differed among genotypes but not among the different disease phases. Density of HBsAg-particles varied among genotypes but not between the stage of infection. In vitro, the HBeAg-negative genomes showed a reduction in HBsAg expression in comparison to the corresponding HBeAg-positive genomes. By WB analyses, intracellular accumulation of LHBs and core protein was found. Further, perinuclear accumulation of LHBs and core protein was observed in HBeAg-negative genomes by immunofluorescence analyses (see fig.). Reintroduction of precore G1896A mutation did not restore HBsAg expression and did not affect intracellular distribution of HBsAg. Furthermore, immunofluorescence microscopy analyses and subcellular fractionation showed a strong intranuclear localization of assembled core protein.



Conclusion: In contrast to other studies, consistent ratios of HBsAg and similar particle densities were observed among the four different phases of active HBV infection. In comparison to HBeAg-positive genomes, HBeAg-negative genomes are characterized by an enhanced intranuclear localization of assembled core protein and a perinuclear accumulation of HBsAg *in vitro*. This is further reflected by an impaired release of HBsAg. Interestingly, neither HBeAg nor presence of precore G1896A mutation seem to be causative for the observed characteristics in HBsAg and core virology in genomes derived from patients with HBeAg-negative chronic infection. Further analyses of the underlying mechanisms might also affect novel antiviral strategies.

THU338

Human stem cell-derived hepatic and intestinal culture systems to study HEV transmission along the gut-liver axis

Viet Loan Dao Thi[1,2], Michael Dill[3,4], Sarah Prallet[1], Ann-Kathrin Mehnert[1], Sabrina Schweiggert[3]. [1]*Center for Integrative Infectious Disease Research (CIID) University Hospital Heidelberg, Department of Infectious Diseases, Virology, Heildeberg, Germany;* [2]*German Centre for Infection Research (DZIF), Heildeberg, Germany;* [3]*University Hospital Heidelberg, Division of Gastroenterology, Heildeberg, Germany;* [4]*German Cancer Research Center (DKFZ), Experimental Hepatology, Inflammation and Cancer (F240) Deutsches Krebsforschungszentrum, Heidelberg, Germany*
Email: vietloan.daothi@med.uni-heidelberg.de

Background and aims: The intestine and the liver are anatomically and functionally linked, often referred to as the gut-liver axis. They cooperate in nutrient uptake and metabolism, as well as provide immunity to pathogens, due to their organization as barrier tissues. Enterically transmitted hepatitis E virus (HEV), the most common cause of acute hepatitis in the world, is dependent on this axis: Once in the gastrointestinal tract, HEV passes the intestinal epithelium to gain access to the blood stream from where it reaches the liver and infects hepatocytes. Conventional cell culture systems fail to recapitulate the intricacy of this axis. Human induced pluripotent and adult tissue stem cell-derived organoid culture systems that reflect *in vivo*-like organ complexity, allow for better and authentic recapitulation of these human epithelial tissues, including polarization and cellular differentiation.
Method: The human induced pluripotent stem cell line iPSC.C3A was differentiated to hepatocyte-like cells (HLCs), which were embedded into Matrigel domes to initiate the formation of hepatic organoids. iPSC.C3A cells were also differentiated to small intestinal organoids using a commercially available kit. In addition, we differentiated human LGR5-positive bipotent cholangiocyte organoids to mature hepatic organoids.
Results: Following organoid formation of iPSC-derived HLCs and further differentiation of both, HLCs-derived and cholangiocyte organoids into mature hepatic organoids, we observed a strong increase in albumin expression, by qRT-PCR analysis and, partially, by IF staining. Both intestinal and hepatic organoid culture systems supported authentic HEV infection using the HEV GT3 Kernow-C1 p6 strain, as evidenced by an increase in HEV viral genomes and the upregulation of interferon-stimulated genes. Interestingly, even immature, bipotent cholangiocyte organoid progenitors were readily permissive for HEV infection.
Conclusion: We have established novel hepatic and intestinal culture systems supporting authentic HEV infection. We will use these systems to study tissue-specific determinants of HEV infection, including the analysis of an HEV-induced innate immune response. In the future, we will combine both systems to study HEV transmission along the gut-liver axis.
Keywords: Hepatitis E virus, induced pluripotent stem cells, hepatic organoids, intestinal organoids, cholangiocyte organoids, gut-liver axis.

Disclosure-Conflict of interest: On behalf of all authors, I hereby confirm that there are no conflicts of interest.

Background and aims: Acute viral hepatitis is most commonly caused by infection with the hepatitis E virus (HEV). It can lead to chronic infection in immunocompromised hosts, as well as severe hepatitis with the risk of liver failure in certain cases. Four main human pathogenic genotypes (gt 1–4) have been described. They differ in their worldwide distribution and route of infection. HEV infected cells secrete glycosylated isoforms of the viral capsid protein (open reading frame 2, pORF2) that are hypothesized to help the virus evade the humoral immune response of infected individuals. However, a gt1 protein-based vaccine has been developed in China and large cohort studies showed that the generated antibody titre correlated with protection from infection. Here, we aimed to generate human monoclonal antibodies neutralising HEV.

Method: Memory B cells of two acutely infected individuals were selected by recognizing the protruding domain (pdomain) of pORF2. Heavy and light chain of the B cell receptor were sequenced and single chain variable fragments (scFv) or monoclonal antibodies (mAb) were expressed in Expi293F cells. To analyse binding, Enzyme-linked Immunosorbent Assays (ELISA) and Biacore experiments were performed. Neutralisation assays were performed using three different HEV strains (gt3: Kernow C1 p6 G1634R and HEV-83–2–27; gt1: Sar55). Additionally, selected scFvs in complex with HEV gt3 pdomain were crystallised and structures were analysed.

Results: *In vitro* neutralization assays led to the identification of 16 hit candidates. ELISA confirmed the identification of at least four mAbs specifically recognizing the non-glycosylated, infectious form of pORF2. Further experiments confirmed neutralisation of genotype 1 and 3 viral strains by selected mAbs. Titration of identified mAbs determined the half-maximal inhibitory concentration of the best neutralizers at ≤0.01 μg/ml. ELISA using patient sera over the course of acute or chronic infection with HEV confirmed the specificity of a subgroup of identified mAbs to infectious viral particles. Additionally, the specific mAbs but not the non-specific mAbs were unaffected in their ability to neutralize HEV by glycosylated pORF2 isoforms. Structure analysis confirmed that specific mAbs directly bind the glycosylation site, which is highly conserved between different HEV genotypes.

Conclusion: Here, we identified a novel subgroup of human mAbs neutralising different genotypes of HEV. They specifically bind to infectious viral particles and neutralisation is not disrupted by the presence of secreted isoforms of pORF2. These antibodies may serve as a novel therapeutic option for severe and chronic HEV infection, for which effective and specific treatment is currently lacking in the clinic. Furthermore, we offer new insights for the development of cross-genotype effective vaccines against HEV in the future.

Increased lymphocyte trafficking and myeloid activation in patients with chronic hepatitis delta

Ester García-Pras[1], Thais Leonel[1], Sergio Rodriguez-Tajes[1], Mireia García-López[1], Sabela Lens[1], Zoe Mariño[1], Alba Díaz[2], Yilliam Fundora[3], Xavier Forns[1], Sofía Pérez-del-Pulgar[1]. *[1]Liver Unit, Hospital Clínic, University of Barcelona, IDIBAPS, CIBERehd, Barcelona, Spain; [2] (2)Pathology Department, Biomedical Diagnostic Center, Hospital Clínic, CIBEREHD, Barcelona, Spain; [3] (3) Hepatobiliopancreatic and Liver Transplant Department, Hospital Clínic, Barcelona, Spain*
Email: egpras@clinic.cat

Background and aims: Hepatitis Delta virus (HDV) is a satellite virus of hepatitis B virus (HBV), as it requires the HBV envelope proteins (HBsAg) to form viral particles. Compared to HBV monoinfection, chronic hepatitis delta (CHD) represents the most aggressive form of viral hepatitis leading to a faster progression towards cirrhosis, liver decompensation and hepatocellular carcinoma. Immune-mediated liver damage upon HDV infection is an important factor of HDV pathogenesis. The aim of the study was to analyze intrahepatic gene expression in CHD patients compared to HBV-infected patients and healthy controls.

Method: Formalin fixed paraffin embedded (FFPE) liver biopsies from 21 anti-HDV positive patients were included in the study. Patients were classified as HDV+ and HDV- based on whether or not they had detectable HDV-RNA in serum. Untreated HBV monoinfected patients and healthy donors were used as control groups. Gene expression analysis of immune-regulatory pathways was performed by using the nCounter® Host Response Panel of Nanostring. Differential expression between groups was considered if log2 fold-change>1 and $p < 0.05$, FDR adjusted by Benjamin-Yekutieli.

Results: The median age of the patients was 51 years; 62% were male, 62% had liver cirrhosis and 43% were on nucleos (t)ide analog (NA) treatment. Gene expression analysis revealed 223 genes significantly upregulated in HDV+ patients compared to healthy donors and 198 compared to HDV- patients. Chemokines were the molecules with the highest differential expression between groups, being CXCL9, CXCL10, CXCL11 (and its cognate receptor CXCR3) the most relevant. Consequently, genes involved in trafficking and activation pathways of myeloid cells (CCR2, CCR5, CCL18) and lymphocytes (CD2, ICOS, CD40L, CD20, CD79A) were significantly upregulated in HDV+ compared to healthy donors and HDV- patients. Consistent with increased immunopathogenesis associated with HDV infection, apoptotic (BCL-2, TNF), cytotoxic (GZMH, GZMA and PRF-1) and inflammasome (NLRP1, PYCARD y AIM2) pathways were enriched in CHD patients. Immune activation and liver damage pathways were also increased in untreated HBV patients, but signicantly less pronounced compared to HDV+ patients. Remarkably, some innate (IFIT1, IFIT2 and IFIT3) and adaptive (CD2, CCL5 and IL17RE) response molecules persisted upregulated after HDV clearance.

Conclusion: HDV infection induces innate and adaptive responses that contribute to aggravating the progression of liver disease. A strong recruitment and activation of myeloid cells and lymphocytes elicits inflammation and cell death processes in CHD. The resolution of HDV infection might not be able to completely reverse altered signaling pathways, due to molecule sequelae or the persistence of HBV.

Email: dlau@bidmc.harvard.edu

Background and aims: Circulating HBsAg can be derived from both intrahepatic cccDNA and integrated HBV DNA. Functional cure may be dependent on the origins of the HBsAg. We sought to correlate cccDNA and integrated DNA from liver tissues of HBeAg (+) and (-) CHB participants with serum virological parameters and intrahepatic HBcAg and HBsAg immunostaining patterns.

Method: Liver tissues from untreated CHB participants of the North American Hepatitis B Research Network (HBRN) were evaluated. For cccDNA analysis, DNA prep was heat denatured and digested by plasmid-safe ATP-dependent DNase (PSAD) to remove rcDNA and integrated DNA prior to qPCR quantification. Mitochondrial DNA COX3 gene qPCR was used for cccDNA normalization. For integrated DNA detection, 100 ng of total DNA was subjected to HBV-enriched next generation sequencing (NGS) assay. Enriched DNA library was sequenced by Illumina MiniSeq. The resulting HBV-host junction sequences were identified by ChimericSeq. Integrated DNA quantity was estimated based on percent of HBV-host junction reads per HBV reads and HBV sequence distribution. Serum HBV RNA was measured by Abbott research assay, HBcrAg by Fujirebio Europe, and qHBsAg by Roche Diagnostics' Elecsys platform.

Results: The cohort [24 HBeAg (+), 32 HBeAg (-)] was predominantly Asian (75%) with mean age of 44 years. The intrahepatic cccDNA, serum HBV DNA, RNA, HBcrAg and qHBsAg were higher among the HBeAg (+) participants (Table). HBeAg (-) vs. (+) participants had larger proportion of integrated HBV DNA in liver (Figure). There were significant Pearson's correlations between cccDNA and serum RNA [$r = .53$, $p < .001$] and HBcrAg [$r = .41$, $p = .002$]. The correlations between serum DNA and RNA were strong among both HBeAg (+) and (-) CHB (Table). Correlations between serum qHBsAg levels with serum DNA or RNA were moderate for HBeAg (+) but very weak for HBeAg (-) participants (Table). The majority [88%] of HBeAg (+) samples had positive intrahepatic HBcAg stain compared to 13% of HBeAg (-) samples. In contrast, 96% of HBeAg (+) and 88% of HBeAg (-) livers had positive HBsAg stain. Granular cytoplasmic HBsAg staining was noted in 57% and 64% of HBeAg (+) and (-) livers respectively. Membranous HBsAg stain pattern was noted in only 14% of HBeAg (-) compared to 78% of HBeAg (+) samples. There was a significant inverse relationship between HBV RNA and integrated HBV DNA that may explain the low level of membranous HBsAg stain in HBeAg (-) livers.

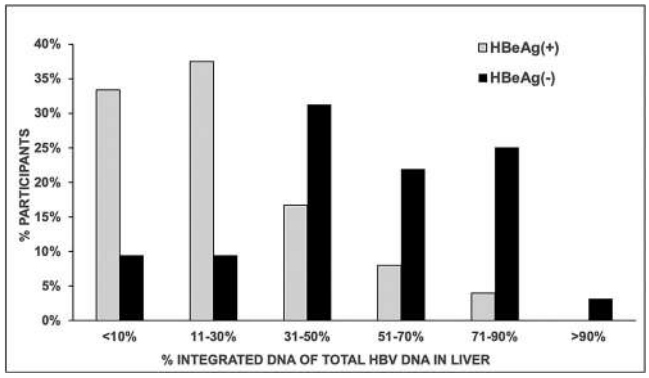

Figure:

Mean (range)	HBeAg(+) n=24	HBeAg(-) n=32	P value
Liver cccDNA (log_{10} copies/1 million cells)	4.97 (3.55 – 5.74)	3.86 (2.86 – 5.24)	0.00001
Serum HBV DNA (log_{10} IU/ml)	7.5 (3.2 - 9.2)	4.5 (2.6 - 7.7)	<0.00001
Serum HBV RNA (log_{10} U/ml)	6.59 (3.11 - 7.97)	2.88 (<1.69 - 6.53)	<0.00001
Serum HBcrAg (log_{10} U/ml)	8.4 (5.8 - 10.3)	3.6 (<3 -10.3)	<0.00001
Serum qHBsAg (log_{10} IU/ml)	4.25 (1.94 – 5.35)	2.96 (0.01 - 4.15)	<0.00001
Pearson's correlations between			
Serum RNA and serum DNA	$r = .93$ ***P= .00001***	$r = .87$ ***P= .000001***	
Serum RNA and serum qHBsAg	$r = .45$ ***P= .03***	$r = .27$ *P= .14*	
Serum DNA and serum qHBsAg	$r = .55$ ***P= .005***	$r = .33$ *P= .06*	

Table:

Conclusion: Serum RNA and HBcrAg reflect the intrahepatic cccDNA concentrations. Participants with HBeAg (-) CHB had high levels of integrated HBV DNA in the liver. The HBsAg derived from the integrated DNA likely contributed to the discordant serum DNA and RNA correlations to qHBsAg and the HBsAg immunostaining patterns in HBeAg (-) participants. These findings are important for the design and monitoring of therapies aiming for HBV functional cure.

Hepatitis B virus-replicating transgenic mice exhibit a functional but restricted responsiveness to exogenous Tlr3 and Rig-I stimuli

Stefan Schefczyk[1], Xufeng Luo[2], Yaojie Liang[1], Mike Hasenberg[3], Bernd Walkenfort[3], Martin Trippler[1], Mengji Lu[4], Heiner Wedemeyer[5], Hartmut Schmidt[1], Ruth Broering[1]. *[1]University Hospital Essen, Department of Gastroenterology, Hepatology and Transplant Medicine, Essen, Germany; [2]Affiliated Cancer Hospital of Zhengzhou University, Institute for Lymphoma Research, China; [3]University Hospital Essen, Institute for Experimental Immunology and Imaging, Essen, Germany; [4]University Hospital Essen, Institute for Virology, Essen, Germany; [5]Medizinische Hochschule Hannover, Klinik für Gastroenterologie, Hepatologie und Endokrinologie, Hannover, Germany*
Email: stefan.schefczyk@uni-due.de

Background and aims: Pathogenesis of Hepatitis B virus (HBV) infection is driven by innate and adaptive immune responses. Although HBV is suggested to be a stealth virus, recent findings indicate that HBV particles activate a Tlr2 response in murine and human hepatocytes. Furthermore, in HBV-transgenic mice lacking the surface antigen (HBsAg) a Tlr3-mediated response in non-parenchymal liver cells has been described. Aim of this study was to investigate how HBsAg influence hepatic innate immune responses in different HBV-transgenic mouse models.

Method: Liver tissue from C57/Bl6 and HBV-transgenic mouse strains (tg[Alb1HBV]44Bri [Alb/HBs], tg1.4HBV-s-mut and tg1.4HBV-s-rec [F1 generation Alb/HBs × tg1.4HBV-s-mut]) was analysed using transmission electron microscopy (TEM). HBV replication was characterized on RNA and protein level. All-in-one liver cell preparation enabled extraction of primary murine hepatocytes, liver sinusoidal endothelial cells and Kupffer cells and remaining non-parenchymal cells (rNPC). Responsiveness to poly (I:C) treatment (Tlr3) and transfection (Rig-I) was determined using quantitative RT-PCR and multiplex-based cytokine assay.
Results: TEM visualised viral particles (tg1.4HBV-s-rec), nuclear spot formations (tg1.4HBV-s-mut and tg1.4HBV-s-rec) and malformation of the endoplasmic reticulum (Alb/HBs). Viral replication did not differ comparing tg1.4HBV-s-rec and tg1.4HBV-s-mut, except HBsAg levels. A distinct cell type-dependent and mouse strain-dependent gene expression pattern for interferon (Ifnb, Ifiti1), cytokine (Tnf, Il1b, Il10) and chemokine (Ccl2, Ccl5) was observed by quantitative RT-PCR and validated using a multiplex-based cytokine assay. Emphasizing that tg1.4HBV-s-rec-derived liver cells responded to poly (I:C) with significantly suppressed expression levels, compared to the other mouse strains. Contrary, rNPC of tg1.4HBVs-rec mice showed the highest induction for Il10, Tnf, Il1b and Ccl5 in response to poly (I:C). In all HBV-transgenic mice, the induction of Ccl2 was significant lower in PMH but increased in rNPC.
Conclusion: Production of HBV particles and release of HBsAg in tg1.4HBV-s-rec mice led to suppressed hepatic Tlr3 and Rig-I signaling. However, rNPC seemed be more potent in producing poly (I:C)-induced inflammatory cytokines.

THU343

Profiling at single hepatocyte level indicates variance in viral replication associated with HBeAg status in chronic hepatitis B patients

Alfonso Blázquez-Moreno[1], Nadia Neto[1], Hinrich Göhlmann[1], Cheng-Yuan Peng[2,3,3], Jeroen Aerssens[1], Marianne Tuefferd[1]. Email: mtueffe1@its.jnj.com

Background and aims: Chronic infection with hepatitis B virus (CHB) is characterized by heterogeneity of viral replication across hepatocytes. Here we report on an approach that assesses multiple viral parameters at single hepatocyte level: status of hepatitis B virus (HBV) surface antigen (HBsAg) and core antigen (HBcAg), presence of covalently closed circular DNA (cccDNA) and quantification of HBV RNA. We applied this method to liver biopsy samples collected from 7 treatment-naïve male patients covering for HBV e-antigen (HBeAg) positive (n = 4) and negative (n = 3) CHB phases.
Method: Cryosections from the liver core biopsies were fluorescently stained for 4′, 6-diamidino-2-phenylindole (DAPI), cytokeratin 18 (CK18), HBsAg and adjacent HBcAg. For each patient, up to 96 (range 60–96, average 85) individual hepatocytes (DAPI and CK18 positive) were randomly collected using a RareCyte Finder II, separately deposited into tubes and subjected to simultaneous DNA and RNA extraction using DNA/RNA Zymo columns. HBV RNA and cccDNA, together with mitochondrial RNA and DNA as positive controls, were measured using the Bio-Rad digital droplet polymerase chain reaction system.
Results: HBeAg (+) vs HBeAg (-) patients showed contrasted expression of viral markers, with higher percentages of individual hepatocytes positive for HBsAg (median: 88% vs 16%), HBcAg (median: 82% vs <1%), HBV RNA (94% vs 21%) and cccDNA (37% vs 17%). The percentage of infected hepatocytes (positive hepatocytes for either cccDNA, RNA or HBsAg) was higher in HBeAg (+) vs HBeAg (-) patients (median: 99% vs 53%). Quantitative assessment of HBV RNA demonstrated that expression levels within individual hepatocytes was higher in HBeAg (+) vs HBeAg (-) patients (median: 84 vs 0 HBV RNA counts/cell). Within HBeAg (+) subjects, cccDNA-positive hepatocytes showed higher transcriptomic activity (median: 87 vs 72 RNA counts/cell) than cccDNA-negative hepatocytes, compared to HBeAg (-) subjects (median: 0 vs 0 RNA counts/cell). Interestingly, CHB patients with lower (<300 IU/ml) peripheral HBsAg levels had also the lowest proportion of HBsAg (+) hepatocytes (<32%), whereas patients with peripheral HBsAg levels >1000 IU/ml showed large variation in percentage of HBsAg (+) (range 31–100%). Peripheral levels of HBV DNA or alanine aminotransferase were not associated with any of the hepatocyte-derived readouts.

	HBeAg (+) patients (n = 4)		HBeAg (-) patients (n = 3)	
% of hepatocytes that are:	Range	Median	Range	Median
HBcAg positive	55 - 100	82	< 1	< 1
HBsAg positive	31 - 100	88	0 - 32	16
HBV RNA positive	88 - 99	94	19 - 25	21
cccDNA positive	13 - 76	37	14 - 27	17
HBV RNA counts	0 - 9620	84	0 - 876	0

Conclusion: We demonstrated that CHB patients at different stages of disease show diverse profiles of viral markers measured at single hepatocyte level.

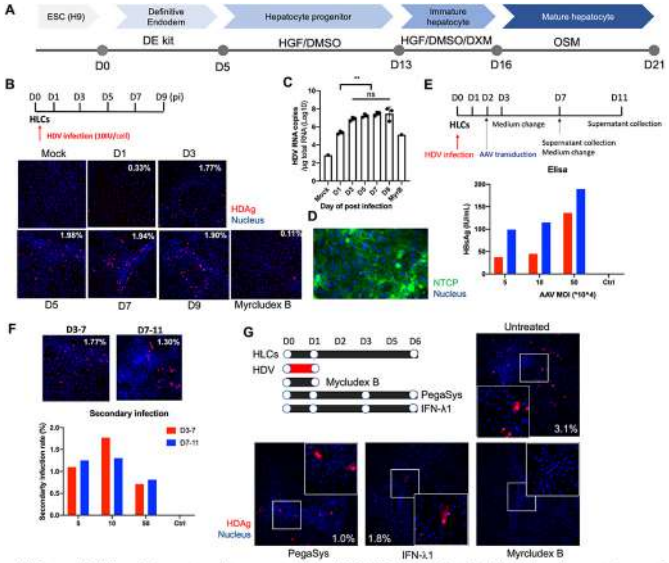
Human stem cell-derived hepatocytes as a model for hepatitis D virus infection

Huanting Chi[1,2], Bingqian Qu[1], Angga Prawira[1], Lars Maurrer[1], Rebecca Fu[1], Florian Lempp[1], Charlotte Decker[1], Zhenfeng Zhang[1], Dirk Grimm[1,2,3], Viet Loan Dao Thi[1,2], Stephan Urban[1,2]. [1]*University Hospital Heidelberg, Department of Infectious Diseases;* [2]*German Centre for Infection Research (DZIF),* [3]*German Center for Cardiovascular Research (DZHK), Partner Site Heidelberg*
Email: chihuanting@gmail.com

Background and aims: An estimated 12~15 million people worldwide are suffering from chronic hepatitis D virus (HDV) infection without a curative therapeutic regimen so far. Primary human hepatocytes represent the most physiological model for HDV research, but their application is restricted. Hepatoma cells can also support the entire HDV life cycle via gene editing techniques, but they only partially resemble hepatocytes due to their aberrant nature. Recently, human pluripotent stem-cell derived hepatocyte-like cells (HLCs) have been proposed as an attractive cell culture system for hepatitis B, C, and E viruses. Here, we show that HLCs support the entire HDV life cycle and propose this model as a new platform for the study of HDV biology and the evaluation of antiviral treatments.
Method: We optimized a stem cell-based differentiation protocol which yields HDV-permissive HLCs (Fig A). Mature HLCs were inoculated with HDV in the presence of 4% Polyethylene Glycol 8000 (PEG8000) and 1.5% dimethyl sulfoxide (DMSO), with samples being harvested for immunofluorescence and quantitative RT-PCR analysis. Adeno-associated viruses (AAVs) encoding hepatitis B virus S antigen (HBsAg) were transduced to HDV infected HLCs for viral assembly and secretion. The supernatant was taken to subsequently infect Huh7 cells to determine infectivity of secreted HDV particles.



(A) Stem cell differentiation protocol to generate HLCs. (B&C) HLCs were infected with HDV and harvested every 2 days for IF and qRT-PCR. (D) NTCP was stained with Atto565-NHS-ester-coupled Myrcludex B. (E&F) AAV encoding HBsAg were transduced to HDV infected HLCs. The supernatant was collected for Elisa and secondary infection. (G) HDV infected HLCs were treated with antivirals respectively.

Results: HDV infection of HLCs was assessed by measuring HDV RNA by quantitative RT-PCR and immunofluorescence staining of delta antigen (HDAg) (Fig B and C). HDV infection could be completely blocked by Myrcludex B, suggesting NTCP-dependent entry in HLCs. In agreement, staining with Atto565-NHS-ester-coupled Myrcludex B showed that HLCs express NTCP on their plasma membrane (Fig D), albeit at lower levels than NTCP overexpressing hepatoma cells. Upon Adeno-associated virus transduction with the HBsAg, HDV-infected HLCs assembled and released infectious HDV progeny particles, showing that HLCs can recapitulate the entire HDV life cycle (Fig E and F). We further found that HLCs could be infected with HDV genotypes 1 from Ethopia, 2 and 4 from Japan, and 3 from Peru. Finally, HDV infection of HLCs could be inhibited by IFN-α and IFN-λ treatment (Fig G). Further testing of other antivirals is currently being performed.
Conclusion: HLCs provide an attractive, genetically tractable, and physiologically relevant platform for studying pan-genotype HDV life cycle and evaluating antiviral treatments.

Hepatitis B viral load variation between the first and third trimesters of pregnancy

Stuart Gallacher[1], Alan Yeung[2,3], Megan Glancy[2,3], Ewan Forrest[4], Stephen Barclay[4]. [1]*NHS Greater Glasgow and Clyde, Department of Infectious Diseases, Brownlee Centre, Glasgow, United Kingdom;* [2]*Glasgow Caledonian University, School of Health and Life Sciences, Glasgow, United Kingdom;* [3]*Public Health Scotland, Glasgow, United Kingdom;* [4]*NHS Greater Glasgow and Clyde, Department of Gastroenterology, Glasgow Royal Infirmary, Glasgow, United Kingdom*
Email: stuart.gallacher3@nhs.scot

Background and aims: Hepatitis B virus (HBV) infection may be transmitted vertically, with maternal HBV viral load (VL) >5.3 $\log_{10}$ IU/ml an indication for prophylactic antiviral therapy in the third trimester. However, no consensus exists on the optimal time to check HBV VL in pregnancy. We sought to identify if VL varied between early pregnancy and week 26, when VL is currently checked according to our local protocol.
Method: HBV screening samples taken at antenatal booking appointments in our health board Jan '10 to Jun '19 were identified from a virology database. Locally, first detection of HBV surface antigen in a patient triggers reflex VL testing (hereafter booking viral load (BVL)). Patients with a BVL and repeat VL 12–20 weeks after booking (hereafter follow-up VL (FVL)), were identified for inclusion. Case note review was performed, and patients were excluded for: inappropriate testing chronology, acute HBV, antiviral therapy started prior to BVL/FVL, or incomplete clinical records. Changes between BVL and FVL were analysed using paired Wilcoxon tests.
Results: 306 pregnancies with both BVL and FVL (median of 14.6 weeks later) were identified. After application of exclusion criteria, 241 pregnancies were included for analysis. Median BVL was 2.61 (1.60–3.59) $\log_{10}$ IU/ml, and median FVL 2.47 (1.78–3.30) $\log_{10}$ IU/ml, with a median reduction from BVL to FVL of – 0.19 $\log_{10}$ IU/ml, 95% CI – 0.33, – 0.09 ($p < 0.001$). Changes according to BVL and e-Antigen (HBeAg) status are shown below. Of 36 patients with a BVL >5.3 $\log_{10}$ IU/ml, 10 (27.8%) had a FVL <5.3 $\log_{10}$ IU/ml.

	Number of Pregnancy-Episodes*	Median (IQR) $\log_{10}$ Viral Load at Baseline	Median (IQR) $\log_{10}$ Viral Load at Follow-Up	Median (95% CI**) Change in $\log_{10}$ Viral Load	p value for Change in Viral Load***
Total	241	2.61 (1.60, 3.59)	2.47 (1.78, 3.30)	−0.19 (−0.33, −0.09)	<0.001
Baseline Viral Load					
<5.3 $\log_{10}$ IU/ml	205	2.48 (1.78, 3.03)	2.22 (1.71, 2.92)	−0.12 (−0.26, −0.01)	<0.001
>5.3 $\log_{10}$ IU/ml	36	7.78 (7.22, 8.46)	7.23 (5.10, 7.95)	−0.57 (−1.70, −0.33)	<0.001
HBeAg Status					
Negative	202	2.53 (1.84, 3.05)	2.27 (1.74, 2.95)	−0.14 (−0.30, −0.03)	<0.001
Positive	39	7.69 (6.50, 8.39)	6.70 (4.08, 7.92)	−0.39 (−0.94, −0.13)	<0.001

*34 patients had two pregnancy-episodes and 1 patient had three pregnancy-episodes.
**95% bootstrap confidence interval generated using 10, 000 random resamplings of the change in viral load data.
***Paired Wilcoxon test with alternative hypothesis as change in median not equal to zero.

Conclusion: Median HBV VL falls during pregnancy regardless of baseline factors. No patients with a BVL <5.3 $\log_{10}$ IU/ml required treatment based on FVL. Falls from above to below treatment threshold were noted in some patients. A BVL rules out the need for treatment in the majority of pregnancies with a BVL <5.3 $\log_{10}$ IU/ml. Repeat sampling at 26–28 weeks gestation for those with a BVL >5.3 $\log_{10}$ IU/ml may prevent unnecessary treatment.

Email: lewynl@assemblybio.com

Background and aims: Vebicorvir (VBR) is a first-generation core inhibitor being developed for the treatment of chronic hepatitis B virus infection (cHBV). In Study 202 (NCT03577171), treatment-naïve HBeAg positive cHBV patients were randomized to VBR+entecavir (ETV) or placebo+ETV for 24 weeks. Eligible patients then received open label VBR+ETV in Study 211 (NCT03780543) for ≥52 weeks. In Study 211, 19 patients discontinued (DCed) VBR and remained on ETV at end of study. Following VBR DC, a mean HBV DNA increase of 1.0 $\log_{10}$ IU/ml was observed, with 11/19 patients having a maximal increase of >1 $\log_{10}$ IU/ml. Here we further characterize the patients who DCed VBR and remained on ETV and describe the results of next

generation sequencing (NGS) analyses to characterize viral quasispecies during treatment.
Method: Viral nucleic acids were purified from Study 202 baseline (BL), Week (Wk) 4, and rebound (if possible) patient plasma and whole genome NGS (Illumina MiSeq) was conducted. 18/19 patients had NGS data available: 11 with ≥1 log_{10} IU/ml HBV DNA maximal increase and 7 with <1 log_{10} IU/ml HBV DNA maximal increase after VBR DC. To determine sequence diversity, Shannon entropy was calculated from demultiplexed FASTQ read files using an in-house pipeline with genotype-specific reference sequences. The pipeline includes data quality control, read trimming and alignment, variant calling, and annotation in a workflow orchestrated by Nextflow.
Results: Patients with <1 log_{10} IU/ml HBV DNA increase had significantly lower HBeAg and HBcrAg ($p < 0.05$) and trended lower for HBV DNA and pregenomic RNA with most having ALT >ULN at BL compared to patients with ≥1 log_{10} IU/ml HBV DNA increase. At BL, similar diversity levels were observed across the viral genome in both groups. At Wk 4, diversity remained stable for patients with <1 log_{10} IU/ml HBV DNA increases, while diversity declined at Wk 4 for patients with ≥1 log_{10} IU/ml HBV DNA increases ($p < 0.01$) (Figure). For patients with a ≥1 log_{10} IU/ml HBV DNA increase, diversity returned towards BL levels at rebound following VBR DC.

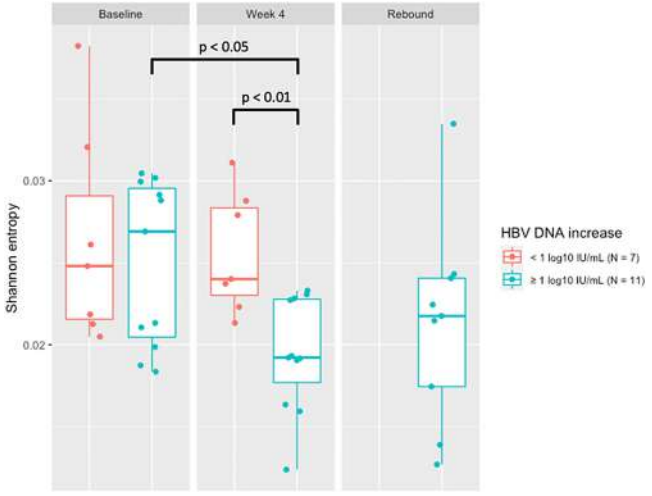

Figure: The dynamic changes of HBV nucleotide sequence diversity along with HBV DNA increase after VBR discontinuation.

Conclusion: Greater sequence diversity was observed during initial HBV DNA decline during HBV treatment among patients with lower rebound when VBR was DCed and ETV continued. The early differences in sequence diversity may reflect differences in HBV specific immune responses (also reflected in ALT levels) and viral load set points between these 2 groups, although the mechanism needs to be further defined.

THU347

Results from a nationwide hepatitis C serosurvey and progress towards HCV elimination in the country of Georgia

Amiran Gamkrelidze[1], Shaun Shadaker[2], Maia Tsereteli[1], Maia Alkhazashvili[1], Nazibrola Chitadze[1], Irina Tskhomelidze[3], Lia Gvinjilia[4], Nino Khetsuriani[5], Francisco Averhoff[6], Gavin Cloherty[6], Giorgi Chakhunashvili[1], Jan Drobeniuc[2], Paata Imnadze[1], Khatuna Zakhashvili[1], Paige A Armstrong[2]. *[1]National Center for Disease Control and Public Health, Tbilisi, Georgia; [2]Centers for Disease Control and Prevention, Division of Viral Hepatitis, Atlanta, United States; [3]The Task Force for Global Health, Tbilisi, Georgia; [4]Eastern Europe and Central Asia (EECA) Regional Office, Centers for Disease Control and Prevention (CDC); [5]Global Immunization Division, CDC, Atlanta, United States; [6]Abbott Diagnostics, Abbott Park, United States*
Email: gamkrelidzea@gmail.com

Background and aims: The country of Georgia launched its national Hepatitis C Virus (HCV) Elimination Program in 2015, and a serosurvey the same year showed prevalence of HCV antibody (anti-HCV) and HCV RNA among adults aged ≥18 years was 7.7%, and 5.4%, respectively. Since then, over 76, 000 people with chronic HCV have been treated, with a cure rate of 98.9%. To monitor progress, a second serosurvey was conducted in 2021 to estimate the prevalence of hepatitis C, hepatitis B, and anti-SARS-CoV-2. This analysis reports hepatitis C results of the serosurvey and progress towards elimination.
Method: The serosurvey used a stratified, multi-stage cluster design with systematic sampling. Adults and children ≥5 years consenting (or assenting with parental consent) to the interview and blood draw were eligible to participate. All blood samples were tested for anti-HCV and if positive, HCV RNA. Nationally representative weighted proportions and 95% confidence intervals (CI) were calculated and compared with 2015 age-adjusted estimates for adults.
Results: A total of 7, 237 adults and 1, 473 children participated in the survey. For adults, the median age was 46 years (interquartile range: 32–60), and 53.3% (95% CI: 51.3–55.2) were female. The prevalence of anti-HCV was 6.8% (95% CI: 5.9–7.7), which was not significantly different from 2015 (7.7% [95% CI: 6.6–8.8]; $p = 0.20$). The HCV RNA prevalence was 1.8% (95% CI: 1.3–2.4), compared to 5.4% [95% CI: 4.5–6.3] in 2015 ($p < 0.001$). This represents a 67% reduction in persons with chronic HCV infection, despite the program having treated 51% of the estimated 150, 000 infected. HCV RNA prevalence decreased among all age groups, most notably among those aged 40–59 years (9.3% in 2015 to 2.2% in 2021; $p < 0.001$). Substantial decreases were also observed among both males (9.0% to 3.1%; $p < 0.001$) and females (2.2% to 0.6%; $p < 0.001$). HCV RNA prevalence also decreased from 51.1% to 17.8% among persons who ever injected drugs, and 13.1% to 3.8% among those who received a blood transfusion (both $p < 0.001$). No children tested positive for anti-HCV or HCV RNA.
Conclusion: These results demonstrate the substantial progress made since Georgia launched its HCV Elimination Program in 2015. The 67% reduction in chronic HCV infections during 2015–2021 also supports treatment as a means for prevention, as the reduction is larger than would be expected based on those treated alone. These findings can inform strategies to meet HCV elimination targets.

THU348

Clinical impact of drug interaction in the use of antipsychotics by HCV patients treated with pangenotypic direct-acting antivirals

Juan Turnes[1], Antonio Garcia Herola[2], Ramón Morillo Verdugo[3], Marinela Mendez Pertuz[4], Cristina De Alvaro[5], Candido Hernández[5], Antoni Sicras-Mainar[6]. *[1]CHU, Pontevedra, Gastroenterology and Hepatology Department, Spain; [2]Hospital Marina Baixa de Villajoyosa, Villajoyosa, Alicante, Spain; [3]Hospital de Valme, AGS Sur de Sevilla, Sevilla, Spain; [4]Gilead Sciences S.L., Madrid, Spain, Medical Affairs, Madrid, Spain; [5]Gilead Sciences S.L., Madrid, Spain, Medical Affairs, Madrid, Spain; [6]Atrys Health, Health Economics and Outcomes Research, Barcelona, Spain*
Email: ansicras@atryshealth.com

Background and aims: Previous analysis showed that central nervous system drugs were the most prescribed in patients with hepatitis C. This sub-analysis describes the use, drug-drug interactions (DDIs), and clinical impact of antipsychotic use in real-world patients treated with Pangenotypic Direct Action Antivirals (DAAp).
Method: Retrospective observational study, using the BIG-PAC database (Atrys Health), in HCV patients treated from 2017 to 2020 with DAAs. Potential DDIs between concomitant medication and the DAAs, Sofosbuvir/Velpatasvir [SOF/VEL] and Glecaprevir/Pibrentasvir [GLE/PIB], were evaluated using the University of Liverpool Hepatitis Interactions database. The risk of DDIs, the report of related adverse effects (AEs), and the clinical actions linked to the management of DDIs with antipsychotics (dose reduction; change of antipsychotic or DAAp; electrocardiogram-ECG and discontinuation) were analyzed.
Results: 187 patients prescribed antipsychotics were included, 150 treated with SOF/VEL [median age: 53 years; men: 59%; F3/4: 44%] and 37 with GLE/PIB [median age 48 years; men: 60%; F3/4: 46%]. The mean pill number was 5.0 and 5.9 tablets/patient, respectively. Accounting for all comedication, GLE/PIB was associated with a higher risk of single and multiple DDIs (≥2 comedications with DDIs with pDAAs) compared to SOF/VEL, [73% vs 43% of patients ($p < 0.001$)] and [24% vs 15% ($p = 0.002$)], respectively.
Regarding antipsychotics, there was a higher number of active ingredients with potential DDIs for GLE/PIB vs SOF/VEL (6 vs 2, respectively), linked to a higher percentage of patients at risk of DDIs (51% vs 23%, $p < 0.001$, respectively). Two AE were reported with GLE/PIB for quetiapine and paliperidone, and none with SOF/VEL. The AE reported with quetiapine and GLE/PIB (extrapyramidal symptoms) occurred at a dose of <300 mg/day.
Quetiapine was the most prescribed antipsychotic (SOF/VEL, 42 and GLE/PIB, 7). Regarding clinical actions reported for patients prescribed quetiapine, a higher percentage of actions were reported for GLE/PIB (86%; 6/7 patients) vs SOF/VEL group (5%; 2/42 patients), $p < 0.001$. These clinical actions were ECG monitoring (1 vs 0), dose reduction (2 vs 1), change of DAA/antipsychotic (2 vs 1), and comedication discontinuation (1 vs 0) for GLE/PIB vs SOF/VEL, respectively.
Conclusion: This analysis confirms that the greater use of SOF/VEL in patients with antipsychotic treatment may be due to its favorable DDI profile, which implies a lower number of adverse effects and required clinical actions.

THU349

Occult hepatitis C infection detection in people who use drugs with or without direct antiviral agents therapy

Eliane Silva[1,2], Sara Marques[1], Sofia Salta[3], José Pedro Sequeira[3], Joao Madaleno[4], Adelia Simao[4], Armando Carvalho[4]. *[1]Research Center in Biodiversity and Genetic Resources (CIBIO/InBIO), University of Porto, Vairão, Portugal; [2]Institute of Biomedical Sciences Abel Salazar (ICBAS) of the University of Porto, Porto, Portugal; [3]Portuguese Oncology Institute of Porto (IPO Porto), Porto, Portugal; [4]Coimbra Hospital and Universitary Center (CHUC), Coimbra, Portugal*
Email: up412743@up.pt

Background and aims: Occult hepatitis C infection (OCI) can occur in anti-HCV (hepatitis C virus) and HCV-RNA peripheral blood mononuclear cells (PBMCs) positive subjects with normal or abnormal values of liver enzymes (LE) without serum HCV-RNA. The goal of HCV therapy is to cure the infection, i.e. achieve a sustained virological response (SVR) after therapy with direct acting antiviral agents (DAAs). Here, we evaluate OCI in people who are injection drug users (IDUs) with or without DAAs therapy.
Method: This study includes 4 patients study groups: AVP-14 patients (SVR 12 with DAAs therapy); SEP-2 patients (spontaneously elimination of HCV after acute infection); CNP-4 patients; CPP-10 patients (HCV positive patients), all anti-HCV positive (Table). HCV-RNA detection from serum at baseline was performed by Real-Time PCR (RT-PCR). After, was performed from serum, plasma, PBMCs and red blood cells (RBCs) by droplet digital PCR (ddPCR).

Table: Characteristics of IDUs patients (%), except sex and age.

**Reference values: ALP (alkaline phosphatase) 30–120 U/L
***Reference values Fibrosis/Fibroscan: F0/F1: <7 kPa; F2: 7–9, 5 kPa; F3: 9, 6–12, 5; F3/F4: 12, 5–14, 5 kPa; F4: >14, 5 kPa
N.D.- Not determined.

Results: At baseline HCV-RNA was detected in the CPP and AVP (both 100%) groups and was negative for AVP-SVR8 or 12 by RT-PCR. Although, OCI was shown in 50% of the CNP and SEP groups, 10% in the CPP group and 29% in the AVP group by ddPCR (Table). Two

patients-CNP, with normal values of LE; 1-SEP, with abnormal values of LE; 1 patient-CPP with normal values of LE, HCV-1a, DAAs therapy; 4-AVP (1 with abnormal values of LE, HCV-1a, DAAs therapy; 1 with abnormal values of LE and advanced fibrosis, HCV-3a, DAAs therapy; and 2-HCV-4a/4c/4d, one with normal values of LE, DAAs therapy, and the other with abnormal values of LE and cirrhosis, DAAs therapy). Positive results were shown in serum (71%), plasma (13%), PBMCs (79%) and RBCs (83%) analyzed samples in the CPP and AVP groups by ddPCR.
Conclusion: A total of 80% HCV-cure with DAAs was shown in the CPP and AVP groups, but 10% and 29% of OCI was shown in these groups, respectively, by ddPCR. HCV/OCI positive results were shown in patients with HCV 1a, 1b, 3a, or 4a/4c/4d genotypes, with normal or abnormal values of LE, and/or advanced fibrosis, and/or cirrhosis. Droplet ddPCR was more sensitive than RT-PCR for OCI detection. OCI and HCV positive patients should be newly evaluated for a reinfection or relapse possibility and avoid HCV transmission.

Email: mbuti@vhebron.net

Background and aims: Several new treatments for chronic hepatitis B are focused in achieving a decline in HBsAg levels. Some of these new molecules are evaluated in patients with chronic hepatitis D (CHD). The aim of this study is to evaluate whether ALT, HBsAg and HDV-RNA levels correlate in untreated patients with CHD.
Method: In this study, hepatitis delta virus (HDV)-RNA, hepatitis B surface antigen (HBsAg) and hepatitis B virus (HBV)-DNA were prospectively quantified in 407 patients with compensated liver disease who enrolled in the on-going Phase 3 HDV D-LIVR trial (NCT03719313). At baseline, demographic data, clinical and biochemical characteristics were collected. HBV and HDV serological and virological markers were measured. Descriptive statistics were used to summarize demographic and clinical baseline characteristics. Pearson correlation coefficients were computed for ALT, HBsAg and HDV-RNA in the full population of 407 subjects, the population of 146 subjects over 45, and the population of 261 subjects younger than 45 years old. Significance levels are provided for the test of the null hypotheses when the correlation is 0.
Results: 407 patients were included, mainly male (69%), with a mean age of 45 years old, Caucasians (73%) and with liver cirrhosis (26.5%). At baseline in the entire cohort, mean HDV-RNA levels were 4.98 ± 1.17 logIU/ml, HBsAg levels 10079 IU/ml and mean ALT 100.05 ± 67.7 IU/ml. HDV-RNA and HBsAg levels showed positive correlation (0.154) with strong statistical significance (0.0018) (Table 1). In patients older than 45, HDV-RNA and HBsAg levels did not show a statistically significant correlation. However, in patients younger than 45, HDV-RNA and HBsAg levels showed positive correlation (0.162) with strong statistical significance (0.0089). HBsAg levels and ALT showed a negative correlation, meaning that ALT levels tend to decline when HBsAg levels are high. This correlation showed statistical significance across all groups.

Table 1. Correlation of ALT, HBsAg, and HDV RNA in the full population, subjects over 45, and subjects 45 years and younger in the D-LIVR study

	Correlation coefficient	Significance level
All subjects N = 407		
HDV RNA – ALT	0.097	0.0499
HBsAg - ALT	-0.248	<0.0001
HDV RNA – HbsAg	0 .154	0.0018
Subjects ≥ 45 years N = 146		
HDV RNA – ALT	0.095	0.2552
HBsAg - ALT	-0.248	0.0026
HDV RNA – HbsAg	0.100	0.2288
Subjects < 45 years N = 261		
HDV RNA – ALT	0.106	0.0862
HBsAg - ALT	-0.242	<0.0001
HDV RNA – HbsAg	0.162	0.0089

Conclusion: In untreated chronic hepatitis D, HDV-RNA and HBsAg levels show positive correlation mostly in younger people. Normal ALT levels are associated with significantly increased HBsAg levels. Monitoring of HDV-RNA and HBsAg serum levels in patients with chronic hepatitis D provides insight in the design of new therapeutic strategies.

Viral hepatitis A/E: Clinical aspects

THU351

Detection of highly variable RNA-containing viral particles on CNT-based electrochemical impedimetric DNA-nanosensors

Andrei Babenka[1], Victor Hryharovich[1], Halina Grushevskaya[2], Igor Lipnevich[2], Nina Krylova[2], Elena Lebedeva[3], Uladzimir Davydau[1], Svetlana Marchuk[1], Dmitry Borisovets[4], Sergei Zhavoronok[1].
[1]Belarusian State Medical University, Minsk, Belarus; [2]Belarusian State University, Minsk, Belarus; [3]Vitebsk State Medical University, Viciebsk, Belarus; [4]Institute of Experimental Veterinary Medicine named after S.N. Vyshelessky, Minsk, Belarus
Email: labmdbt@gmail.com

Background and aims: Due to the high variability of RNA-containing viruses genome, neither PCR nor ELISA methods give a 100% guarantee. For example, in the case of infection with the hepatitis E virus (HEV), the likelihood of a false negative diagnosis is considered very high. One of the possible ways to overcome this problem in general and for the diagnosis of HEV in particular, may be the use of alternative, non-PCR technologies. CNT-based electrochemical impedimetric DNA-nanosensors make it possible to recognize HEV RNA/cDNA using short probes (less than 20 bp), which sharply increases the likelihood of capturing variable genomes. This ensures high specificity of recognition. We offer a novel highly-performed and selective impedimetric DNA sensor with redox-active nanoporous transducer based on bundles of carbon nanotubes (CNTs) for diagnosing of HEV RNA in clinical samples.
Method: A target double-stranded (ds) cDNA was synthesized by reverse transcription of the total RNA isolated by standard commercial spin-column based kits from the whole blood, serum, feces and urine of patients with confirmed acute HEV diagnosis. A non faradaic impedimetric DNA-sensor is fabricated by depositing the two monomolecular layer of carboxylated multiwalled CNTs with probe single-stranded (ss) DNA molecules. A short (24 bp) DNA oligonucleotide was used as a probe, which was complementary to the most conserved region of the HEV genome and, according to preliminary estimates, is able to recognize about 99% of all sequences

of the HEV genome presented in the GeneBank database (more than 500) and sequenced in Belarus (more than 100). DNA-nanosensors are interdigital electrode structures with the sensitive coating. The electron-dense layers of the probe oligonucleotide and CNTs were fabricated by Langmuir-Blodgett technique. The impedance DNA-nanosensors are utilized as measured capacitance C entering a resistor (R) -capacitor (C) -oscillator. Impedance measurements are performed using the non faradaic impedance spectroscopy at quasi-resonance frequencies of the RC-oscillator.

Results: The capacitive characteristics of the DNA sensors in the frequency range from 100 kHz to 1 MHz after hybridization with targeted DNA at various concentrations have been investigated. It was found that the addition of molten target DNA at low concentrations leads to a significant decrease in capacity over the entire frequency range. Interacting the probe ss-DNA and target ss-cDNA molecules form homoduplexes on the sensor surface that leads to increasing the electron density of the nucleotide CNT-cover, providing capacity reduction due to an emerging screening surface effect.

Conclusion: The novel highly-performed and high-sensitive electrochemical method reliably detects the presence or absence of HEV in a sample in dose-dependent manner and does not demand expensive consumable materials.

THU352

Hepatitis B Delta: assesment of knowledge and practices of French non academic hepato-gastroenterologists

Jean-François David Cadranel[1], Honore Zougmore[1], Bertrand Hanslik[2], Jean-René Ngele[1], Xavier Causse[3], Denis Ouzan[4], Thierry Thévenot[5], Philippe Halfon[6], Dominique Roulot[7], Veronique Loustaud-Ratti[8], Tristan Lemagoarou[9]. *[1]GHPSO DE CREIL, liver and diseases department, Creil, France; [2]cabinet gastroenterologie, liver and diseases department, MONTPELLIER, France; [3]Hospital Center Régional D'orléans Hospital La Source, liver and diseases department, Orléans, France; [4]Arnault Institute Tzanck, liver and diseases department, Saint-Laurent-du-Var, France; [5]Centre hospitalier régional universitaire de Besançon, liver and diseases department, Besançon, France; [6]liver and INFECTIOIS diseases department, MARSEILLE, France; [7]liver and DIGESTIVE diseases department, bobigny, France; [8]liver and ANDF DIGESTIVE diseases department, limoges, France; [9]GHPSO DE CREIL, DIM, Creil, France*
Email: jcadranel5@gmail.com

Background and aims: Hepatitis B-Delta (BD) is uncommon or underestimated in France; there are no data from hepato-gastro-enterologists (HG) practicing in non-university hospitals or in private practice on the management of BD hepatitis in France. The aim of this study was to evaluate the knowledge and practices concerning the diagnosis and treatment of BD hepatitis among HGs practicing in non-academic settings.

Method: A Google form questionnaire was sent to senior or junior non-academic from May to September. The following were evaluated: demographic data, predominant specialty, status, modality of virological diagnosis and screening for hepatitis BD according to HBs status, evaluation of hepatic fibrosis, modalities of treatment (Pegylated interferon, Bulevirtide, combination).

Results: 129 HGs (H 58, 1%) of age :44, 8 (13, 4) answered this survey. The number of patients (pts) followed by HG was: : 1 (0–30). The search for delta infection in all HBs antigen positive pts was performed by 89.1% of HGs and not by 10%: juniors 77.8%, seniors 84.4%, p = 0.009; in any pts carrying HBs antigen with anti HBe: juniors 67%, seniors 92%, p = 0.002, in any pts infected with HIV (juniors 83.8%, seniors 95.4%, p = 0.064. Concerning fibrosis assessment, among the non-invasive markers of fibrosis: the fibrotest was never used by 47% of the respondents, the fibrometer was never used by 55% of the respondents. APRI and FIB 4 were not used; the delta fibrosis score adapted to hepatitis Delta was used by 13% of the HGE. Fibrosis assessment was mainly done by Fibroscan® in 77% of cases and liver biopsy in 81% of cases. Treatment was proposed for patients >F2 in 49% of cases, whatever the transaminase level, and for all patients by 39% of the Gs. The HGE proposed treatment with pegylated interferon in 48.4% of cases, Bulevirtide in 43% of cases, and a combination of the two in 42% of cases. Half of the HGs referred their patients to an academic collegue. Among the criteria for treatment efficacy, a decrease or normalization of transaminases was retained by 84% of the HGs; 60% of the HGs defined VR by a cancellation or a 2-log decrease of viral replication; and a PVR by a disappearance of RNA after 12 (45.4%) or 24 months (16%) with normal transaminase activity. Discussion: The number of respondents to this survey is low despite the number of reminders, reflecting the rarity of the disease or its lack of awareness in non-academic settings, HGs often refer their patients to another colleague, the search for BD infection is not systematically performed, elastometry and liver biopsy are most often used to assess fibrosis.

Conclusion: The results of this survey show a certain degree of ignorance of BD hepatitis by non-academic HGs; the modalities of diagnosis and the need for systematic screening of BD infection in any HBsAg patient should be recalled by the learned societies.

THU353

Hepatitis E seroprevalence in solid organ transplant recipients in Croatia

Petra Dinjar Kujundžić[1], Tatjana Vilibic-Cavlek[2,3], Alan Ayoub[2], Adriana Vince[2,4], Anna Mrzljak[2,5]. *[1]Merkur Clinical Hospital, Zagreb, Croatia; [2]School of Medicine, University of Zagreb, Zagreb, Croatia; [3]Croatian Institute for Public Health, Zagreb, Croatia; [4]University Hospital for Infectious Diseases Dr. Fran Mihaljevic, Zagreb, Croatia; [5]University Hospital Centre Zagreb, Zagreb, Croatia*
Email: petra.dinjar@gmail.com

Background and aims: Hepatitis E virus (HEV) is an emerging infectious disease and growing concern in Europe. After solid organ transplantation (SOT), patients are at greater risk of developing acute and chronic graft hepatitis with progression to cirrhosis. The consumption of undercooked or raw pig meat is the main route of HEV infection in developed countries. However, risk factors for the acquisition of HEV among SOT recipients are incompletely understood. This study aimed to determine the exposure of HEV in the SOT cohort.

Method: In this cross-sectional study, 639 SOT recipients were screened during routine post-transplant outpatient visits during 2002–2017 for anti-HEV IgG seroprevalence; 420 after liver transplantation (LT) and 219 after kidney transplantation (KT). Serum samples were tested for anti-HEV IgG using an enzyme immunoassay (Mikrogen, Neuried, Germany). All participants completed a risk factor assessment questionnaire.

Results: Anti-HEV IgG seroprevalence in LT recipients was 21%, and in KT recipients was 16.4%. The majority of the recipients were male (68.4%), median age 58 years (18–80). Anti-HEV IgG positive recipients were older (p = 0.029) and lived more often in a rural area (p = 0.045) than anti-HEV negative recipients. There was no significant difference in HEV seroprevalence regarding the type of transplanted organ, gender, level of education, number of household members, having a farm within a household, type of sewage system, or type of drinking water. Contrary to initial assumptions, production and/or consummation of cured meat and occupational exposure had no statistically significant strength of association with anti-HEV IgG seropositivity.

Conclusion: Our results show that anti-HEV IgG seroprevalence is high among SOT recipients (19, 4%). Socio-demographic factors for exposure to HEV are the basis for further research of sources and routes of transmission and clinical significance of HEV infection after SOT.

THU354

Microarray analysis of virus-specific IgM and IgG antibodies significantly improves the serological diagnosis of hepatitis E virus infection

David Springer[1], Christian Borsodi[1], Stephan Aberle[1], Lukas Weseslindtner[1]. [1]*Medical University of Vienna, Center for Virology, Vienna, Austria*
Email: lukas.weseslindtner@meduniwien.ac.at

Background and aims: Due to the limited availability of PCR, the rapid decrease of viral RNA in the blood, and the possibility of unspecific reactivity in serological assays, the laboratory diagnosis of hepatitis E virus (HEV) infection remains challenging. Therefore, we evaluated a commercial microarray for HEV-specific IgM and IgG antibodies featuring nine target antigens (HEV Virachip®, Viramed).
Method: The evaluation panel comprised 408 serum samples first characterized by HEV-PCR (in-house) and Anti-HEV-IgM- and IgG-ELISAs (Wantai-HEV-IgG/IgM ELISA®, Wantai Biological Pharmacy Ent). Based on these results and additional IgG avidity testing, samples were staged as early viremic (serum PCR+, IgM ± , IgG ± ; n = 94), progressed non-viremic (serum PCR-, IgM+, IgG+; n = 80) and past HEV infection (PCR-, IgM-, IgG+; n = 117). Additional 117 samples negative for all HEV parameters served as controls.
Results: Microarray results significantly concurred with the ELISAs in 94.8% of IgM positive and 97.7% of IgG positive samples, indicating a high concordance of the applied serological assays. However, IgM and IgG antibodies against specific antigens included in the microarray (e. g., IgM and IgG against O2–1C4 and O2-1N, respectively) were earlier detectable in 14.9% of still ELISA-IgM negative and 35.3% of ELISA-IgG negative samples. In addition, samples with negative PCR but positive IgM ELISA results (progressed HEV infection) were reliably identified as HEV infection by the microarray and constituted a specific infection stage based on the serological microarray profile. Finally, we calculated an algorithm to identify HEV infection (with PCR positivity as reference) with the highest accuracy using all serological parameters provided by the microarray (ROC-AUC 0.90, p <0.005).
Conclusion: Microarray analysis of HEV-specific IgM and IgG antibodies displays high sensitivity to diagnose HEV infection, especially in the early phase of the infection, and identifies the progressed infection stage when PCR from serum already tests negative.

Viral hepatitis B/D: Clinical aspects except therapy

THU355

Hepatitis delta virus reflex testing in patients with hepatitis B improves the HDV screening cascade: 10 years of real-world experience from Avicenne University Hospital, France

Segolene Brichler[1,2,3], Dominique Roulot[2,3,4], Samira Dziri[1,3], Athenais Gerber[1,3], Frédéric Le Gal[1,3], Heloise Delagreverie[1,2], Chakib Alloui[1,3], Emmanuel Gordien[1,2,3]. Email: segolene.brichler@aphp.fr

Background and aims: Chronic infection with Hepatitis delta virus (HDV) leads to the most severe form of chronic viral hepatitis, with higher rates of cirrhosis and hepatocellular carcinoma than with Hepatitis B virus (HBV) mono-infection. EASL international guidelines recommend systematic HDV screening for all HBsAg positive patients. However, it is not performed in most areas. In our university hospital, hepatologists and virologists have implemented a "HDV reflex testing" protocol, consisting of the systematic addition of a serological HDV test on all samples with a first diagnosis of hepatitis B (HBsAg+). We report the effectiveness of this strategy over a 10-year period.
Method: This is a single-centre retrospective survey in Avicenne University Hospital (Assistance Publique-Hôpitaux de Paris, France). The hospital is set in a suburban area, home to many patients originating from countries with a high burden of viral hepatitis. Our laboratory database was screened for all HDV tests performed in HBsAg positive patients from June 2012 to February 2022. Duplicates were excluded based on name, sex and date of birth. Patient serum samples were assayed for HBsAg using the Abbott Architect HBsAg qualitative II and quantitative HBsAg kits, and for total HDV antibodies (HDV-Abs) using the ETI-DELTAK or the Diasorin Liaison XL Murex anti-HDV kits. HDV viral loads were obtained first by in-house RT-qPCR, then by using the EurobioPlex HDV kit since 2016.
Results: A total of 84, 671 patients were screened at least once for HBV during the evaluation period. Among the 3198 HBsAg positive patients (3.8%, median age 39.0, sex ratio 2.04), 2886 (90.2%) were screened for HDV-Abs, 172 of them being positive (6.0%, median age 39.5, sex ratio 1.92). At least one HDV-RNA assay was available for 149 of them (86.6%) and was found positive for 91 patients (61.1%). HDV screening rate steadily improved with time, from 85–87% in the initial 2012–2015 period to 95–98% in the 2019–2022 years, while the annual frequency of HDV-Abs positivity among tested HBsAg+ samples remained stable (range: 4.4–7.7%).
Conclusion: HDV reflex testing in our centre was effective, allowing earlier identification of most HBV-HDV infected patients and a fast referral to hepatologists for adequate clinical management. The prevalence of HDV co-infection in HBsAg positive patients is twice higher than that initially reported in France among HBsAg positive blood donors. Active HDV replication was present in more than 60% of co-infected patients identified through our systematic screening. In the future, further molecular HDV reflex testing in HDV-Ab positive patients may improve the complete HDV screening cascade in our centre.

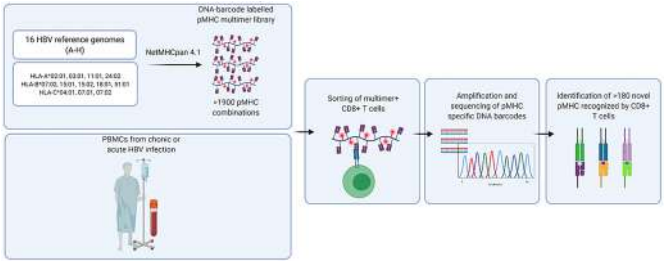
T cell epitope mapping of hepatitis B virus in chronic infection

Marie Viuff[1], Marianne Tuefferd[2], Christina Heeke[1], Kamilla Kjærgaard Munk[1], Mohammad Kadivar[1], Georg Lauer[3], Jacques Bollekens[2], Sine Reker Hadrup[1]. [1]*Technical University of Denmark, Department of Health Technology, Kgs. Lyngby, Denmark;* [2]*Janssen Pharmaceuticals, Infectious Diseases and Vaccines, Beerse, Belgium;* [3]*Massachusetts General Hospital, Department of Medicine, Boston, United States*
Email: macviu@dtu.dk

Background and aims: Affecting more than 250 million patients worldwide, chronic hepatitis B virus (HBV) infection still poses a substantial global health threat, without available curative therapy. CD8 T cells are known to be crucial for the elimination of the virus, however, in chronically infected patients, the cellular immune response proves inefficient. Thus, uncovering the full repertoire of HBV epitopes and functionality of the HBV-specific CD8 T cells is highly relevant for understanding the immune response. Identification of HBV epitopes recognized by T cells has historically been limited to few HLA types and selected viral proteins. Here, we have performed a large-scale screening covering HBV genotypes A-H to identify T cell recognition restricted by 12 different HLA molecules, in patients with acute and chronic hepatitis. This data is substantially extending the present knowledge about the T cell recognition of HBV.
Method: A library of >1, 900 peptide-MHC combinations was used generate DNA-barcode labelled multimers to screen CD8 T cells from peripheral blood for recognition of hepatitis B epitopes in HLA-matching patients with either acute, chronic, or resolved chronic hepatitis (n = 40). The peptide-MHC library was generated by

selecting specific 8–11mers from HBV genotypes A-H, predicted to bind to 12 different HLA types.
Results: Performing the large-scale multimer screening we found a total of 212 unique peptide-MHC, which were recognized by CD8 T cells across all patient groups. Out of these, 189 peptide-MHC have not previously been described. Furthermore, 45% of the peptide-MHCs were recognized in multiple patients. T cell recognition was detected in both acute and chronic patients, with no significant difference observed between chronic and HBsAg loss patients. Interestingly, T cells recognizing the identified peptides display different level of functional responses upon peptide stimulation, which will be further investigated.



Conclusion: In this study, we were able to fully map the CD8 T cell recognition towards HBV genomes A-H and identify >180 novel CD8 T cell epitopes of potential relevance for viral control and clearance.

THU357
The Comparison of tenofovir alafenamide fumarate with tenofovir disoproxil fumarate in preventing hepatitis B transmission in mothers with high viral load: a retrospective cohort study

Yunxia Zhu[1], Jinhua Wang[2], Ming Wang[2], Xin Zhou[1], Shuangxia Zhang[1], Shujie Zhang[1], Bo Yang[1], Ping Yang[1], Zhongjie Hu[3]. *[1]Beijing Youan Hospital, Capital Medical University, Obstetrics and Gynecology, Beijing, China; [2]Beijing Obstetrics and Gynecology Hospital, Capital Medical University, Department of Gynecologic Oncology, Beijing, China; [3]Beijing Youan Hospital, Capital Medical University, Hepatology, Beijing, China*
Email: zyxno7@163.com

Background and aims: Tenofovir disoproxil fumarate (TDF) is most commonly utilized in the prevention of maternal-to-child transmission of the hepatitis B virus. The previous studies show antiviral prophylaxis with tenofovir alafenamide fumarate (TAF) was also generally safe for both mothers and infants and reduced the mother-to-child transmission (MTCT) rate to 0%. However, few safety and effectiveness results have been published regarding the comparison of two drugs during pregnancy for the prevention of MTCT of HBV, especially for the early markers of bone metabolism like alkaline phosphatase (ALP) and Z value for bone mineral density (BMD) of infants.
Method: We performed a prospective cohort study involving women who had HBV DNA ≥2*105IU/ml and initiated TAF or TDF for preventing MTCT during gestational weeks 24~28 weeks. All enrolled patients had normal liver function and had not received antiviral therapy before pregnancy. We collected the name, ID, age, and drug duration of the maternal, monitoring HBV viral load and ALP at the same time besides infants' HBV marks and their Z value for BMD. The primary outcomes were the decrease in virus load and the rates for MTCT, which was defined as the proportion of infants who had a serum HBV DNA level of more than 20 IU per milliliter (i.e. above the lower limit of detection) or who were positive for hepatitis B surface antigen (HBsAg). The secondary outcomes were the changes in serum ALP expression of the mother and the BMD of newborns.
Results: A total of 61 patients received TAF treatment and 73 patients received TDF.51 pairs of patients were matched by Propensity Score Match (PSM). The levels of HBV-DNA decline in TDF-treated mothers were compared to TAF treated mothers (3.70 ± 0.91 log10IU/ml vs 3.43 ± 1.30 log10IU/ml, P > 0.05) before delivery. The rates of MTCT in the TAF group were similar to the TDF group (with the transmission of 0.00% [0 of 39] vs 0.00% [0 of 29], p > 0.05) in the per-protocol analysis. As for BMD, no significant difference in the Z value of newborns was found between the two groups. However, the expression level of ALP was significantly higher in the TDF group than TAF group.

Variables	TDF Treated (n = 51)	TAF Treated (n = 51)	t/X2	p
Age (years)	30.75 ± 2.95	30.43 ± 3.70	0.473	0.637
Drug Duration (weeks)	12.52 ± 4.54	12.74 ± 4.86	0.229	0.819
HBV DNA before Drug Use (log10IU/ml)	8.06 ± 8.13	8.07 ± 8.10	0.023	0.982
Decline of HBV DNA (log10IU/ml)	3.43 ± 1.20	3.70 ± 0.91	1.244	0.216
ALP (U/L)	162.06 ± 42.30	144.67 ± 45.71	1.995	0.049
Z for BMD	0.69 ± 0.46	0.66 ± 0.41	0.259	0.797

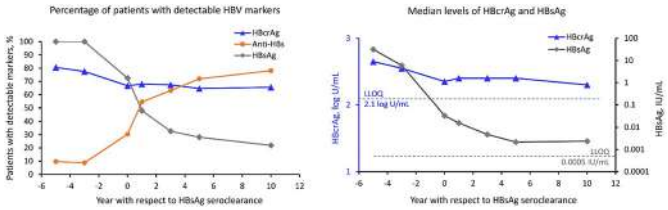
Conclusion: TDF and TAF use in MTCT for highly viremic mothers was equally effective and the study showed both two drugs have no statistically different effect on neonatal BMD. However, TAF has less influence on serum ALP in pregnant women than TDF.

THU358
Detection of notable hepatitis B virus serologic activity after hepatitis B surface antigen seroclearance

Danny Ka-Ho Wong[1,2], Takako Inoue[3], Lung Yi Loey Mak[1,2], Yan Yue James Fung[1,2], Ka-Shing Cheung[1], Wai-Kay Seto[1,2], Yasuhito Tanaka[4], Man-Fung Yuen[1,2]. *[1]The University of Hong Kong, Medicine, Hong Kong; [2]The University of Hong Kong, State Key Laboratory of Liver Research, Hong Kong; [3]Nagoya City University Hospital, Clinical Laboratory Medicine, Nagoya, Japan; [4]Kumamoto University, Gastroenterology and Hepatology, Kumamoto, Japan*
Email: dannykhwong@gmail.com

Background and aims: Undetectable serum hepatitis B surface antigen (HBsAg) measured by conventional assays (lower limit of detection ~0.05 IU/ml) is regarded as functional cure to chronic hepatitis B (CHB). It has been demonstrated that some HBV proteins are detectable in patients after HBsAg seroclearance (SC). We evaluated the use of two novel investigational assays to detect hepatitis B core-related antigen (HBcrAg) and HBsAg in serial patient samples collected before and after SC.
Method: Serum samples were collected from 98 CHB patients (72 males and 26 females) with SC at the following 7 time-points: 5 years and 3 years before SC, at the time of SC, and 1 year, 3 years, 5 years and 10 years after SC. HBsAg and HBcrAg were measured using the iTACT-(stands for Immunoassay for Total Antigen including Complex via pre-Treatment)-HBsAg and iTACT-HBcrAg assays (Fujirebio, Tokyo, Japan) respectively. The lower limit of quantitation (LLOQ) of the iTACT-HBsAg and iTACT-HBcrAg assays are 0.0005 IU/ml and 2.1 log U/ml respectively, which are 100 times and approximately 10 times more sensitive than the current HBsAg and HBcrAg assays (LLOQ 3 log U/ml). Anti-HBs was measured by the Lumipulse Presto anti-HBs assay (LLOQ 10 mIU/ml).
Results: The median age of SC was 52 years (IQR: 45–57). A total of 572 samples (142 collected before SC and 430 collected after SC) were tested. HBsAg was detectable by iTACT-HBsAg in all the 142 samples collected before SC (median level: 10.9 IU/ml) and in 165/430 (38.4%) samples collected after SC (median level for those with detectable HBsAg: 0.0082 IU/ml). 61.6% of samples collected after SC had detectable anti-HBs. Of these anti-HBs positive samples, 70 (26.4%) had detectable HBsAg. HBcrAg was detectable in 78.9% of samples collected before SC and 66.4% after SC. There was a positive correlation between HBsAg and HBcrAg levels (r = 0.330, P <

0.00001). The detectability rate and median levels of both HBsAg and HBcrAg progressively decreased over time from before to after SC, while the detectability rate of anti-HBs increased after SC (Figure 1). Of the 98 patients, 9 (9.2%) had detectable HBsAg and HBcrAg at all time points after SC, and 11 (11.2%) patients had undetectable HBsAg and HBcrAg at all time points after SC. 87 (88.8%) patients had detectable HBsAg and/or HBcrAg at least one time point after SC. Of note, at 10 years after SC, 21.9% and 65.6% of the patients still had detectable HBsAg and HBcrAg, respectively.



Conclusion: The iTACT-HBsAg assay could detect a low level of HBsAg in >20% patients even at 10 years after SC. A relatively stable expression of HBcrAg was also detected in >60% patients after SC. The findings suggested that the threshold of SC may be raised using an ultrasensitive HBsAg assay and that expression of HBV proteins could still be detected after SC. The association between the expression levels of these proteins and disease progression deserves further studies.

Comparison of on-treatment ALT or FIB-4 as an on-treatment biomarker of hepatitis B treatment for liver cirrhosis patients

Joo Hyun Oh[1], Dong Hyun Sinn[2], Sang Bong Ahn[1], Wonseok Kang[2], Geum-Yon Gwak[2], Yong-Han Paik[2], Moon Seok Choi[2], Joon Hyeok Lee[2], Kwang Cheol Koh[2], Seung Woon Paik[2]. [1]*Nowon Eulji Medical Center, Department of Medicine, Korea, Rep. of South;* [2]*Samsung Medical Center, Department of Medicine, Korea, Rep. of South*
Email: dh.sinn@samsung.com

Background and aims: Alanine aminotransferase (ALT) levels are usually mildly elevated in patients with cirrhosis. Therefore, it is unclear whether 'normalization of ALT' with antiviral therapy is associated with a lower risk of hepatic events in hepatitis B virus (HBV)-related cirrhosis patients. We tested on-treatment ALT and several other potential on-treatment biomarkers that can be clinical surrogate or end point of antiviral therapy.
Method: A total of 911 hepatitis B virus-related liver cirrhosis patients who started entecavir or tenofovir were analyzed. We tested 'ALT normalization', 'undetectable serum HBV DNA', 'fibrosis-4 (FIB-4) index improvement', and 'serum HBeAg loss or seroconversion' at 1 year as a potential on-treatment biomarker for future HCC risk.
Results: During 6.6 (3.8–10.2) years of follow-up, 222 patients (24.4%) newly developed HCC. Among 747 patients with elevated ALT levels, ALT normalization was observed in 49.5% at one year. HCC incidence rate was not different between those with and without ALT normalization (17.6% vs. 16.8% at 5-years, p = 0.39). Undetectable HBV DNA level was observed in 73.2% at one year, and HCC incidence rate was significantly different between those with and without undetectable HBV DNA levels (16.6% vs. 20.9% at 5-years, p = 0.004). FIB-4 improvement (FIB-4 <3.25) was observed in 163 patients (34.1%) among 478 patients with elevated FIB-4 index (FIB-4 ≥3.25). HCC incidence rate was lower for those with FIB-4 improvement than those without (14.9% vs. 25.6% at 5-years, p = 0.006), and was associated with lower risk of HCC (adjusted hazard ratio 0.59, 95% CI 0.55–0.82). HBeAg loss or seroconversion was observed in 55 patients (15.0%) at one year among 367 HBeAg positive patients, and the HCC incidence rate was not different between those with and without HBeAg seroconversion (19.7% vs. 20.1% at 5-years, p = 0.55).

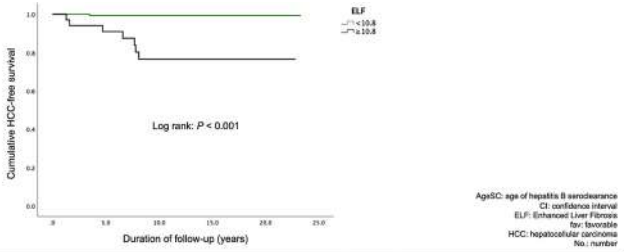
Conclusion: Among HBV-related liver cirrhosis patients who started antiviral therapy, complete virological response and improvement of FIB-4 index at one-year was independently associated with future HCC risk, while ALT normalization and serological biomarkers were not. This indicate HBV DNA and FIB-4 index can be better on-treatment clinical end points of antiviral therapy for cirrhotic patients.

THU360

Liver fibrosis burden determines risk of hepatocellular carcinoma among patients with hepatitis B surface antigen seroclearance

Lung Yi Loey Mak[1,2], Ka-Shing Cheung[1], Rex Wan-Hin Hui[1], Danny Ka-Ho Wong[1,2], Yan Yue James Fung[1,2], Man-Fung Yuen[1,2], Wai-Kay Seto[1,2,3]. [1]*The University of Hong Kong, Medicine, Hong Kong, Hong Kong;* [2]*State Key Laboratory for Liver Research, The University of Hong Kong, State Key Laboratory for Liver Research, Hong Kong, Hong Kong;* [3]*The University of Hong Kong-Shenzhen Hospital, Medicine, Shenzhen, China*
Email: loeymak@gmail.com

Background and aims: Hepatitis B surface antigen (HBsAg) seroclearance is regarded as functional cure in chronic hepatitis B infection (CHB). We investigated the risk of hepatocellular carcinoma (HCC) in CHB patients after achievement of HBsAg seroclearance.
Method: 337 Asian CHB patients (69.1% male) who developed spontaneous HBsAg seroclearance between April 1996 to October 2012 with retrievable blood samples before HBsAg seroclearance were recruited and prospectively followed up for a median duration of 12.7 (interquartile range [IQR] 9.5–16.2) years. Blood levels of Enhanced Liver Fibrosis (ELF) were determined. Variables of interest included gender, age of HBsAg seroclearance (ageSC), presence of diabetes mellitus (DM), ELF score, and antibody to HBsAg (anti-HBs). Independent risk factors of HCC were determined by univariate then multivariate Cox regression and Kaplan Meier survival analysis.
Results: The median ageSC was 51.6 (IQR 42.6–58.1) years old, and 24.6% patients had DM. ELF at a median interval of 3.4 (IQR 0.4–4.9) years before HBsAg seroclearance was 9.5 (IQR 9.0–10.1). 216/337 (64.1%) developed anti-HBs at a median time of 2.3 (IQR 0–4.0) years after HBsAg seroclearance with median level of 42 (IQR 18–138) mIU/ml. Nine cases of HCC were diagnosed at a median time of 6.6 (IQR 2.6–7.9) years after HBsAg seroclearance. At Cox regression analysis, ageSC (hazard ratio [HR] univariate: 1.118, multivariate: 1.096, both p < 0.01) and ELF (HR univariate: 3.282, multivariate: 3.090, both p < 0.001) were significant variables associated with HCC, while DM (HR 2.490, p = 0.273), anti-HBs (HR 1.17, p = 0.876) and gender (HR 1.695, p = 0.514) were not significant variables. The area under receiver-operating characteristic curve value for ELF was 0.856 (95% confidence interval [CI] 0.714–0.997, p < 0.001). By maximizing the Youden's index, ELF <10.8 was associated with lower risk of HCC with 77.8% sensitivity and 90.2% specificity. Among patients with ageSC ≥50 (known to be associated with residual risk of HCC; n = 190), ELF <10.8 before HBsAg seroclearance was associated with >97% reduction in risk of HCC development [Figure 1].



ELF	Number at risk						No. of events	Cumulative risk of HCC	Hazard ratio (Cox regression)
	Year 0	Year 5	Year 10	Year 15	Year 20	Year 25			
<10.8	156	148	99	46	17	0	1	0.6%	0.027 (95% CI 0.003-0.219, P=0.001)
≥10.8	34	28	15	7	1	0	7	20.6%	1.000 (reference)

Figure: Cumulative HCC-free survival in Asian CHB patients who achieved HBsAg seroclearance at or after age of 50 years-old

Conclusion: ELF <10.8 was associated with markedly reduced risk of HCC development upon long-term follow-up among CHB patients with ageSC ≥50. Ongoing HCC surveillance is required for patients who achieved HBsAg seroclearance at an older age and had advanced liver fibrosis before HBsAg seroclearance. [Supported by SK Yee Medical Foundation (reference number: 2171213)]

THU361

Estimating the prevalence of hepatitis delta infection among foreign-born adults with chronic hepatitis B in the United States

Robert Wong[1], Carol Brosgart[2], Steven Wong[3], Jordan Feld[4], Jeffrey Glenn[5], Saeed Sadiq Hamid[6], Kate Moraras[7], John Ward[8], Heiner Wedemeyer[9], Cihan Yurdaydin[10], Robert G. Gish[7]. *[1]Stanford University School of Medicine, Veterans Affairs Palo Alto Healthcare System, Palo Alto, United States; [2]University of California San Francisco Parnassus Campus, San Francisco, United States; [3]S Wong Consulting, LLC, United States; [4]University Health Network, Toronto, Canada; [5]Stanford University School of Medicine, Stanford, United States; [6]Aga Khan University Hospital, Karachi, Pakistan; [7]Hepatitis B Foundation, Doylestown, United States; [8]The Task Force for Global Health, Decatur, United States; [9]Hannover Medical School, Department of Gastroenterology, Hepatology and Endocrinology, Germany; [10]Koç University School of Medicine, Department of Gastroenterology and Hepatology*
Email: rwong123@stanford.edu

Background and aims: Suboptimal awareness and testing for hepatitis delta virus (HDV) infection among adults with chronic hepatitis B (CHB) contributes to the poor understanding of the true prevalence of HDV and appropriate policy development. Our recent study estimated 1.47 million (M) foreign-born (FB) persons with CHB were living in the United States (US) in 2018. FB persons with CHB contribute to the majority of the burden of HDV infection in the U.S., given the high burden of HDV in many world regions from which CHB patients emigrate from. This study aims to provide an estimate of HDV prevalence among FB adults with CHB in the US.
Method: We updated analyses of CHB prevalence among FB adults in the US by performing systematic reviews and meta-analyses (surveys published from 1980 to 2019) that combined country-specific CHB prevalence rates with number of FB living in the US in 2019 by country of birth from the US Census Bureau. To estimate HDV prevalence among FB adults with CHB, we combined country-specific HDV prevalence rates (anti-HDV or HDV RNA positive) for persons with CHB from meta-analyses and applied these estimates to the number of FB with CHB in the US in 2019 by country of birth to estimate the number of FB CHB patients with combined HDV infection.
Results: In 2019, the overall FB population in the US was 48.0M, among which the estimated prevalence of CHB was 3.10% (95% CI 2.55–3.65), resulting in 1.49M (95% CI 1.22–1.75) FB adults with CHB, which accounts for nearly 80% of all adults with CHB in the US. Among FB adults with CHB, overall estimated pooled prevalence of HDV infection was 9.22% (95% CI 4.90–15.73), resulting in 137, 158 FB adults with HDV (95% CI 72, 936–233, 984). World region-specific estimates of HDV infection among adults with CHB were 8.73% in Asia, 6.98% in the Americas, 22.52% in Oceania, 11.18% in Africa, and 14.08% in Europe, representing 76, 817 (Asia), 19, 327 (Americas), 2, 789 (Oceania), 25, 442 (Africa), and 12, 782 (Europe), FB CHB adults with HDV infection in the US.

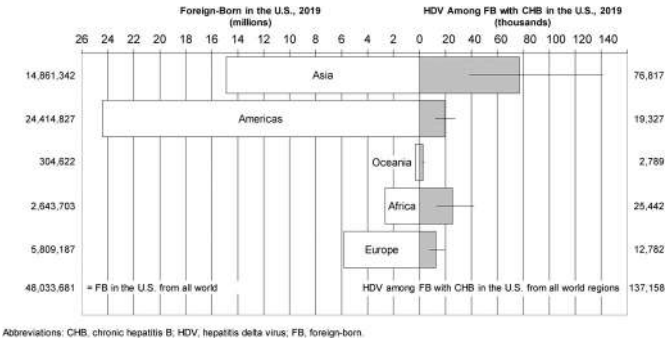


Figure: FB Populations Living in the U.S. and Number of HDV among FB with CHB Living in the U.S. by World Region of Origin, 2019.

Conclusion: This analysis provides an estimate of the number of FB adults with CHB living in the US who are also infected with HDV, which is expected to further grow with patterns of increased immigration into the US. The burden of HDV will be even greater when factoring in US-born CHB patients who have combined HDV infection acquired primarily through high-risk activities.

THU362

Secular trend of the accuracy of hepatocellular carcinoma risk scores in treated chronic hepatitis B patients in 2005–2020: a territory-wide study of 48, 706 subjects

Terry Cheuk-Fung Yip[1], Mandy Sze-Man Lai[1], Vincent Wai-Sun Wong[1], Yee-Kit Tse[1], Yan Liang[2], Vicki Wing-Ki Hui[2], Henry LY Chan[3,4], Grace Lai-Hung Wong[1]. *[1]The Chinese University of Hong Kong, Medical Data Analytics Centre (MDAC), Department of Medicine and Therapeutics, Institute of Digestive Disease, Faculty of Medicine, Hong Kong; [2]The Chinese University of Hong Kong, Medical Data Analytics Centre (MDAC), Department of Medicine and Therapeutics, Faculty of Medicine, Hong Kong; [3]Union Hospital, Department of Internal Medicine, Hong Kong; [4]The Chinese University of Hong Kong, Medical Data Analytics Centre (MDAC), Faculty of Medicine, Hong Kong*
Email: wonglaihung@cuhk.edu.hk

Background and aims: Patients with chronic hepatitis B (CHB) are aging with more comorbidities such as diabetes mellitus (DM). In contrast, the reimbursement of antiviral treatment has been less restrictive over time, leading to better coverage. We aimed to examine whether the resulting change in patients' clinical characteristics over time affects the accuracy of risk scores for hepatocellular carcinoma (HCC).
Method: Adult CHB patients who received entecavir or tenofovir for at least 6 months between January 2005 and March 2020 were identified using a territory-wide electronic healthcare database in Hong Kong. DM was defined by any use of non-insulin antidiabetic agents, continuous use of insulin for ≥28 days, haemoglobin A_{1c} ≥6.5%, fasting glucose ≥7 mmol/L, and/or diagnosis codes. Four HCC risk scores for treated CHB patients including PAGE-B and modified PAGE-B (mPAGE-B) scores; cirrhosis, age, male sex, and DM (CAMD) score; and Real-world Effectiveness from the Asia Pacific Rim Liver Consortium for hepatitis B virus (REAL-B) score were studied. The accuracy of scores was assessed by area under the time-dependent receiver operating characteristic curves (AUROCs) with death as a competing risk. Comparisons were done based on 1, 000 bootstrap samples.
Results: Of 48, 706 patients included, 2, 792, 11, 563, 15, 471, and 18, 880 patients started antiviral treatment in 2005–08, 2009–12, 2013–16, and 2017–20 respectively; their mean age at treatment initiation were 50, 52, 54, and 57 years respectively. DM prevalence rose from 16% in 2005–08 to 19% in 2009–12, 21% in 2013–16, and 24% in 2017–20, whereas the prevalence of cirrhosis dropped from 21% to 17%, 9%, and 5% respectively through the 4 periods. The median follow-up time was 5, 5, 5, and 2 years in 2005–08, 2009–12, 2013–16, and

2017–20 respectively; 7.4%, 6.8%, 5.2%, and 1.9% of patients developed HCC respectively. PAGE-B and modified PAGE-B scores performed well across the 4 periods with comparable AUROCs ranged from 0.75–0.77 for PAGE-B score (p = 0.726) and 0.76–0.80 for mPAGE-B score (p = 0.150). For the other two scores with DM as a predictor, CAMD score was less predictive in the most recent period (p = 0.025). REAL-B score tended to be less predictive in the most recent period (p = 0.085) (Figure).

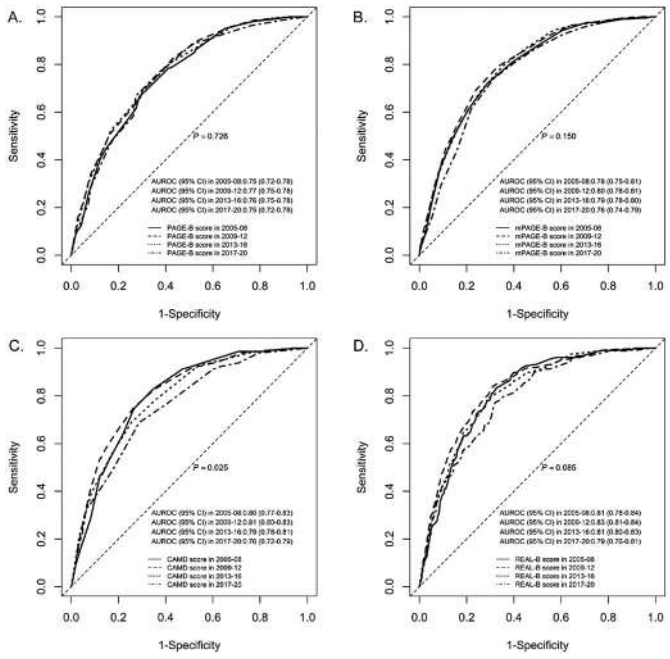

Figure: The area under the time-dependent receiver operating characteristic curves (AUROCs) of A. PAGE-B score; B. mPAGE-B score; C. CAMD score; and D. REAL-B score for predicting the development of hepatocellular carcinoma among chronic hepatitis B patients who started nucleos (t) ide analogue treatment in the 4 periods.

Conclusion: Two PAGE-B scores performed well regardless of the change in clinical characteristics of CHB patients over time. HCC risk scores that have DM as a predictor may however be less predictive in recent years.

THU363

Risk prediction of hepatocellular carcinoma in chronic hepatitis B patients outside current treatment criteria

Gi-Ae Kim[1], Seungbong Han[2], Young-Suk Lim[3], Gwang Hyeon Choi[4], Jonggi Choi[3], Dong Hyun Sinn[5], Yong Han Paik[5], Jeong-Hoon Lee[6], Ju-Yeon Cho[7]. *[1]Kyung Hee University School of Medicine, Department of Internal Medicine, Korea, Rep. of South; [2]Korea University, Department of Biostatistics; [3]Asan Medical Center, Department of Gastroenterology, Liver Center; [4]Seoul National University Bundang Hospital, Department of Internal Medicine, Seongnam-si, Korea, Rep. of South; [5]Samsung Medical Center, Department of Medicine, Korea, Rep. of South; [6]Seoul National University College of Medicine, Department of Internal Medicine and Liver Research Institute, Korea, Rep. of South; [7]Chosun University, Department of Internal Medicine, Korea, Rep. of South*
Email: limys@amc.seoul.kr

Background and aims: A considerable number of chronic hepatitis B (CHB) patients outside the current treatment criteria develop hepatocellular carcinoma (HCC), suggesting many patients at high risk are left untreated and risk prediction for this population is called for. Thus, we aimed to investigate the risk of HCC in CHB patients who are not indicated for antiviral treatment including a broader range of HBV DNA levels and develop a risk prediction model for them.

Method: This multi-center study recruited 9, 058 treatment-naïve, non-cirrhotic CHB patients with ALT <2 × upper limit of normal: 6, 949 for training cohort from Asan Medical Center and 2, 109 for validation cohort from two tertiary hospitals in Korea. A risk prediction model for HCC was developed using predictors based on multivariable cox models, and bootstrapping was performed for validation.

Results: In the training cohort, 363 patients (5.2%) developed HCC during 8.0 years of median follow-up. By multivariable cox regression analysis, HCC risk was the highest with HBV DNA levels of 6–7 $\log_{10}$ IU/ml (adjusted hazard ratio [aHR] 4.98; $P < 0.001$), and lowest with >8 $\log_{10}$ IU/ml (aHR 0.90; $P = 0.71$) and ≤4 $\log_{10}$ IU/ml (aHR 1.00; reference). HBV DNA levels, male sex, older age, and lower platelet counts were independent predictors of HCC but ALT levels did not predict HCC risk (p = 0.33). An ALT-independent 24-point risk prediction model ("ABC model 1") was developed including the 4 independent predictors: sex, age, platelet counts, and HBV DNA levels combined with HBeAg status. HCC risk was calculated to range widely (0.19%-72.46%) at 10 years. The model showed good prediction performance with a concordance index (c-index) of 0.845. The area under receiver operating curves in the validation cohort was 0.79 (CI, 0.71–0.88) and 0.85 (CI, 0.72–0.99) at 5 and 10 years. A calibration plot showed a satisfactory calibration function. The model excluding HBeAg status ("ABC model 2") showed a c-index of 0.843.

Conclusion: Incorporating the parabolic association between HBV DNA levels and HCC risk with the risk prediction models for untreated non-cirrhotic CHB patients is reliable for risk estimation. Our novel risk prediction model may help identify patients at high risk but left untreated and serve as a steppingstone to extend treatment indication.

Funding: Patient Centered Clinical Research Project (grant number: HC20C0062) and the National RandD Program for Cancer Control through the National Cancer Center (grant number: HA21C0110), funded by the Ministry of Health and Welfare, Republic of Korea.

THU364

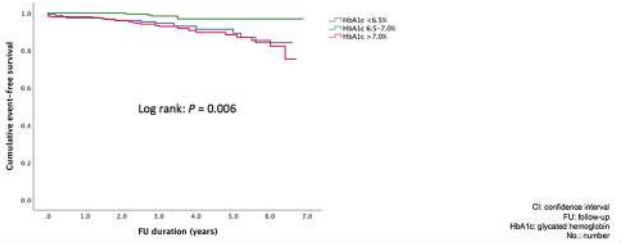
Suboptimal glycemic control is associated with adverse clinical outcomes in patients with chronic hepatitis B and diabetes mellitus

Lung Yi Loey Mak[1,2], Rex Wan-Hin Hui[1], Ka-Shing Cheung[1], Danny Ka-Ho Wong[1,2], Yan Yue James Fung[1,2], Man-Fung Yuen[1,2], Wai-Kay Seto[1,2,3]. *[1]The University of Hong Kong, Medicine, Hong Kong, Hong Kong; [2]The University of Hong Kong, State Key Laboratory of Liver Research, Hong Kong, Hong Kong; [3]The University of Hong Kong-Shenzhen Hospital, Shenzhen, China, Medicine, Shenzhen, China*
Email: loeymak@gmail.com

Background and aims: Diabetes mellitus (DM) is common among patients with chronic hepatitis B infection (CHB) and has been associated with increased risk hepatocellular carcinoma (HCC) and liver decompensation. We investigated the factors associated with adverse clinical outcomes among CHB patients with DM.

Method: 624 Asian CHB patients (64.4% male, 65.1% antiviral-treated for median duration of 5.5 years) who had concomitant DM (median duration of 8.0 years) were prospectively recruited for transient elastography and followed-up (FU) for a median of 3.2 (interquartile range [IQR] 2.9–5.3) years. Adverse clinical outcome was defined as any liver decompensation event including ascites, variceal bleeding, hepatic encephalopathy (HE), HCC, liver transplantation (LT) or death. Variables of interest included age, cigarette smoking, antiviral therapy, liver stiffness (LS), controlled attenuation parameter (CAP), liver function, renal function, and glycemic control as reflected by individual mean glycated hemoglobin (HbA1c) during FU period. Good glycemic control was defined as mean HbA1c 6.5–7.0%. Advanced fibrosis and cirrhosis were defined by LS ≥9.0 and ≥12.0 kPa, respectively for normal alanine aminotransferase (ALT) or ≥12.0 and 13.5 kPa, respectively for raised ALT.

Results: The median age was 62.1 (IQR 56.0–67.9) years old, and 25.2% were smokers or ex-smokers. 17.5% had cirrhosis at recruitment. Mean HbA1c was 6.9%, with 24.0% and 46.3% patients having levels of <6.5% and >7.0% (both are defined as suboptimal glycemic control), respectively. A total of 45 events (HCC, n = 29; ascites, n = 10; variceal bleeding, n = 7; HE, n = 7; death, n = 13; LT, n = 0) were observed during FU. Using multivariate Cox regression analysis, age (hazard ratio [HR] 1.038), smoking history (HR 2.814), LS (HR 1.037), suboptimal glycemic control (HR 3.362) **[**Figure 1**]** and albumin (HR 0.921; all p < 0.05) were independently associated with adverse clinical outcomes, while CAP (HR 0.995, univariate p = 0.082), antiviral therapy (HR 2.311, multivariate p = 0.088) and HBV DNA (HR 1.000, univariate p = 0.65) were not significant variables. For the specific outcome of HCC, multivariate Cox regression showed that smoking history (HR 2.706), LS (HR 1.032) and mean HbA1c >7.0% (HR 2.252; all p < 0.05) were independent variables.



Mean HbA1c	Number at risk							No. of events	Cumulative risk	Hazard ratio (Cox regression)
	Year 0	Year 1	Year 2	Year 3	Year 4	Year 5	Year 6			
<6.5%	150	146	144	98	58	43	19	13	8.7%	4.037 (95% CI 1.316 – 12.388, p=0.015)
6.5-7.0%	185	185	185	142	62	48	25	4	2.2%	1.000 (reference)
>7.0%	289	283	277	204	80	65	28	28	9.7%	4.719 (95% CI 1.654 – 13.477, p=0.004)

Figure: Cumulative event-free survival in Asian CHB patients with DM, stratified by mean HbA1c level. Event was defined as any adverse clinical outcome including ascites, variceal bleeding, hepatic encephalopathy (HE), HCC, liver transplantation (LT) or death.

Conclusion: Suboptimal glycemic control (<6.5% or >7%) and history of cigarette smoking are associated with liver decompensation and HCC in CHB patients with DM.

THU365

Statin use and surface antigen loss in patients with chronic hepatitis B

Shahed Iqbal[1], Ruidong Li[2], Silpa Suthram[2], Jeffrey Wallin[1], James Trevaskis[3], Anastasia Hyrina[4], Simon Fletcher[4], Meghan Holdorf[4]. *[1]Gilead Sciences, Inc., Biomarker Sciences, FOSTER CITY, United States; [2]Gilead Sciences, Inc., Research Data Science, FOSTER CITY, United States; [3]Gilead Sciences, Inc., Fibrosis Biology, FOSTER CITY, United States; [4]Gilead Sciences, Inc., Discovery Virology, FOSTER CITY, United States*
Email: shahed.iqbal1@gilead.com

Background and aims: Statin use has been associated with reduced risk of liver outcomes (e.g., cirrhosis, liver cancer). One explanation is that the lipid composition of hepatitis B surface antigen (HBsAg) contains cellular cholesterol that is modified by statin use. We explored the association between statin use and sAg loss in patients with chronic hepatitis B (CHB).

Method: Adults (≥18 years) with CHB were identified from the IQVIA Ambulatory EMR database using International Classification of Disease (ICD) codes (ICD 9: 070.22–23, 070.32–33, ICD 10: B18.0, B18.1) or by HBsAg positive test. sAg loss was defined by having a negative HBsAg or positive hepatitis B surface antibody test. HIV disease, cancer, long-term steroid use, chronic liver disease, other hepatitis, or pregnancy were exclusion criteria. Statin use was measured using WHO recommended defined daily dose for statin. Multivariate (age, race, sex, statin use) logistic regression was used to determine association between statin use and sAg loss. Due to limited data, virologic measures (e.g., HBV DNA) were not included in the model.

Results: Patients with CHB (N = 12, 314) diagnosed between 2001–2020 were included (mean age: 49.5 years, 47% men). The study comprised Caucasian (39%), Asian (27%), African American (10%) and other races (2%). Mean BMI was 26.1; 17% (n = 2054) of patients had any antiviral use and 4% (n = 505) had sAg loss (median time to sAg loss = 820 [121–4516] days). Current statin use (>28 days during follow-up) was recorded for 11.5% (n = 1421) of patients (2.4% used statin for 1–2 years and 2.2% for >2 years). Compared to no statin use, current statin use of >28–365 days (odds ratio[OR], 95% confidence interval [95% CI] = 1.9, 1.5–2.5), and 1 – 2 years (OR, 95% CI = 2.3, 1.4–3.4) were associated with sAg loss, but >2 years was not (OR, 95% CI = 1.2, 0.6–2.0). Current statin use was also associated with sAg loss (OR, 95% CI = 1.5, 1.2–2.0) after adjusting for age, sex, and race. In a stratified analysis, statin use was associated with sAg loss among patients who did not use antiviral (OR, 95% CI = 2.1, 1.6–2.7) but not among those who did (OR, 95% CI = 0.7, 0.2–1.5).

Table: Statin use and sAg loss in patients with chronic hepatitis B (N = 12, 314)

Variable	Odds Ratio	95% Confidence interval	p-Value
Statin use (yes vs. no)	1.5	(1.2, 2.0)	0.002
Age ≥45 to 65 vs. 18–44 yrs	1.6	(1.3, 2.1)	<0.001
Age ≥65 vs. 18–44 yrs	1.5	(1.1, 2.1)	0.013
Male vs. Female	1.3	(1.0, 1.5)	0.027
African American vs. Caucasians	1.7	(1.3, 2.2)	<0.001
Asian vs. Caucasians	1.1	(0.9, 1.4)	0.317
Other race vs. Caucasians	0.9	(0.4, 1.6)	0.683

Conclusion: In this large cohort of CHB patients, while statin use was associated with spontaneous sAg loss with dose response correlation up to two years of statin use, the interplay between age, virologic parameters, antiviral use, and statins need further research. These findings provide impetus for exploring the therapeutic role of statins in patients with CHB.

THU366

Patient engagement in hepatitis B clinical trials: 'HBV cure' is a motivation for participation in all ethnically diverse patients

Almuthana Mohamed[1], Akudo Nwaogu[1], Dusan Jovovic[1], James Lok[1], Maria Guerra Veloz[1], Khin Aye Wint Han[1], Jeya Anice Sundararaj[1], Andrew Ayers[1], Ivana Carey[1], Kosh Agarwal[1]. *[1]King's College Hospital, Institute of Liver Studies, London, United Kingdom*
Email: almuthana700@gmail.com

Background and aims: Despite advances in treatment, chronic hepatitis B (CHB) remains a global health challenge. Clinical trials are key to the development of novel therapies for 'HBV cure'. Patient enrolment can be challenging, especially in ethnic minorities, with reported participation rates of less than 20%. This study aimed to explore the experiences of patients enrolled in phase I or II CHB clinical trials at our hospital, and their motivation for participation.

Method: In this study, a constructivist research paradigm was implemented with the use of questionnaires as the primary modality of data collection. The questionnaire was carefully designed to contain a mixture of question styles, including open and Likert style questions. Baseline patient characteristics, including age and ethnicity, were also collected. The questionnaire was sent to all individuals enrolled in phase I or II CHB clinical trials at King's College Hospital between 2019 and 2021. Open space answers underwent emergent coding and thematic analysis, whilst the results of the Likert scale questions were expressed as median (± IQR). Quantitative data analysis was performed using SPSS.

Results: Online questionnaires were sent to 83 CHB patients who had recently participated in clinical trials at our hospital and a total of 50 patients responded to our survey (60.3%). The ethnic distribution of

our cohort was representative of our local CHB population spread and the global burden of CHB. As shown in figure 1, the majority of our cohort resided within the Greater London region (80.7%). Most responders to the survey had undergone higher levels of education (86%). However, those from Sub-Saharan Africa were less likely to respond compared to other ethnicities ($p = 0.0048$). Thematic analysis of the qualitative data found that the concept of finite therapy and curative options are key drivers that encourage patients to participate in clinical trials. Whilst most responders to the survey (78%) would participate in future clinical trials, a significant proportion ($n = 12$, 24%) expressed difficulty in attending the extra clinic appointments.

Figure 1: Patient characteristics of all subjects included in analysis

Characteristics	Total Cohort	Responders	Non-responders	P-value
Age (Years)	83	50	33	
18-40	26	17	9	
41-60	41	23	18	
61-65	16	10	6	0.604
Gender				
Male	58	36	22	
Female	25	14	11	0.604
Ethnicity				
Caucasian	18	13	5	
Sub-Saharan African	33	16	17	
Asian	13	12	1	
South Asian	7	1	6	
Other/Mixed	12	8	4	0.0048
Level of Education				
Primary School	-	1	-	
Secondary school	-	7	-	
College Degree	-	10	-	
Undergraduate Degree	-	19	-	
Postgraduate Degree	-	14	-	
Geographic Distribution				
Within Greater London	67	37	30	
Outskirts of London	16	13	3	0.0559

Conclusion: 'HBV cure' is a motivation for patients' participation in early phase clinical trials. Whilst most patients are happy to be re-involved in clinical trials, provisions must be taken to minimise the potential disruption of extra clinic appointments. Further work needs to be done in wider education for CHB patients to optimise participation in clinical trials.

THU367

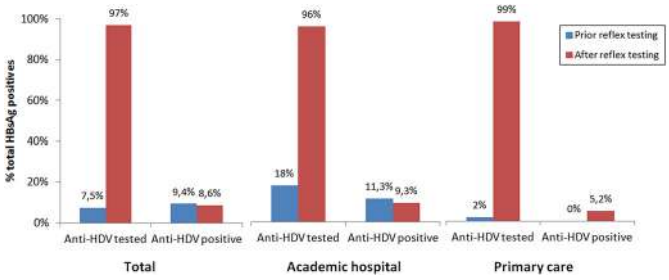
Anti-HDV reflex testing increases the number of hepatitis D cases diagnosed in both academic and community centers

Adriana Palom[1], Ariadna Rando-Segura[2], Francisco Rodríguez-Frías[2,3], Ana Barreira[1,3], Jordi Llaneras[1], Mar Riveiro Barciela[2,3], Rafael Esteban[1,3], Maria Buti[1,3]. [1]*Hospital Vall Hebron, Liver Unit, Barcelona;* [2]*Hospital Vall Hebron, Department of Microbiology, Barcelona;* [3]*Centro de investigación biomédica en red de enfermedades hepáticas y digestivas, Madrid*
Email: mbuti@vhebron.net

Background and aims: Although EASL guidelines recommend anti-HDV testing in all HBsAg-positive individuals, HDV still remains underdiagnosed. In a study in Barcelona (Spain) in a catchment population of 400, 000 inhabitants, only 9.4% of HBsAg-positive (HBsAg+) patients were tested for anti-HDV (Palom *et al.* AASLD 2021). We describe the initial results of a nontargeted HDV screening program using anti-HDV reflex testing of all HBsAg+ individuals and compare the results with those obtained before implementation of this strategy.

Method: We reviewed 2144 consecutive HBsAg+ samples sent to a central laboratory (January 2018–October 2021). Before reflex testing, we determined the rate of anti-HDV testing in 1553 HBsAg+ samples (January 2018–December 2020). Prospective anti-HDV reflex testing was done in all HBsAg+ serum samples (January to October 2021). Demographics and clinical characteristics were recorded in patients testing anti-HDV, including HDV-RNA.

Results: Before implementation of anti-HDV reflex testing, anti-HDV had been tested in 7.5% (117/1553) of HBsAg+ individuals: 18% (97/532) of those attending an academic hospital and only 2% (20/1021) of those in primary care centers. After starting reflex testing, 97% (572/591) were tested for anti-HDV: 96% (475/493) attending an academic hospital and in 99% (97/98) in primary care. (Figure 1).



The overall prevalence of anti-HDV+ among those tested was similar before and after reflex implementation: 9.4% (11/117) and 8.6% (49/572), respectively. However, the absolute number of patients diagnosed with HDV increased from 3 cases in 2018, 2 cases in 2019 and 6 cases in 2020, to 49 cases in 10 months of 2021. Among 56 anti-HDV+ patients, HDV-RNA was detectable in 33 (66%) of 50 tested. HDV-RNA positive patients were more likely to be young, white, and HBeAg-negative, 69% had undetectable HBV-DNA and 58% elevated ALT.

Conclusion: In summary, anti-HDV reflex testing in all HBsAg+ individuals led to 5-fold increase in chronic hepatitis D diagnoses. Before reflex testing, a large percentage of HBsAg+ individuals were not tested for anti-HDV, particularly in primary care centers. The cost-effectiveness of anti-HDV reflex testing should be evaluated to inform testing guidelines.

THU368

HBVoice: a framework to enhance advocacy for patients and communities affected by hepatitis B virus infection

[1]*The Francis Crick Institute, London, United Kingdom;* [2]*Nottingham University Hospitals NHS Trust Queen's Medical Centre Campus, United Kingdom;* [3]*World Hepatitis Alliance, United Kingdom;* [4]*Barts Health NHS Trust, United Kingdom;* [5]*Royal Free London NHS Foundation Trust, United Kingdom;* [6]*Waverley Care Milestone, United Kingdom;* [7]*Mortimer Market Centre, United Kingdom;* [8]*Find and Treat, University College Hospitals, London, United Kingdom;* [9]*Rutgers Robert Wood Johnson Medical School, New Brunswick, United States;* [10]*Yellow Warriors Society of the Philippines, Inc.;* [11]*British Liver Trust, United Kingdom;* [12]*Sheffield Children's NHS Foundation Trust, United Kingdom;* [13]*Hepatitis B Foundation, Doylestown, United States;* [14]*University Hospitals Birmingham, United Kingdom;* [15]*Global Health-Trasplante Capilar en Turquia-1.960 €, Barcelona, Spain*
Email: philippa.matthews@crick.ac.uk

Background and aims: Hepatitis B virus (HBV) is hidden from public view, with a long history of stigma and neglect, despite an estimated 300 million individuals being chronically infected worldwide. To make progress towards WHO elimination targets, it is essential to improve awareness of HBV among patients, the public, healthcare workers, funders, industry, academia and policy makers. As new HBV drugs enter clinical trials, the engagement of a diverse community is urgently required to deliver studies that engage and represent real-world populations. We present the rationale and groundwork for a

new network, 'HBVoice', to increase HBV patient representation. Our aim is to develop this activity by promoting dialogue, connecting to a wider community and relevant stakeholders, and stimulating engagement between sectors.

Method: We have drawn on the published literature and data, and personal testimony in the public domain, alongside dialogue with patients, The British Liver Trust, Hepatitis B Foundation and the World Hepatitis Alliance. Context is also provided by the first externally led patient forum focused on HBV, convened by the Hepatitis B Foundation in partnership with the U.S. Food and Drug Administration (FDA) in 2020.

Results: We have established an expanding interdisciplinary group, representing healthcare workers, academia, non-governmental organisations, and people living with HBV. We are expanding to increase reach into diverse communities and sectors, and to identify and promote HBV champions. Our developing portfolio of activities includes hosting webinars, sharing lived experience of HBV infection, linking the HBV community to opportunities for involvement in clinical research, production of educational materials, political advocacy, and developing plans for industry funding to support a sustainable platform for patient engagement.

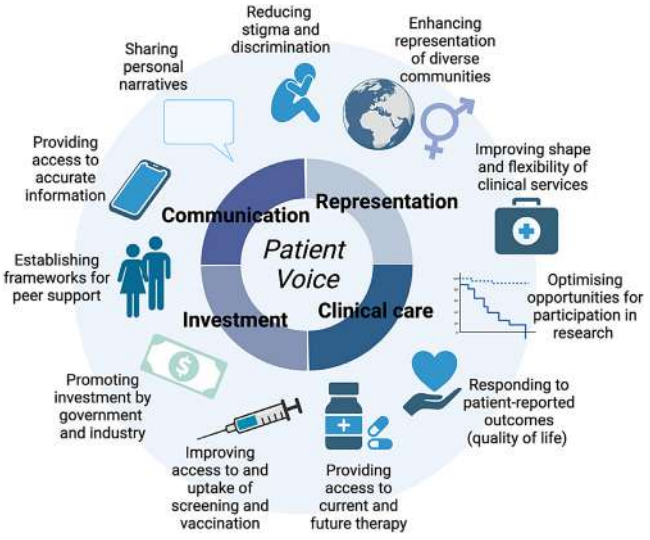


Figure: Aims of 'HBVoice' network

Conclusion: We highlight the urgent need for patient voice to represent HBV infection, supported by interdisciplinary professionals. Sharing experiences of HBV infection will inform awareness and education, and build partnerships to support enhanced clinical care, public health initiatives, policy and funding, and patient-centric research. We will provide a platform through which the substantial physical, emotional and psychosocial impacts of HBV infection can be better addressed, supporting advances towards 2030 elimination goals.

THU369

HBeAg-positive patients with HBsAg < 135IU/ml or HBcrAg < 3.6logU/ml have more chance to be HBsAg loss after nucleos (t)ide analogue cessation

Yandi Xie[1], Minghui Li[2], Xiaojuan Ou[3], Sujun Zheng[4], Yinjie Gao[5], Xiaoyuan Xu[6], Ying Yang[7], Anlin Ma[8], Jia Li[9], Lai Wei[10], Yuemin Nan[11], Huanwei Zheng[12], Bo Feng[1]. *[1]Peking University People's Hospital, Peking University Hepatology Institute, Beijing, China; [2]Beijing Ditan Hospital, Capital Medical University, Department of Hepatology Division, Beijing, China; [3]Beijing Friendship Hospital, Capital Medical University, Liver Research Center, Beijing, China; [4]Beijing Youan Hospital, Capital Medical University, Complicated Liver Diseases and Artificial Liver Treatment and Training Center, Beijing, China; [5]The Fifth Medical Center, General Hospital of PLA, Department of Infectious Diseases, Beijing, China; [6]Peking University First Hospital, Department of Infectious Diseases, Beijing, China; [7]The Second Hospital of Xingtai, Department of Infectious Diseases, Xingtai, China; [8]China-Japan Friendship Hospital, Department of Infectious Diseases, Beijing, China; [9]Tianjin Second People's Hospital, Department of Liver Disease, Tianjin, China; [10]Beijing Tsinghua Changgung Hospital, School of Clinical Medicine, Tsinghua University, Department of Hepatopancreatobiliary Disease, Beijing, China; [11]The Third Hospital of Hebei Medical University, Department of Traditional and Western Medical Hepatology, Shijiazhuang, China; [12]Shijiazhuang Fifth Hospital, Department of Liver Disease, Shijiazhuang, China*
Email: xyfyfb_1@sina.com

Background and aims: Cessation of nucleos (t)ide analogue (NAs) may increase hepatitis B virus (HBV) surface antigen (HBsAg) loss rate in chronic hepatitis B (CHB) patients. We aimed to identify predictor of HBsAg loss using serum quantitative HBsAg, HBV RNA and hepatitis B core-related antigen (HBcrAg) in CHB patients who stopped NAs treatment.

Method: Initially HBV e antigen (HBeAg)-positive CHB patients without cirrhosis who met the stopping criteria were included in 12 hospitals in China. Enrolled patients ceased NAs and were followed up with clinical and laboratory assessments every 3 months for 24 months after NAs cessation or until clinical relapse (CR).

Results: This is a multicenter prospective cohort study, in which 158 patients were included. Patients were divided into two groups according to the HBsAg status when NAs cessation. Group A included patients with HBsAg positive when NAs cessation (n = 139) and Group B included patients with HBsAg negative when NAs cessation (n = 19). In Group A, the 12-month and 24-month cumulative rates of HBsAg loss were 4.3% and 9.4%, respectively. End of treatment (EOT) HBsAg (hazard ratio (HR) = 0.152, p < 0.001), EOT HBcrAg (HR = 0.257, p = 0.001) were found to independently predict possibility of HBsAg loss. To predict HBsAg loss, the area under the receiver operating characteristic (AUROC) value of the EOT HBsAg and HBcrAg were

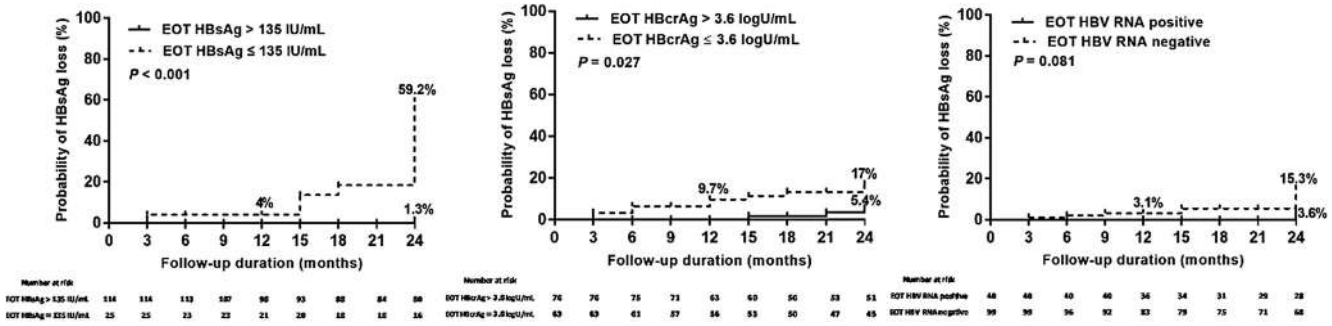

Figure 1: (abstract: THU369): Cumulative incidences of hepatitis B surface antigen (HBsAg) loss stratified by end of treatment (EOT) HBsAg, hepatitis B core-related antigen (HBcrAg) and hepatitis B virus (HBV) RNA in Group A patients.

0.952 (p <0.001) and 0.765 (p <0.001), respectively. Cumulative rates of HBsAg loss stratified by EOT HBsAg, HBV RNA or HBcrAg levels, results showed that patients with EOT HBsAg ≤ 135 IU/ml (59.2% vs 1.3%, P < 0.001) or HBcrAg ≤ 3.6 logU/ml (17% vs 5.4%, P = 0.027) had higher 24-month cumulative HBsAg loss rate. In Group B, none of the patients had virological relapse (VR) or CR after NAs cessation. Only 1 (5.3%) patient had HBsAg reversion with HBV DNA detectable but less than 2000 IU/ml and without ALT elevation.

Conclusion: Some patients may get HBsAg loss after NAs cessation. An EOT HBsAg ≤ 135 IU/ml or HBcrAg ≤ 3.6 logU/ml, identified a patient with more chance to be HBsAg loss after NAs cessation. Patients with HBsAg negative when NAs cessation had a low risk of HBsAg reversion after NAs discontinuation.

THU370

Serum markers of cccDNA transcriptional activity (HBcrAg and pre-genomic HBV RNA) and large HBsAg (LHBs) protein are predicting response to pegylated interferon in HDV infection

Ivana Carey[1], Mark Anderson[2], Christiana Moigboi[1], Gavin Cloherty[2], Geoffrey Dusheiko[1], Kosh Agarwal[1]. *[1]King's College Hospital, Institute of Liver Studies, London, United Kingdom; [2]Abbott Diagnostics, Department of Infectious Diseases, North Chicago, United States*
Email: ivana.kraslova@kcl.ac.uk

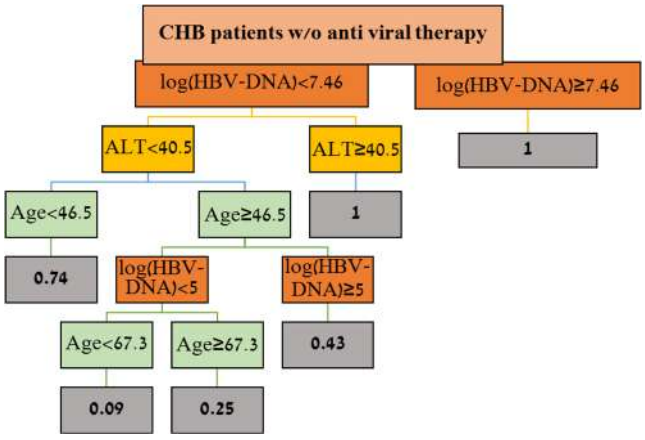
Background and aims: Hepatitis delta virus (HDV) requires HBsAg envelope for propagation. The large, (LHBs), containing preS1+preS2 +S mediates HBV attachment to the NTCP receptor. A response to pegylated-interferon (Peg-IFN) treatment is achieved in less than 50% of patients, and unless HBsAg loss is achieved, patients are at a risk of late relapse. We aimed to compare baseline and post treatment virological serum biomarkers (total HBsAg and LHBs levels, HBcrAg and pgRNA concentrations, HDV genotypes and HDV RNA viral load) in HDV-positive responders versus non-responders (NR) to Peg-IFN.
Method: Serum samples of 33 HDV RNA-positive patients (median age 38 yrs, 21 (63%) males, 2 (6%) HBeAg+, 12 (36%) with compensated cirrhosis) were tested at the start and 3 years after completing therapy for the following markers: total HBsAg levels by Abbott Architect [IU/ml], LHBs levels by in-house ELISA [ng/ml and % of total HBsAg], HBcrAg by CLEIA Fujirebio [log_{10}U/ml] and pgRNA by real-time PCR Abbott Molecular Diagnostic RUO assay (LLQD = 1.65 log_{10}U/ml), HDV RNA by in-house real-time PCR assay (LLQD = 640 IU/ml) and HDV genotypes by direct sequencing. The outcome was correlated with the concentrations of these biomarkers. All results are shown as medians.
Results: 3 years post Peg-IFN therapy, 15 (45%) patients were HDV RNA negative (responders), (2 patients with HBsAg loss), whereas 18 patients had persistent HDV RNA (NR). Age and total HBsAg levels (6801 vs. 8326 IU/ml, p = 0.16) at baseline were similar in responders and NR. Responders were less likely to have cirrhosis (13% vs. 55%, p = 0.03) and were infected with HDV genotype 5 (93% vs. 27%, p < 0.01). PEG-IFN responders had significantly lower baseline levels of LHBs (20607 vs. 81106; 7.6% vs. 19%, p < 0.01), HBcrAg (3.1 vs. 4.3, p < 0.01), pgRNA (1.7 vs. 2.3, p = 0.04) and HDV RNA (23, 300 vs. 671, 000, p = 0.016) levels than NR. Total HBsAg (6801 to 452, p < 0.01), as well as LHBs (20806 to. 4316, 7.6% to 2.4%, p < 0.01), HBcrAg (3.1 to 2.2, p < 0.01) and pgRNA (1.7 vs. undetectable, p < 0.01) reduced significantly in responders. In NR, although we observed a decline in LHBs levels (81106 to 39506; 19% to 11.5%, p < 0.05), HBcrAg (4.3 to 3.4, p < 0.01) and pgRNA (2.3 to 1.72, p < 0.01) these did not reach median baseline levels seen in responders. Total HBsAg and HDV RNA did not change significantly from the start of treatment in NR.
Conclusion: Lower baseline levels of LHBs, HDV RNA, HDV genotype 5 and lower concentrations of markers of cccDNA transcriptional activity were associated with response to Peg-IFN. Transcriptional changes induced by PEG-IFN may reduce LHBs and HDV assembly and thus spreading of hepatitis D. Measurement of cccDNA transcriptional activity and the LHBs isoform may be of greater utility than total HBsAg in predicting a response to PEG-IFN in HDV infection and could be considered before PEG-IFN therapy for HDV.

THU371

A decision-making model for prediction of a stable disease course in chronic hepatitis B patients

Imri Ofri[1,2], Noam Peleg[3], Moshe Leshno[4], Amir Shlomai[1,2]. *[1]Rabin Medical Center, Beilinson Hospital, Department of Medicine D, Petah Tikva, Israel; [2]Tel Aviv University, The Sackler Faculty of Medicine, Tel Aviv, Israel; [3]Rabin Medical Center, Beilinson Hospital, The Institute of Gastroenterology, Petah Tikva, Israel; [4]Tel Aviv University, The Coller Faculty of Management, Tel Aviv, Israel*
Email: ofriimri@gmail.com

Background and aims: Patients with chronic Hepatitis B (CHB) infection are regularly monitored for HBV DNA and liver enzyme levels in order to assess disease progression and the need for antiviral therapy. Identifying patients with a stable course of disease (i.e long-lasting low HBV DNA and normal liver enzymes) can potentially prolong the intervals between visits, withhold unnecessary tests, resulting in reduced expanses. Accordingly, we aimed to find predictors for a stable disease course in patients with CHB.
Method: An inception cohort of 579 patients with CHB, who were followed in a tertiary referral center between January 2004 to December 2018, was retrospectively analyzed. Patients with low and steady viral load titer (<2000 IU/ml) and normal ALT levels (<40 IU/ml) in 6 consecutive clinic encounters were considered to have a stable course of CHB. A stepwise multivariate logistic regression analysis and a random forest decision tree model were used to identify predictors of a stable disease course.
Results: Following exclusion for various reasons, a total of 220 patients, with no active anti-viral treatment, were included in the final analysis. 64 had a stable disease course, whereas 156 had an unstable course. Patients with a stable disease were older and had lower baseline levels of AST, ALT and HBV DNA. In a multivariate analysis, age (OR 0.95, 95% CI 0.928–0.986), baseline ALT (OR 1.083, 95% CI 1.041–1.127) and Log HBV-DNA (OR 1.056 95% CI 1.032–1.08), were significantly associated with a stable disease. In a decision tree model, patients between 46–67 years old, with Log HBV-DNA below 5 IU/ML and ALT below 40.5 IU/ML had the best probability (0.91) for a stable disease course.



Conclusion: Integrating baseline viral DNA, ALT levels and patients' age can predict the disease course in patients with CHB. Thus, stratification of CHB patients according to these simple parameters can determine the required intervals between scheduled clinic visits and may economize patients' management.

Healthcare resource utilization and costs of hepatitis delta in the United States: an analysis of all-payer claims database

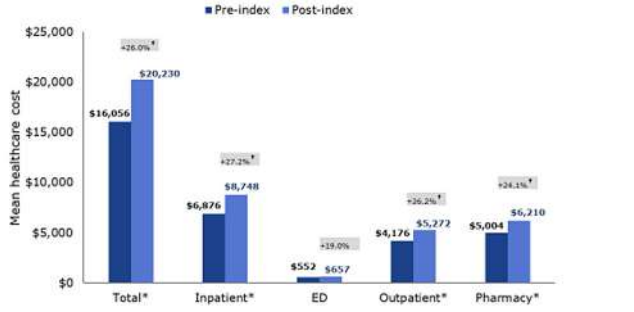
Joseph Lim[1], Vinod Rustgi[2], Robert G. Gish[3,4], Ira M Jacobson[5], Ankita Kaushik[6], Yan Liu[6], Emily Acter[7], Robert Wong[8]. [1]*Yale School of Medicine, New Haven, United States;* [2]*Rutgers Robert Wood Johnson Medical School, New Brunswick, United States;* [3]*University of Nevada, Reno School of Medicine, Kirk Kerkorian School of Medicine at UNLV, Las Vegas, United States;* [4]*UC San Diego Skaggs School of Pharmacy and Pharmaceutical Sciences, Hepatitis B Foundation, La Jolla, United States;* [5]*NYU Grossman School of Medicine, New York, United States;* [6]*Gilead Sciences, Inc., Foster City, United States;* [7]*STATinMED, Plano, United States;* [8]*Stanford University School of Medicine, Stanford and VA Palo Alto Healthcare System, Palo Alto, United States*
Email: joseph.lim@yale.edu

Background and aims: Hepatitis delta is the most severe form of viral hepatitis, causing rapid progression to advanced liver disease. Hepatitis delta is caused by the hepatitis D virus (HDV), a defective RNA virus that requires the presence of the hepatitis B surface antigen (HBsAg) for its complete replication and transmission. This study assesses the healthcare resource utilization and costs associated with HDV infection among adults with chronic HBV infection in the United States (US).

Method: Using the All-Payer Claims Database (APCD), adult patients (≥18 years) with ≥1 inpatient claim or ≥2 outpatient claims spaced ≥30 days apart for HDV infection based on ICD-9/10-CM diagnosis codes were identified from 01/01/2015 to 12/31/2019. Patients were required to have ≥12 months continuous enrolment before and after their first date of HDV infection diagnosis in the study period. All-cause healthcare-related resource utilization and costs were assessed in the 12 months pre- and post-HDV diagnosis period.

Results: Among 6, 719 adults with HDV who met inclusion criteria, mean total number of all-cause healthcare utilization claims were significantly greater in the postdiagnosis than pre-diagnosis period (20.3 vs 15.9, $p < 0.0001$). Patients had more inpatient admissions (mean, 1.6 vs 1.3, $p < 0.0001$), emergency department visits (mean, 1.1 vs 0.9, $p < 0.0001$), outpatient visits (mean, 10.6 vs 7.9, $p < 0.0001$), and pharmaceutical claims (mean, 8.2 vs 6.7, $p < 0.0001$) postdiagnosis compared to prediagnosis. Furthermore, the mean total annual cost of healthcare services (Figure 1) was significantly greater postdiagnosis than prediagnosis (mean, $20, 230 vs $16, 056, $p < 0.0001$), including inpatient admissions (mean, $8, 748 vs $6, 876, $p < 0.0001$), outpatient visits (mean, $5, 272 vs $4, 176, $p < 0.0001$), and pharmaceutical claims (mean, $6, 210 vs $5, 004, $p < 0.0001$). Mean emergency department costs were $657 vs $552 ($p = 0.4346$).

Figure 1: Annual Healthcare Costs Pre- and Post-index Diagnosis Among HDV-infected Adults by Cost Category (n = 6,719)



NOTE: ED: Emergency department; An asterisk indicates a statistically significant difference ($p < 0.05$)

Conclusion: In a large national US healthcare claims database, representing ~80% of the US insured population, patients experienced significantly greater overall healthcare resource utilization and costs following diagnosis of HDV infection. These findings underscore a need for more effective strategies for the screening, diagnosis, and treatment of HDV, which may translate into cost savings for the healthcare system.

THU373

Validation of an internal hepatitis D virus DNA quantitative assay: developing assay suitable for global clinical application and clinical trials assessment

Natalie Bolton[1], Dazhuang Shang[1], Kosh Agarwal[1], Ivana Carey[1]. [1]*King's College Hospital, Institute of Liver Studies, London, United Kingdom*
Email: natalie.bolton@nhs.net

Background and aims: Patients co-infected with both hepatitis B virus (HBV) and hepatitis D virus (HDV) have an increased risk of developing severe liver disease. HDV displays high genetic diversity, with previous studies identifying eight distinct genotypes. Robust, standardised assays for quantifying HDV viral load are needed to assess treatment impact, including standardisation of viral load reported units; two units currently used are copies/ml and international units (IU)/ml, with differing correction factors between these. This retrospective study aimed to assess the quality of an existing internal, pan-genotypic HDV RNA quantitative nucleic acid amplification test (NAAT), utilising the World Health Organisation (WHO) HDV international standard (WHO-HDV-IS), in a diverse South London population.

Method: Data was collected on 163 specimens taken from 89 HBV and HDV co-infected patients between January 2020 and October 2021, with HDV infection confirmed by a positive result on DIA.PRO Delta Ab (Total) assay. HDV viral load was quantified using an internal HDV RNA quantitative assay (Cobas® TaqMan® 48). Assay quality was assessed each run by inclusion of one negative internal control, two positive internal controls (low and high viral load dilutions of the same patient specimen), and the WHO-HDV-IS (genotype 1). Results for the WHO-HDV-IS were analysed using a previously described calculation to determine the correction factor for the assay. HDV genotyping was performed by direct sequencing and phylogenetic tree analysis using neighbor-joining distances analyses software.

Results: 84 (52%) of samples had a viral load below the limit of detection of the HDV RNA quantitative assay (6.40×10^2 copies/ml) whilst 5 (3%) did not have viral load analysed. Within the remaining 74 (45%) samples with quantifiable viral load the median HDV RNA level was 1.31×10^5 copies/ml. 40 (45%) and 36 (40%) of the patients were infected with genotype 1 and genotype 5 HDV, respectively. The internal low and high positive controls were found to be genotype 5. The correction factor calculation determined that the correction factor for the in-house HDV RNA quantitative assay was 1.06, meaning the limit of detection can be recalculated from 6.40×10^2 copies/ml to 6.76×10^2 IU/ml.

Conclusion: The correction factor of 1.06 shows that our internal HDV RNA quantitative NAAT calibrates extremely well in comparison with the WHO-HDV-IS. Despite the WHO standard derivation from genotype 1 HDV (the most prevalent genotype worldwide), our assay accurately quantitates HDV RNA in genotype 5 patients. More work is needed in the future to improve sensitivity and further standardize pan-genotypic HDV RNA quantification, in particular the introduction of a panel of standards across genotypes 1–8. Developing standardized assays suitable for HDV RNA quantitation in clinical trials of new therapeutic agents is an urgent need.

THU374

Early increase in HBcrAg levels after peginterferon withdrawal predicts subsequent ALT flares

Sylvia Brakenhoff[1], Andre Boonstra[1], Robert De Man[1], Bettina Hansen[2], Robert De Knegt[1], Harry Janssen[1,2], Milan Sonneveld[1]. [1]*Erasmus MC, Gastroenterology and Hepatology, Rotterdam, Netherlands;* [2]*Toronto Western and General Hospital, Toronto Center for Liver Disease*
Email: s.brakenhoff@erasmusmc.nl

Background and aims: Chronic hepatitis B (CHB) patients are at risk for ALT flares after antiviral therapy withdrawal. Since serum levels of hepatitis B core-related antigen (HBcrAg) and HBsAg may reflect intrahepatic transcriptional activity, we hypothesized that early post-treatment kinetics could predict off-treatment ALT flares.
Method: We included HBeAg-positive CHB patients who achieved HBeAg loss after one year of peginterferon (± lamivudine) treatment. Serum HBV DNA, HBcrAg and HBsAg were quantified at end of treatment (EOT) and at weeks 8 and 12 post-treatment; the peak value was used for analysis. An ALT flare was defined as ALT ≥5x ULN during the first 6 months after EOT.
Results: A total of 67 patients were included, the majority of whom were Caucasian (78%) and had HBV genotype A/D (52/27%). ALT flares occurred in 18%, after a median of 20 weeks (IQR 20–24). Patients who experienced flares had a median post-treatment HBcrAg increase of 0.71 log, compared to a decline of 0.19 log in patients without a flare ($p = 0.003$). Among patients with an HBcrAg increase of >0.5 log, 53% experienced a flare, versus 8% of the patients without an HBcrAg increase ($p < 0.001$). In contrast, HBsAg kinetics were not associated with ALT flares ($p = 0.313$). As expected, patients with flares also experienced a more prominent HBV DNA rebound; we observed a median HBV DNA increase of 4.79 log vs 0.66 log in patients with and without flares ($p = 0.005$). Among patients with an HBV DNA increase of >3 log, 60% experienced a flare, versus 8% of the patients with <3 log HBV DNA increase. Patients with both HBcrAg and HBV DNA increase experienced a flare in 86% versus 8% in patients without a concomitant increase ($p < 0.001$). Consistent results were observed in the subset of patients with HBV DNA <200 IU/ml at EOT (n = 36), 67% of the patients with an HBcrAg increase >0.5log experienced a flare, compared to 4% of patients without an HBcrAg increase ($p < 0.001$).
Conclusion: Early increase in HBcrAg levels after therapy withdrawal predicts subsequent ALT flares, and a combined increase of HBcrAg and HBV DNA identifies patients at very high risk of flares. These findings suggest that HBcrAg could be used to guide off-treatment follow-up. Our findings warrant further confirmation among patients treated with other finite treatment regimens.

THU375

Hepatitis B pre-genomic RNA differentiates HBeAg-negative disease from infection: time to refine disease stages with new biomarkers?

Bo Wang[1], Mark Anderson[2], Natalie Bolton[1], Christiana Moigboi[1], James Lok[1], Gavin Cloherty[2], Ivana Carey[1], Geoffrey Dusheiko[1], Kosh Agarwal[1]. [1]*King's College Hospital, Institute of Liver Studies, United Kingdom;* [2]*Abbott Laboratories, Lake Bluff, United States*
Email: bo.wang@nhs.net

Background and aims: Hepatitis B core-related antigen (HBcrAg) and hepatitis B pre-genomic RNA (HBV RNA) are serological biomarkers of cccDNA transcription in patients with hepatitis B virus (HBV) infection. We examined the potential of these markers to differentiate HBeAg-negative disease from HBeAg-negative infection.
Method: In this single-centre retrospective case-control study, HBeAg-negative patients followed for 5 years from 2014 were grouped by whether they started treatment with a nucleos (t)ide analogue. Baseline characteristics including patient demographics, ALT, liver disease stage, and virological data (HBV DNA, quantitative HBsAg, HBcrAg and HBV RNA) were collated. Statistical analysis was performed to examine differences between the groups and assessed the predictive value of viral markers.
Results: 199 patients were included in the study, with a mean age of 40 years and infected with a range of HBV genotypes (A-11%, B-5%, C-7%, D-17%, E-51%). 62% were male. 111 patients remained untreated for 5 years and were defined as having HBeAg-negative infection, whereas 88 patients started treatment for ostensible HBeAg-negative disease. Our analysis showed significant differences at baseline between the groups (table). A logistic regression analysis showed only HBV DNA and HBV RNA to be significant separators of these HBeAg-negative states. However, the odds ratio for HBV DNA was 2.0 ($p = 0.006$) and for HBV RNA was 10.1 ($p < 0.001$). ROC curve analysis showed these variables to be a good model for prediction, with AUROC of 0.90 (95% CI 0.85–0.95). HBV RNA concentration <1.65 U/ml (i.e. below lower limit of quantification) when HBV DNA was between 2000–20, 000 IU/ml (so called "grey zone") had 92.3% sensitivity for identifying inactive HBeAg-negative infection.

Table: Baseline characteristics, median (range).

	HBeAg-negative infection (n = 111)	HBeAg-negative disease (n = 88)	P
ALT IU/L	23 (5–121)	40 (10–253)	<0.001
Mean liver stiffness kPa	4.5 (2.5–8.7)	6.2 (3.7–21.3)	0.001
HBV DNA logIU/ml	2.62 (0.00–5.59)	4.01 (1.37–6.85)	<0.001
qHBsAg logIU/ml	3.51 (0.15–4.59)	3.54 (1.89–4.99)	0.296
HBcrAg logU/ml	2.80 (2.00–5.60)	3.90 (2.00–6.20)	<0.001
HBV RNA logU/ml	0.00 (0.00–1.99)	2.12 (0.00–4.84)	<0.001

Conclusion: Serum HBV RNA in addition to HBV DNA provides an excellent discriminator between HBeAg-negative phases. This study demonstrates the potential of a single-point HBV RNA measurement to unequivocally define an indication to start treatment reducing uncertainty. As HBV RNA measurement at current levels of sensitivity reflects ongoing cccDNA transcription, the biomarker provides an additional tool to refine disease status and aid treatment decisions.

THU376

Evaluating hepatitis delta virus disease prevalence and patient characteristics among adults in the United States: an analysis of all-payer claims database

Robert G. Gish[1,2], Ira M Jacobson[3], Joseph Lim[4], Ankita Kaushik[5], Yan Liu[5], Anissa Cyhaniuk[6], Robert Wong[7]. [1]*University of Nevada, Reno School of Medicine, Kirk Kerkorian School of Medicine at UNLV, Las Vegas, United States;* [2]*UC San Diego Skaggs School of Pharmacy and Pharmaceutical Sciences, Hepatitis B Foundation, La Jolla, United States;* [3]*NYU Grossman School of Medicine, New York, United States;* [4]*Yale School of Medicine, New Haven, United States;* [5]*Gilead Sciences, Inc., Foster City, United States;* [6]*STATinMED, Plano, United States;* [7]*Stanford University School of Medicine, Stanford and VA Palo Alto Healthcare System, Palo Alto, United States*
Email: rgish@robertgish.com

Background and aims: Hepatitis delta virus (HDV) infection leads to the most severe form of viral hepatitis and is always associated with hepatitis B virus (HBV) infection. This study estimates the prevalence and describes patient characteristics for HDV-infected adults in the US using real-world insurance claims data.
Method: Adults (≥18 years) with ≥1 inpatient claim or ≥2 outpatient claims (ICD-9/10-CM diagnosis codes) ≥30 days apart for HDV infection or HBV monoinfection in the All-Payer Claims Database from 1/1/2014 to 12/31/2020 (study period) were identified. Prevalence was the proportion of HDV-infected among HBV-infected patients. Patient characteristics were reported for a subcohort of patients with HDV. The HDV index date was defined as the first HDV diagnosis from 1/1/2015 to 12/31/2019 with ≥12 months pre- and post-diagnosis continuous enrolment. Patient characteristics included age, gender, race, geographic region, and payer type. Socioeconomic status data captured annual household income and

education. Comorbidities were assessed over the 12-months pre-index (baseline) period.
Results: Among 194, 573 adults with HBV, 9, 376 (4.8%) were coinfected with HDV. Among 6, 719 adults in the HDV subcohort, mean age was 51.9 ± 15.1 years, mean Charlson Comorbidity score was 1.7 ± 2.3, 50.5% were female; 44.9% lived in the north-central and 23.7% in the northeast region of US. Among those with available data on race and socioeconomic status, the majority were white (48.8%), followed by black (36.6%) and Asian (13.7%); mean annual household income was $41, 515 (± $44, 697); 64.0% had high school as the highest education category. Patients most commonly had commercial insurance (42.7%), followed by Medicaid (34.2%), or Medicare (19.9%). At Baseline, 16.3% of patients had compensated cirrhosis, 10.4% had decompensated cirrhosis, 2.8% had liver cancer, and 2.2% had liver transplant. Diabetes (50.5%), hypertension (49.8%), HIV infection (30.9%), substance abuse (28.7%), and smoking history (28.1%) were the top five comorbidities.
Conclusion: Among a large database capturing approximately 80% of the US insured population, HDV infection prevalence was 4.8% among HBV-infected adults. HDV-infected patients had high rates of baseline comorbidities and liver complications. Earlier identification of HDV infection among HBV-infected patients may provide opportunities to reduce the risk of liver-related morbidity and mortality.

THU377
Hepatitis delta in Northern Portugal-a long-term follow-up study

Isabel Garrido[1], Rodrigo Liberal[1], Sofia Teixeira[1], Carmo Koch[1], Guilherme Macedo[1]. [1]*São João Universitary Hospital Center, Porto, Portugal*
Email: isabelmng@hotmail.com

Background and aims: Hepatitis delta virus (HDV) occurs worldwide but prevalence data are limited due to inaccurate reporting and delayed detection. In fact, no data are available on the epidemiologic status of HDV infection in Portugal. In addition, long-term data on clinical follow-up is limited. This study aimed to investigate the prevalence, clinical features and long-term outcomes of a cohort of Portuguese patients with HDV infection.
Method: All adult patients diagnosed with hepatitis B virus (HBV) infection in the past 10 years at Centro Hospitalar Universitário de São João were retrospectively evaluated. Demographic and laboratory data of those with HDV infection were assessed.
Results: Five hundred and eighty individuals tested positive for hepatitis B surface antigen HBsAg (HBsAg) between January 2010 and December 2020. Twenty patients (3.4%) had also positive anti-HDV antibodies. Of these, most were male (80%), former injection drug users (55%) and native Portuguese (70%). The median age was 42 years old (IQR 33–47). Positive serum hepatitis B e-antigen was present in 3 (15%) patients and 6 (30%) had undetectable HBV-DNA. Tenofovir was prescribed as antiviral therapy in 40% of individuals and entecavir in 15%. Coinfection with human immunodeficiency virus was found in 9 (45%) patients, and 6 (30%) had hepatitis C virus antibodies. It is noteworthy that since year 2011 the rate of HDV diagnosis significantly decreased. Although 7 (35%) patients had cirrhosis at the time of diagnosis, only one of them had hepatic decompensation during follow-up, and eventually died. Patients were followed for a period of 5 years (IQR 2–10). They were periodically screened for hepatocellular carcinoma and none of them developed it. The majority of individuals (95%) had stable disease or improved outcomes during follow-up. Interestingly, 4 (20%) patients have cured HBV infection. The overall survival rate of this cohort was 90%.
Conclusion: The prevalence of chronic hepatitis delta is currently very low (<5%) among positive HBsAg carriers in Portugal, with lower rates in recent years. We show that HDV infection has favorable outcomes, assuming adherence to therapy and lack of other insults to their liver, and an adequate quality of life can be achieved, resulting in longer overall survival. Therefore, HDV co-infection does not seem to have a significant clinical impact in Portuguese patients.

THU378
Impact of hepatitis B virus infection on liver-related death among people tested for HBV in British Columbia: results from a large longitudinal population-based cohort study

Makuza Jean Damascene[1,2,3], Dahn Jeong[1,2], Mawuena Binka[2], Prince Adu[2], Sofia Bartlett[2], Amanda Yu[2], Stanley Wong[2], Georgine Cua[1,2], Hector Velasquez[1,2], Maria Alvarez[2], Mel Krajden[2], Mohammad Ehsanul Karim[1], Naveed Janjua[1,2]. [1]*The University of British Columbia, School of Population and Public Health, Vancouver, Canada;* [2]*BC Centre for Disease Control, BC HTC, Vancouver, Canada;* [3]*Rwanda Biomedical Center (RBC), IHDPC, Kigali, Rwanda*
Email: makorofr@gmail.com

Background and aims: A substantial number of people are living with hepatitis B virus (HBV) infection in Canada, which may result in higher morbidity and mortality among them. However, data on the contribution of HBV infection to liver-related mortality in Canada is limited. We assessed the impact of HBV infection on liver-related deaths in British Columbia (BC), Canada.
Method: We used data from the BC Hepatitis Testers Cohort (BC-HTC), a large population-based cohort that integrates data on HCV, HBV testing and diagnoses with data on primary care visits, hospitalizations, deaths and medication dispensations. Individuals who tested for HBV in the BC-HTC were followed from the first test date among HBV positive individuals and last test date among HBV negative individuals until the end of the study period (2020/06/30) or liver-related death. Liver-related mortality rates were computed for HBV positive and negative individuals. Multivariable Cox proportional hazards model was used to assess the impact while adjusting for confounders. Propensity scores (PS) pair matching analysis was conducted as a sensitivity analysis to assess the robustness of the main findings.

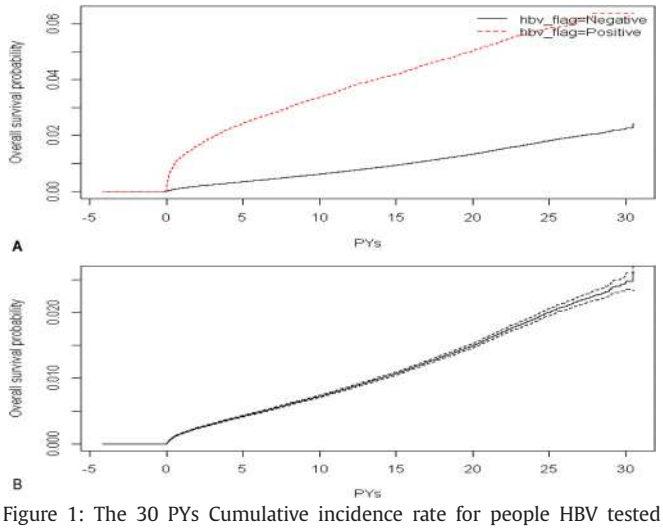


Figure 1: The 30 PYs Cumulative incidence rate for people HBV tested positive vs. those HBV tested negative in BC from 1990–2015. (A) Cumulative incidence of liver-related mortality in individuals with and without HBV infection, over30 PYs of follow-up. Solid lines: cumulative incidence of liver-related mortality; dashed lines: 95% confidence intervals. (B) Cumulative incidence of liver-related mortality in all individuals, over 30 years of follow-up. Solid lines: cumulative incidence of liver-related mortality; dashed lines: 95% confidence intervals. PYs, Person years; CI, confidence interval; HBV, hepatitis B virus.

Results: During the study duration, 40, 704 people tested positive for HBV. Among them, 38, 847 HBV-positive individuals were matched to HBV-negative individuals. The mean follow-up time for the study sample was 13.46 (standard deviation 6.53) years. A higher

proportion of those testing positive compared to negative were males (54% vs 43%), born in 1945–64 (46% vs 30%) and of East Asian ethnicity (63% vs 14%). The liver-related mortality rate was higher among people with HBV infection than those without [2.76 per 1, 000 PYs (95%CI: 2.64, 2.89) vs. 0.66 per 1, 000 PYs (95%CI: 0.65, 0.68), respectively]. In multivariable analysis, HBV infection was associated with increased liver-related mortality [adjusted hazard ratio (aHR): 3.35; 95%CI: 3.02, 3.71]. We found similar results in the PS-matched analysis (aHR: 3.36; 95%CI: 3.17, 3.57).

Conclusion: HBV infection is associated with a higher risk of liver-related mortality. Findings highlight an urgent need for HBV screening and diagnosis and continued monitoring for liver-related diseases to prevent mortality.

THU379

Comparable risk of hepatocellular carcinoma between immune-tolerant and active phase in hepatitis B e antigen-positive patients

Han Ah Lee[1], Seung Up Kim[2], Yeon Seok Seo[3], Chai Hong Rim[4]. *[1]Inje University College of Medicine, Internal Medicine, Seoul, Korea, Rep. of South; [2]Yonsei University College of Medicine, Internal Medicine, Seoul, Korea, Rep. of South; [3]Korea University College of Medicine, Internal Medicine, Seoul, Korea, Rep. of South; [4]Korea University College of Medicine, Radiation Oncology, Seoul, Korea, Rep. of South*
Email: crusion3@naver.com

Background and aims: Antiviral therapy is not indicated for patients with chronic hepatitis B (CHB) in the immune-tolerant (IT) phase. We compared the treatment outcomes between untreated IT-phase and treated immune-active (IA) phase in patients with CHB.

Method: We systematically searched four databases including Pubmed, Medline, Embase, and Cochrane database until August, 2021. The cumulative incidence of hepatocellular carcinoma (HCC) and mortality in IT and IA cohorts and that of CHB phase change in IT cohort was investigated. Studies regarding patients who have

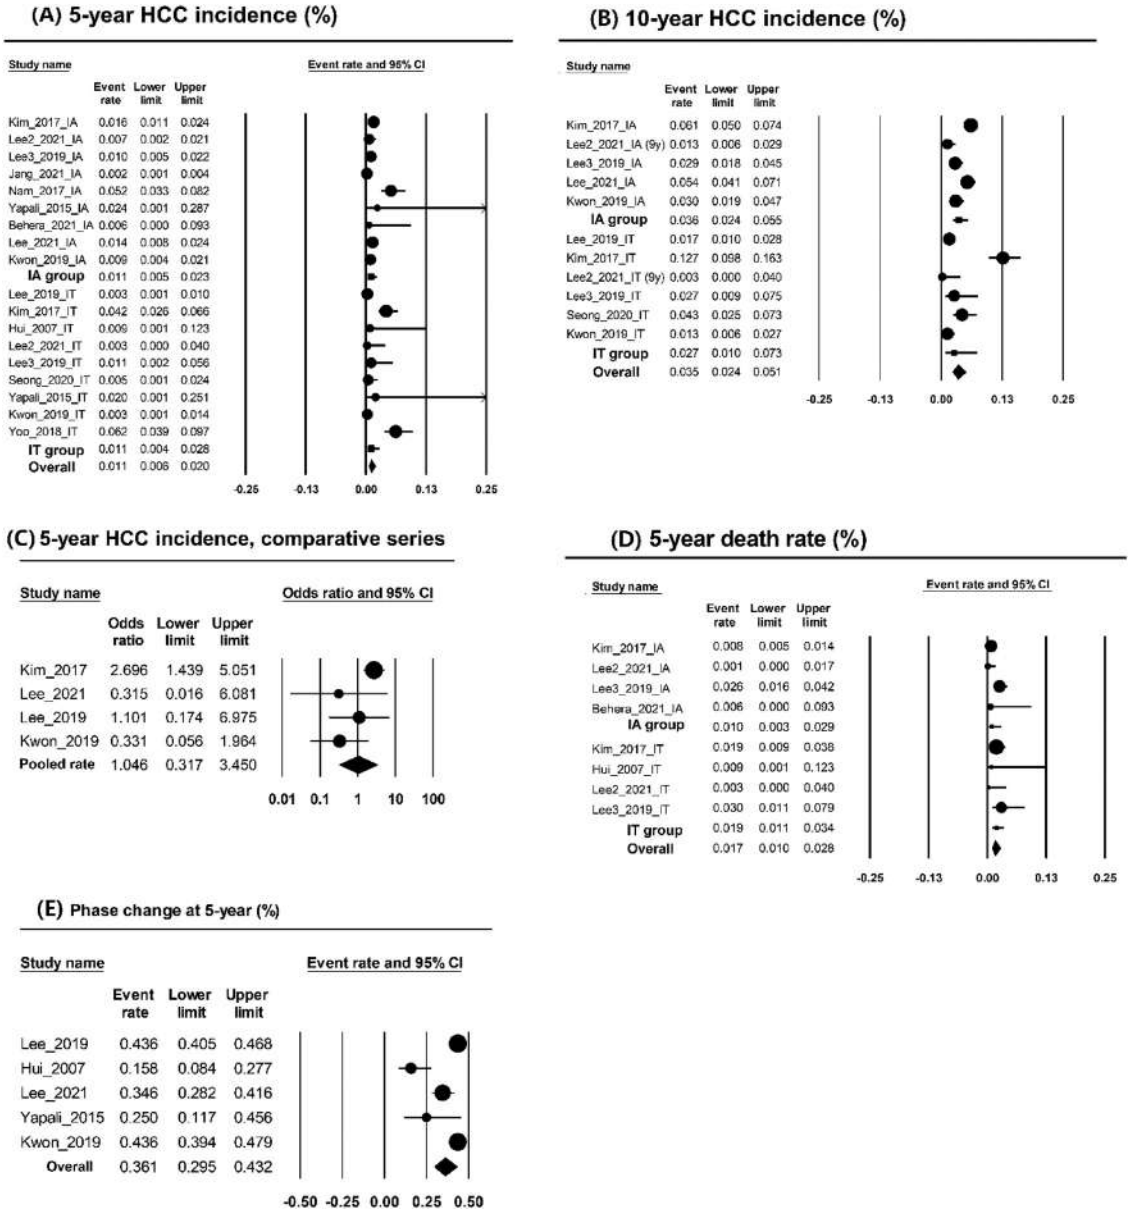

Figure: (abstract: THU379)

clinically or pathologically diagnosed liver cirrhosis were excluded. Random effects model was used for pooled analyses. The study adhered PRISMA and referenced Cochrane handbook v6.2 for methodologic regards.

Results: A total of 13 studies involving 19 cohorts, including 11, 903 patients were included. Quantitative quality assessment was performed and five and eight studies were regarded to have high and moderate quality; therefore none of 13 studies were dropped from formal analysis for quality issue. The overall median of median follow-up period was 62.4 months, (range: 51–103 months). The overall median value of median age was 40 (range: 29–53.5), and proportion of male was 59.6% (31.8–68.9). Possible publication bias was noted in pooled analyses of 5- (Egger's test p = 0.082) and 10-year HCC incidence (Egger's test p = 0.019).

The pooled HCC incidence rate at 5-years was 1.1% (95% confidence interval [CI]: 0.6–2.0%) in all cohorts. No statistical difference in HCC incidence rate at 5-years was observed between IT [1.1% (95% CI, 0.4–2.8%)] and IA cohorts [1.1% (95% CI, 0.5–2.3%) (p = 0.976). The pooled odds ratio of comparative series between IT and IA cohorts was 1.05 (95% CI, 0.32–3.45; p = 0.941). Pooled HCC incidence rate at 10-years was 3.5% (95% CI, 2.4–5.1%) in all cohorts. No statistical difference in HCC incidence rate at 10-years was observed between IT [2.7% (95% CI, 1.0–7.3%)] and IA cohorts [3.6% (95% CI, 2.4–5.5%)] (p = 0.587). No statistical difference in pooled mortality rates at 5-years was observed between IT [1.9% (95% CI, 1.1–3.4%)] and IA cohorts [1.0% (95% CI, 0.3–2.9%)] (p = 0.285). Finally, pooled incidence rate of CHB phase change in IT cohort was 36.1% at 5 years (95% CI, 29.5–43.2%).

Conclusion: The long-term risks of HCC and mortality were similar between the IT and IA phase. However, various definitions of CHB phase in different studies have to be considered.

THU380

Evidence of extensive transcriptionally active HBV integrations involving genetic regions crucial for cell proliferation in the setting of HBeAg positive infection

Romina Salpini[1], Luca Carioti[1], Arianna Battisti[1,2], Lorenzo Piermatteo[1], Livia Benedetti[1], Francesca Ceccherini Silberstein[1], Upkar Gill[2], Valentina Svicher[1], Patrick Kennedy[2]. *[1]University of Rome Tor Vergata, Department of Experimental Medicine, Rome, Italy; [2]Blizard Institute, Barts and The London SMD, QMUL, London, United Kingdom, Barts Liver Centre, United Kingdom*

Email: rsalpini@yahoo.it

Background and aims: HBV integration into the human genome can mediate oncogenic activity. Limited information is available about initial HBV integration events, particularly in the early phases of infection. Here, we characterize chimeric HBV-human RNAs reflecting transcriptionally active HBV integrations in the setting of eAg positive phases of HBV infection.

Method: Liver tissues from 42 eAg+ chronically infected patients (27 with eAg+ hepatitis [eAg + CH] and 15 with eAg+ infection [eAg + CI]) were studied to perform total RNA-seq by NGS [Illumina, median (IQR) RNA reads per sample: 22 (18–27) millions]. An ad-hoc bioinformatic pipeline was applied to recognize chimeric HBV-human transcripts (present in >2 reads), resulting from HBV integration. Role of genes involved in HBV integration was assessed by GeneCards and Protein Atlas.

Results: Patients with eAg+CI were significantly younger than eAg +CH [27 (22–29) vs 29 (25–35) years, p < 0.001). Median (IQR) serum HBV DNA and HBsAg were 8.0 (5.7–8.6) logIU/ml and 4.4 (4.1–4.8) logIU/ml respectively, with no significant difference according to HBV infection status. Overall, >1 chimeric HBV-human RNA was revealed in almost all patients (98%, 41/42) for a total number of 1048 unique HBV-human transcripts, reflecting an abundance of transcriptionally active HBV integration events. The number of unique chimeric transcripts in each patient did not differ in eAg+CH and eAg+CI groups [median (IQR): 13 (11–22) and 14 (10–39); P = 0.46], highlighting an early occurrence of HBV integration in young patients with no or limited fibrosis. 69.6% of integration events originated from HBx/Core, indicating double stranded linear DNA as a major source of HBV integration. Moreover, 20.7% of chimeric transcripts involved HBsAg coding region, posing the basis to produce truncated/aberrant HBsAg forms.

Notably, by gene ontology, 18% (189/1048) of HBV-human chimeric transcripts involved human exons and splicing signals, crucial for gene expression. Among them, 35.4% corresponds to genes playing a pivotal role in modulating cell survival/proliferation, including genes (BIRC6, SYF2, EVI5, BTG1) known to be dysregulated in HCC.

Conclusion: Transcriptionally active HBV integrations occur frequently in the eAg-positive phases of HBV infection, even in young patients with no or limited liver fibrosis. These events result in the production of chimeric HBV-human aberrant transcripts, that mostly involve genes regulating crucial intracellular pathways, that could confer a proliferative advantage to the hepatocytes. This is further evidence to support early treatment initiation in eAg positive chronic infection.

THU381

In the setting of HIV-infection, HBV-reactivation is revealed by highly sensitive assays in a conspicuous fraction of anti-HBc-positive/HBsAg-negative patients switching to Tenofovir-sparing therapy

Romina Salpini[1], Stefano D'Anna[1], Mohammad Alkhatib[1], Lorenzo Piermatteo[1], Alessandro Tavelli[2], Eugenia Quiros-Roldan[3], Antonella Cingolani[4], Chiara Papalini[5], Stefania Carrara[6], Massimo Puoti[7], Loredana Sarmati[8], Antonella d'Arminio Monforte[9,10], Francesca Ceccherini Silberstein[1], Carlo Federico Perno[11], Valentina Svicher[1]. *[1]University of Rome "Tor Vergata", Department of Experimental Medicine, Rome, Italy; [2]ICONA Foundation, Milan, Italy; [3]Spedali Civili di Brescia, Division of Infectious and Tropical Diseases, Brescia, Italy; [4]Fondazione Policlinico Universitario A. Gemelli, Unit of Infectious Diseases, Roma, Italy; [5]University of Perugia, Department of Medicine, Perugia, Italy; [6]National Institute of Infectious Diseases Lazzaro Spallanzani, Microbiology Biobank and Cell Factory Unit, Roma, Italy; [7]ASST Great Metropolitan Niguarda, Unit of Infectious Diseases, Milano, Italy; [8]Hospital Tor Vergata Roma, Unit of Infectious Diseases, Roma, Italy; [9]ASST Santi Paolo e Carlo, Clinic of Infectious Diseases, Milano, Italy; [10]University of Milan, Department of Health Sciences, Milano, Italy; [11]Bambino Gesù Children's Hospital, Roma, Italy*

Email: stefanodanna26@gmail.com

Background and aims: Tenofovir-sparing antiretroviral therapy (ART) is increasingly used in the setting of HIV-infection, raising the issue to properly identify those anti-HBc-positive/HBsAg-negative patients (pts) who can safely suspend this drug. Here, we aim at unravelling HBV replication kinetics after tenofovir withdrawal in HIV-infected anti-HBc-positive/HBsAg-negative pts.

Method: This study includes 101 HIV-infected anti-HBc-positive/HBsAg-negative pts from ICoNA cohort, treated with TDF/TAF-containing ART for >12 months and switching to TDF/TAF-sparing ART: 73 with LAM and 28 with no active HBV drugs. At switching (T0) 98% of pts has undetectable HIV-RNA.

For each pt, a plasma sample is analyzed at T0 and during the first 12 months of TDF/TAF-sparing ART (T1). HBV-reactivation (HBV-R) during TDF/TAF-sparing ART is defined as HBV-DNA>1IU/ml in pts with negative HBV-DNA at T0 or a >2-fold increase in HBV-DNA from T0 to T1. HBV-DNA and -RNA are quantified by highly sensitive droplet digital PCR (HS-ddPCR, LLOD:1IU/ml) and anti-HBc by Fujirebio (anti-HBc>15COI indicating active HBV reservoir based on Salpini, 2020).

Results: At T0, despite TDF/TAF therapy, 34 (33.7%) pts have detectable HBV-DNA by HS-ddPCR (median[IQR]: 2[1–5]IU/ml). Among the remaining 67 pts, 9% has detectable HBV-RNA (median [IQR]:6[5–7]IU/ml) and anti-HBc>15COI, indicating a transcriptionally active cccDNA.

At T1, after TDF/TAF withdrawal, HBV-R occurs in 40 (39.6%) pts (median[IQR] HBV-DNA: 4[2–13]IU/ml) with no difference between LAM- vs no LAM-group (42.5% vs 32.1%, P = 0.34). Among HBV-R cases, 32.5% has HBV-DNA>10IU/ml (median[IQR]:31[15–73]IU/ml) and 25% has ALT>40U/L.
Notably, HBV-R is confirmed in 77.3% of pts with an additional sample available during TDF/TAF-sparing ART (median [IQR] HBV-DNA:24 [13–31]IU/ml), supporting persistent HBV replication.
Finally, pts with a nadir CD4+T cell count <100cells/ul have a higher risk to develop HBV-R (15/27[55.6%] with vs 25/74[33.8%] without nadir <100cells/ul, P = 0.04), suggesting a role of immunecompromission in promoting reuptake of HBV replication under suboptimal/absent drug pressure.
Conclusion: A conspicuous fraction of HIV-infected anti-HBc-positive/HBsAg-negative pts has a transcriptionally active intrahepatic reservoir that can predispose to HBV-reactivation under suboptimal/absent drug pressure. The status of HIV-driven immunecompromission can exacerbate this phenomenon. Highly sensitive and accurate assays to measure HBV replicative activity are crucial for a proper management of HIV-infected anti-HBc-positive/HBsAg-negative pts candidate to TDF/TAF-sparing regimen.

THU382

Absence of hepatitis B virus (HBV) in at-risk infants receiving early antiretroviral therapy in a cohort of HIV-transmitting mothers in KwaZulu-Natal, South Africa

Jane Millar[1], Gabriela Cromhout[2], Noxolo Mchunu[2], Philip Goulder[1], Philippa Matthews[3,4], Anna McNaughton[3,5]. *[1]University of Oxford, Department of Paediatrics, Oxford, United Kingdom; [2]University of KwaZulu-Natal, HIV Pathogenesis Programme, South Africa; [3]University of Oxford, Nuffield Department of Medicine, Oxford, United Kingdom; [4]Department of Infectious Diseases and Microbiology, Oxford University Hospitals NHS Foundation Trust, Oxford, United Kingdom; [5]University of Bristol, Population Health Science, Bristol Medical School, Bristol, United Kingdom*
Email: anna.mcnaughton@bristol.ac.uk

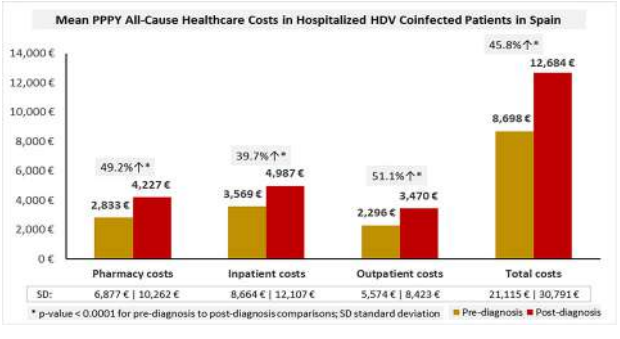
Background and aims: Both HIV and hepatitis B virus (HBV) prevalence are high in KwaZulu-Natal (KZN), South Africa (ZA). HIV co-infection can negatively impact HBV prognosis, and is associated with an increased likelihood of HBV mother-to-child-transmission (MTCT) in the absence of appropriate treatment/prophylaxis. This study worked with an established cohort of HIV-transmitting mother-child pairs in KZN, in which HIV-positive infants were treated with antiretrovirals (ART) within 48hrs of life. We generated a detailed characterisation of HBV serological makers in the maternal cohort, and tested the infants at-risk of HBV MTCT.
Method: Maternal serum samples (n = 175) were screened for active HBV infection (HBsAg), exposure to HBV (anti-HBc) and vaccination responses (anti-HBs-positive in the absence of other HBV markers). HBV vaccination has been part of the routine ZA infant immunization schedule since 1995, with the first dose given at age 6 weeks. HBV infections in HBsAg-positive mothers were further characterised with HBeAg and HBV DNA testing. Infants of HBV infected mothers were screened for HBsAg.
Results: Evidence of HBV exposure was present in 31.4% (55/175) mothers and HBV infection was present in 8.6% (15/175). Anti-HBc responses were absent in 53.3% (8/15) HBV-positive cases, suggesting it may be a poor biomarker in HIV-positive cohorts. A lone anti-HBs profile, indicating HBV vaccination, was present in 8.0% (14/175) mothers. HBV DNA was detectable in 46.7% (7/15) HBsAg-positive mothers, with 26.7% (4/15) also HBeAg-positive. Where HBV-DNA was detected, median viral load was 3.8log^{10} IU/ml (range 1.9->8.2log^{10} IU/ml). Among HBV-infected mothers, CD4+ counts were lower in those also testing HBV DNA positive (mean 264 vs 643; p = 0.003). Using a threshold of >5.3 log^{10} IU/ml, 20% (3/15) HBV-positive mothers were defined as high risk of MTCT. Screening of infants found no cases (0/15) of HBV MTCT.
Conclusion: Within this vulnerable cohort of HIV-transmitting mothers, we found evidence of a high HBV prevalence, and indications that 20% of the HBV-positive mothers are also high-risk for HBV MTCT. ART regimens prescribed to the infants early in life contained agents active against HBV (lamivudine), and this may have prevented MTCT in high-risk cases. Larger studies, incorporating long-term follow-up would be informative. Prevention of HBV MTCT at a population level requires consistent antenatal HBV screening and birth-dose immunisation of infants, together with specific antiviral prophylaxis.

THU383

Rising clinical and economic burden among hepatitis D patients who attended Spanish hospitals

Maria Buti[1], Ankita Kaushik[2], Mertixell Ascanio[3], Josep Darba[3], Nandita Kachru[4]. *[1]Hospital Universitario Valle Hebron, Barcelona, Spain; [2]Gilead Sciences, Inc., Foster City, United States; [3]BCN Health Economics and Outcomes Research SL, Barcelona, Spain; [4]Gilead Sciences, HEOR-Global Value and Access, Foster City, United States*
Email: mbuti@vhebron.net

Background and aims: Hepatitis D virus (HDV) coinfects with hepatitis B virus (HBV) causing the most severe form of viral hepatitis. This study examined the epidemiology, baseline characteristics and healthcare resource use (HRU) and costs among hospitalized HDV coinfected patients in Spain.
Method: Adult patients with ≥1 HDV or HBV diagnosis (ICD-9/10-CM) were identified retrospectively from Jan 2000 to Dec 2019 (study period) using the Spain hospitalization database that covers 192 private and 313 public hospitals, with >40 million patients. HDV patients were identified from Jan 2001 to Dec 2018 (identification period) with their first diagnosis defined as the diagnosis date, having ≥12 months of continuous enrollment (CE) before and after the diagnosis date. Prevalence was measured as the proportion of HDV patients among HBV. Baseline characteristics were assessed over the entire duration prior to diagnosis date. Mean per patient per year (PPPY) all-cause HRU and costs (pharmacy, inpatient, outpatient, total) were obtained over 12 months before and after the diagnosis date.
Results: The study included 12, 317 patients diagnosed with HDV or HBV, of which only 597 had HDV diagnosis, and 536 had a new diagnosis (no evidence of HDV during 1 year prior to diagnosis date)-5% prevalence and 4.7% incidence over the study duration. After applying CE criteria, the analytical cohort included only 159 HDV patients (mean age 42.7 ± 14.4 years; 73.6% males). High rates of liver disease severity were reported-26.4% compensated cirrhosis, 49.7% decompensated cirrhosis, 5.7% hepatocellular carcinoma and 5% liver transplant. Other comorbidities included smoking 23.9%, alcohol abuse 19.5%, substance abuse 18.9%, HIV 13.8%, HCV 8.8%. Mean PPPY number of admissions, readmissions and length of stay increased significantly from pre- to post-diagnosis. Mean PPPY all-cause healthcare costs among incident patients totaled to €8, 698 (pre-diagnosis) and €12, 684 (post-diagnosis), representing 45.8% increase (p < 0.001). Inpatient costs were the major contributors of total pre-diagnosis (41%) and post-diagnosis costs (39%), at €3, 569 and €4, 987, respectively.



Conclusion: Hospitalized HDV patients in Spain have a high comorbidity burden. Total healthcare costs are high, with inpatient costs as the primary driver, posing a high economic burden. Novel treatment strategies are needed to improve patient outcomes and reduce the economic burden among HDV coinfected patients in Spain.

THU384

Analysis from national hospital discharge records database in Spain : increased baseline comorbidity burden including liver severity among HDV coinfection versus HBV monoinfection patients

Maria Buti[1], Ankita Kaushik[2], Mertixell Ascanio[3], Josep Darba[4], Nandita Kachru[2]. *[1]Hospital Universitario Valle Hebron, Liver Unit, Barcelona, Spain; [2]Gilead Sciences, HEOR-Global Value and Access, California, United States; [3]BCN Health Economics and Outcomes Research SL, Barcelona, Spain; [4]University of Barcelona, Department of Economics, Barcelona, Spain*
Email: mbuti@vhebron.net

Background and aims: Hepatitis D virus (HDV) is considered as the most severe form of chronic viral hepatitis, given its relatively rapid progression to cirrhosis and liver-related complications. This retrospective study compares baseline characteristics of adult patients with HDV coinfection versus (vs.) hepatitis B virus (HBV) monoinfection in a national hospital database in Spain.
Method: The study population included subjects ≥18 years having ≥1 ICD-9/10-CM diagnosis code for HDV or HBV in the Spanish National Health System's Hospital Discharge Records Database (Conjunto Mínimo Básico de Datos) from 01/01/2000 to 12/31/2019 (study period). HDV and HBV cohorts were identified from 01/01/2001 to 12/31/2018 (identification period) with their first diagnosis defined as the diagnosis date, having ≥12 months of continuous enrollment before and after the diagnosis date. Baseline characteristics were assessed over the entire duration prior to diagnosis date. Descriptive statistics were summarized, and comparisons were made via chi-square tests.
Results: The study reported 12, 317 patients diagnosed with HDV or HBV, of which 3, 079 met the inclusion criteria-159 HDV and 2, 920 HBV patients. HDV patients [mean age 42.7 ± 14.4 | Charlson Comorbidity Index (CCI) score 0.92] were significantly younger than HBV patients [mean age 46.6 ± 15.9; p = 0.0034 | CCI score 0.77]. The male to female ratio (roughly 3:1) was similar across the two cohorts. Both the cohorts were largely covered by public insurance (93.7% HDV vs. 95.4% HBV; p = 0.3311) and roughly half were seen by gastroenterologists (44.7% HDV vs. 50.3% HBV; p = 0.1673) followed by other specialists (36.5% HDV vs. 29.8% HBV; p = 0.0763). HDV patients were significantly more likely to have decompensated cirrhosis (49.7% vs. 29%; p < 0.0001), compensated cirrhosis (26.4% vs. 9.8%; p < 0.0001) and liver transplant (5% vs. 1.8%; p = 0.0109) than HBV patients, whereas hepatocellular carcinoma rates were at 5.7% and 3%, respectively. Further, HDV patients reported significantly higher rates of HCV (8.8% vs. 3.6%; p = 0.0043), HIV (13.8% vs. 3.3%, p < 0.0001) and substance abuse (18.9% vs. 7%; p < 0.0001) than HBV patients.
Conclusion: In a national hospital Spanish database, HDV coinfected patients had greater comorbidities and significantly higher liver disease severity than HBV monoinfected patients. These findings underscore the need for early screening and diagnosis, and eventual treatment of HDV to mitigate future disease progression.

THU385

Value of intrahepatic HBV markers in virologically suppressed HBV and HDV infected patients

Ester García-Pras[1], Thais Leonel[1], Yabetse Girma[1], Sergio Rodriguez-Tajes[1], Alba Díaz[2], Sabela Lens[1], Mireia García-López[1], Maria Saez-Palma[1], Yilliam Fundora[3], Xavier Forns[1], Sofía Pérez-del-Pulgar[1]. *[1]Liver Unit, Hospital Clínic, University of Barcelona, IDIBAPS, CIBERehd, Barcelona, Spain; [2]Department of Pathology, Centre of Biomedical Diagnosis, CIBERehd, Hospital Clínic; [3]HBP and Liver Transplant Surgery, IDIBAPS, Hospital Clinic de Barcelona*
Email: sofiapp@clinic.cat

Background and aims: The utility of measuring HBV and HDV markers in liver biopsies (including cccDNA levels) to assess clinical outcomes is currently under evaluation. A recent study has shown high variability in cccDNA and HBV-RNA levels in multiple pieces of explant liver tissue in patients with different viral loads (Rydell GE et al. 2021). The aim of our study was to investigate whether the liver biopsy is representative for the detection of cccDNA in patients with low levels of HBV replication, either induced by NUCs or in the context of HDV coinfection.
Method: We included 10 patients undergoing liver transplantation due to end-stage liver disease related to HBV (n = 5) or HDV (n = 5) infection. From each liver explant, we obtained 9–10 fresh-frozen tissue pieces and we quantified total intrahepatic HBV-DNA (iHBV-DNA), cccDNA and HDV-RNA by Taqman real-time PCR. The presence of HBsAg and HDAg was assessed by IHC in FFPE liver samples.
Results: HBV replication was suppressed in all patients (undetectable serum HBV-DNA, n = 4; ≤27 IU/ml, n = 6) either because of NUC therapy, HDV coinfection or both. iHBV-DNA was detectable in all HBV and HDV liver samples (n = 98). In contrast, detection of cccDNA in HBV patients was very heterogeneous, ranging from 10% to 80% of liver samples. Remarkably, no cccDNA was detected in any of the pieces from 4 out of 5 HDV-infected patients despite having higher iHBV-DNA levels than HBV monoinfected patients (median 1.342 vs 0.004 copies/cell, p = 0.03). Interestingly, HBsAg immunostaining in liver tissue samples showed a higher proportion of HBsAg-positive hepatocytes in HDV-infected patients compared to HBV-monoinfected patients (>80% vs 5–60%), suggesting greater HBsAg expression from HBV integrants in HDV-infected patients. HDV-RNA was detected in all the liver pieces (n = 49) from the HDV-infected patients, showing higher variability in patients with low serum HDV-RNA levels (2–4 Log IU/ml).
Conclusion: Based on our data, cccDNA detection is highly variable in virologically suppressed HBV-infected patients, and frequently undetectable in HDV-infected patients. The variability of intrahepatic viral markers, along with the potential interference of HBV integrants, should be considered when defining end points for drug development studies.

THU386

Hepatitis Delta virus infection in patients with chronic hepatitis B is associated with greater risk of liver disease progression and liver-related mortality: a systematic review and meta-analysis

Robert G. Gish[1], Robert Wong[2], Gian Luca Di Tanna[3], Ankita Kaushik[4], Nate Smith[5], Patrick Kennedy[6]. *[1]University of Nevada, Reno School of Medicine, Las Vegas, United States; [2]Veterans Affairs Palo Alto Healthcare System, Division of Gastroenterology and Hepatology, California, United States; [3]University of New South Wales, The George Institute for Global Health, Sydney, Australia; [4]Gilead Sciences Inc, Foster City, United States; [5]Maple Health Group, LLC, New York, United States; [6]Blizard Institute, Department of Hepatology, Centre for Immunobiology, London, United Kingdom*
Email: rgish@robertgish.com

Background and aims: Previous studies have suggested more aggressive liver disease progression in chronic hepatitis B (CHB) patients with hepatitis delta virus (HDV) infection. We conducted a

systematic literature review and meta-analysis to examine whether HDV RNA positivity (HDV RNA+) vs. RNA negativity (HDV RNA-) is associated with increased risk of advanced liver disease events (ALDEs), including compensated cirrhosis (CC), decompensated cirrhosis (DCC), hepatocellular carcinoma (HCC), liver transplant (LT), and liver-related mortality (LRM).

Method: PubMed, Embase and Cochrane Central were searched in August 2021. Observational, case-control, and cross-sectional studies along with clinical trials reports addressing the clinical question of the review were included. Data extraction focused on data related to the relative rate of progression to advanced liver disease events for HDV RNA+/detectable versus HDV RNA-/undetectable patients and quality evaluation was based on the modified Risk of Bias in Non-randomised Studies-of Interventions (mROBINS-I) checklist. Data were pooled using the Hartung-Knapp-Sidik-Jonkman method for random-effects models for both risk (RR) and hazard ratios (HRs). We assessed the proportion of variability due to between-study heterogeneity with the I^2 statistics.

Results: Among a total of 2, 034 studies identified, 34 met analysis inclusion criteria. After meta-analysis, presence of HDV RNA+ was associated with a significant increased risk of any ALDE (mean effect [95% CI]: RR: 1.85 [1.11, 3.09]; HR: 2.39 [1.56, 3.68]). When compared to HDV RNA- patients, HDV RNA+ was associated with a significantly higher risk of progressing to CC (RR 2.19 [1.60, 2.99]), DCC (RR 2.07 [1.45, 2.96]; HR 3.82 [1.94, 7.49]), HCC (RR: 1.59 [1.02, 2.50]; HR 2.91 [1.98–4.29]), LT (HR 7.07 [1.61, 31.00]), and LRM (RR 1.92 [1.02, 3.63]; HR 4.58 [2.72, 7.70]).

Conclusion: This comprehensive systematic review and meta-analysis demonstrates that HDV RNA+ patients have significantly greater risk of liver disease progression compared to HDV RNA- patients. These findings highlight the need for improved HDV screening in patients with chronic HBV, leading to early detection of HBV/HDV, linkage to care, and timely initiation of appropriate antiviral therapies to reduce the risk of liver-related morbidity and mortality.

THU387

The serum markers of cccDNA transcriptional activity have a role in predicting long-term outcomes in children with perinatally acquired HBV infection

Christiana Moigboi[1], Mark Anderson[2], Gavin Cloherty[2], Kosh Agarwal[1], Ivana Carey[1]. *[1]King's College Hospital, Institute of Liver Studies, London, United Kingdom; [2]Abbott Diagnostics, Department of Infectious Diseases, North Chicago, United States*
Email: christiana.moigboi@nhs.net

Background and aims: Perinatally acquired chronic hepatitis B (CHB) has often indolent course in childhood, but persistent viral infection leads to progressive liver disease in 40% of patients in adulthood. The combination of non-invasive serological (HBeAg, HBsAg levels) and virological (HBV DNA) markers together with liver enzyme activity (ALT) and liver damage scores (APRI or FIB-4) aids in monitoring disease stages and progression. Novel serological markers of cccDNA transcriptional activity-HBV core-related antigen (HBcrAg) and pre-genomic HBV RNA (pgRNA) might add more insight and were not studied in paediatric populations. We aimed to investigate whether markers of cccDNA transcriptional activity in serum: HBcrAg and pgRNA can help to predict future disease progression (need for therapy) in patients with perinatally acquired chronic hepatitis B infection.

Method: A retrospective study was carried out with samples from 29 chronic hepatitis B (CHB) paediatric patients diagnosed in childhood (median age 12 years, 48% males, 52% HBeAg positive) with long-term follow-up in the same centre (median follow-up duration 6.5 years, range 3–16 years) with available serum samples at the time of diagnosis. HBV DNA viral load was tested by TaqMan PCR [IU/ml], HBeAg status and HBsAg plasma levels by Abbott Architect® [$\log_{10}$IU/ml], HBcrAg concentrations by CLEIA Fujirebio [$\log_{10}$U/ml] and pgRNA concentrations by real-time PCR Abbott Molecular Diagnostic RUO assay (LLQD = 1.65 $\log_{10}$U/ml). Only 5 patients required to be started on antiviral therapy during follow-up.

Results: At diagnosis 79% patients had detected HBV pgRNA and HBcrAg was detected in all patients. There were strong positive correlations between serum pgRNA and HBV DNA levels ($r = 0.82$ $p < 0.01$), pgRNA and HBsAg levels ($r = 0.74$, $p < 0.01$) and pgRNA and HBcrAg concentrations ($r = 0.859$, $p < 0.01$). When compared untreated vs. patients who required therapy-pgRNA was detected in 100% of untreated patients vs. 80% of patients needing therapy, but patients who needed therapy had higher pgRNA levels than untreated cohort (median: 3.02 $\log_{10}$U/ml vs. 1.94 $\log_{10}$U/ml, $p < 0.05$). In contrast, HBcrAg was detected in all patients irrespective of therapy status, but patients who required therapy had lower HBcrAg concentrations than untreated patients (median: 3.84 $\log_{10}$U/ml vs. 5.15 $\log_{10}$U/ml, $p < 0.05$) likely reflecting higher proportion of HBeAg negative patients in patients needing therapy (80% vs. 29%, $p < 0.05$).

Conclusion: The markers of cccDNA transcriptional activity-pgRNA and HBcrAg-combined with the traditional serological/virological markers (HBeAg, HBsAg and HBV DNA levels) were helpful to predict at diagnosis patients who might require antiviral therapy in future and represent a valuable tool to be applied in regular diagnostics. Studies in larger paediatric cohorts to further assess this are needed.

THU388

Presence of liver inflammation and fibrosis in Asian patients with chronic hepatitis B in the grey zone

Jiacheng Liu[1], Jian Wang[2], Yiguang Li[3], Li Zhu[4], Weimao Ding[5], Chuanwu Zhu[4], Yuanwang Qiu[3], Jie Li[2], Rui Huang[2], Chao Wu[2]. *[1]Nanjing Drum Tower Hospital Clinical College of Traditional Chinese and Western Medicine, Nanjing University of Chinese Medicine, Department of Infectious Diseases, Nanjing, China; [2]Nanjing Drum Tower Hospital, The Affiliated Hospital of Nanjing University Medical School, Department of Infectious Diseases, Nanjing, China; [3]The Fifth People's Hospital of Wuxi, Department of Infectious Diseases, Wuxi, China; [4]The Affiliated Infectious Diseases Hospital of Soochow University, Department of Infectious Diseases, Suzhou, China; [5]Huai'an No. 4 People's Hospital, Department of Hepatology, Huai'an, China*
Email: dr.wu@nju.edu.cn

Background and aims: Over a quarter of chronic hepatitis B (CHB) patients did not meet criteria of the traditional natural phases and hence classified as grey zone (GZ). However, few studies reported the liver inflammation and fibrosis of Asian CHB patients in the GZ.

Method: This multicenter, retrospective study included 1, 064 CHB patients underwent liver biopsy (LB). Phases of natural history were determined according the AASLD 2018 Guidance. GZ patients were divided into four categories: HBeAg-positive, normal ALT and HBV-DNA $\leq 10^6$ IU/ml (GZ-A); HBeAg-positive, elevated ALT and HBV-DNA $< 2 \times 10^4$ IU/ml (GZ-B); HBeAg-negative, normal ALT and HBV-DNA $\geq 2 \times 10^3$ IU/ml (GZ-C); HBeAg-negative, elevated ALT and HBV-DNA $< 2 \times 10^3$ IU/ml (GZ-D).

Results: 263 (24.7%) patients were in the GZ with the median age of 41.5 years and male of 67.2%. Among the GZ patients, GZ-D (44.1%) was the dominate category, followed by GZ-C (37.6%), GZ-A (9.9%) and GZ-B (8.4%). Surprisingly, as high as 60.4% of GZ patients had significant inflammation (≥G2) and 89.7% GZ patients had significant fibrosis (≥S2), which were higher than that of patients with immune-tolerant and inactive phases. Over half of patients had significant inflammation or fibrosis in each GZ category. GZ-B patients had the highest proportions of significant inflammation (95.5%) and fibrosis (81.9%) compared to other GZ categories (GZ-A: 76.9% and 69.3%; GZ-C: 53.5% and 52.5%; GZ-D: 56.1% and 60.4%, respectively).

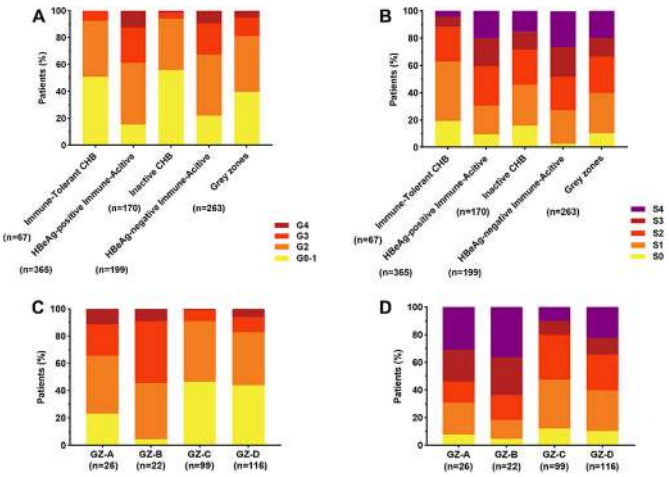


Figure: Liver inflammation and fibrosis in chronic hepatitis B with different phases of natural history and grey zones.

Conclusion: A substantial GZ patients had significant liver inflammation or fibrosis, especially for CHB patients with GZ-B. Using liver biopsy to assess the liver histological activity should be encouraged in GZ patients.

THU389

Characteristics and renal function in patients with chronic hepatitis B virus infection: baseline data from the phase 2b B-Clear study

Background and aims: Chronic hepatitis B (CHB) infection has been associated with the development of chronic kidney disease. Bepirovirsen (BPV; GSK3228836) is an antisense oligonucleotide known to distribute into the kidneys and liver. Here, we aim to characterise the baseline renal parameters in patients (pts) enrolled in B-Clear and to understand any associations between renal parameters (estimated glomerular filtration rate [eGFR]), nucleos(t)ide analogue (NA) treatment status and other baseline laboratory/clinical characteristics.
Method: B-Clear is an ongoing trial (NCT04449029) to assess the efficacy and safety of BPV in pts with CHB infection on stable NA treatment (+NA) or not on NA (-NA) at study start. Pts were grouped based on eGFR (in ml/min/1.73m^2): low (60-<90), normal (90-<120) and high (≥120). Frequency counts, descriptive statistics and 95% confidence intervals (CI) were used for comparison.
Results: A total of 455 pts were enrolled: 225 +NA and 230 -NA (Table). Mean age and length of diagnosis was inversely related to eGFR status for both those +NA and -NA. For both +NA and -NA pts, the highest proportion of pts with low eGFR were Asian (74% and 70%, respectively), and within race groups, Asians had the highest proportion of pts with low eGFR. +NA pts in the high eGFR group had higher HBsAg (mean [95% CI]: 10, 939.4 [6264.0, 15614.8]) vs pts in the low eGFR group (2723.5 [1545.9, 3901.1] IU/ml); this was not observed in -NA pts. In the -NA group, mean eGFR was lower in HBeAg negative pts (mean [95% CI]: 107.1 [105.0, 109.2]) vs HBeAg positive pts (114.4 [110.2, 118.6]). The number of pts with baseline non-steroidal anti-inflammatory drug (NSAID) or angiotensin-converting enzyme inhibitor/angiotensin receptor blocker use, or pts with diabetes or hypertension were low, but mean eGFR tended to be lower in these pt groups than in those without concomitant medication use or comorbidities, except for -NA pts with baseline NSAID use or diabetes. The most common NA used at baseline was entecavir (reported by 41% of those on NA).
Conclusion: Preliminary assessment of pts enrolled in B-Clear indicates that renal function may be associated with characteristics such as age, length of CHB diagnosis, race, HBsAg level, HBeAg status, and concomitant medications/comorbidities. [on behalf of the B-Clear study group].

Background and aims: The immune system plays an important role in disease pathogenesis and viral clearance of hepatitis B virus (HBV) infection, but the impact of HBV on the complement system, the inflammatory/immune state of patients (pts) and implications for disease and treatment are poorly understood. Here we present associations between baseline complement factors, other laboratory and clinical characteristics, and nucleot(s)ide analogue (NA) treatment status in pts screened in the B-Clear trial.
Method: B-Clear is an ongoing phase IIb trial (NCT04449029) to assess the efficacy and safety of bepirovirsen (BPV, GSK3228836), an antisense oligonucleotide, in pts with chronic HBV. Pts on either

CI, confidence interval; NA, not applicable; SD, standard deviation.

Table: (abstract: THU390)

stable NA therapy (+NA), or not receiving NA therapy (-NA) were enrolled. All pts screened for B-Clear were included in this analysis; pts were grouped based on baseline values of complement C3 ([in g/L] low <0.9; normal 0.9–1.8; high >1.8) and C4 ([in g/L] low <0.1; normal 0.1–0.4; high >0.4) at screening. Descriptive statistics and 95% confidence intervals were used for comparison.

Results: Of the 725 screened pts with data (N = 718 [+NA: n = 286; -NA: n = 432]): 83 had low C3 (+NA: n = 25; -NA: n = 58), 23 had low C4 (+NA: n = 4; -NA: n = 19), and 17 had both low C3 and C4 (+NA: n = 2; -NA: n = 15) (Table). A greater proportion of females had low C3 in the -NA group versus the +NA group (18%, versus 9%, respectively). Most pts with low C3 were Asian (+NA: 68%; -NA: 72%). In the +NA low C3 group, the mean hepatitis B virus surface antigen (HBsAg; 5911 IU/ml) and hepatitis B virus e-antigen (HBeAg; 41.5 U/ml) was higher vs the normal C3 mean HBsAg (4624 IU/ml) and HBeAg (11.9 U/ml). In the -NA low C3 group, the mean HBV DNA (12, 276, 923 IU/ml) and HBeAg (473 U/ml) was higher vs the normal C3 group (HBV DNA 7, 345, 220 IU/ml; HBeAg 249 U/ml), while HBsAg was lower (low C3 group 15735 IU/ml; high C3 group 18048 IU/ml).

The complement split product C5a and factor Bb were similar, and mostly in the normal range, in pts with low, normal or high C3 in both the +NA and -NA groups.

Conclusion: Preliminary findings indicate that gender, race, HBsAg, HBV DNA, and HBeAg level may all contribute to low C3 among pts with HBV. Observed differences may be due to different stages of disease or level of immune status for pts +NA, versus -NA. Due to low numbers of pts with low C4, no conclusions could be made regarding associations with baseline characteristics. [on behalf of the B-Clear study group].

Estimations of the global prevalence and clinical burden of occult hepatitis B infection (OBI): a systematic review and meta-analysis

Yu Ri Im[1], Rukmini Jagdish[1], Damien Leith[2], Jin Un Kim[1], Gibril Ndow[3], Kyoko Yoshida[1], Amir Majid[4], Yueqi Ge[5], Yusuke Shimakawa[6], Maud Lemoine[1]. *[1]Imperial College London, Section of Hepatology, Division of Digestive Diseases, Department of Metabolism, Digestion and Reproduction, London, United Kingdom; [2]Glasgow Royal Infirmary, Department of Gastroenterology, Glasgow, United Kingdom; [3]London School of Hygiene and Tropical Medicine, MRC Unit The Gambia, Fajara, Gambia; [4]West Middlesex University Hospital, Department of Anaesthetics, Isleworth, United Kingdom; [5]Chelsea and Westminster Hospital, Department of Gastroenterology, London, United Kingdom; [6]Institut Pasteur, Unité d'Épidémiologie des Maladies Émergentes, Paris, France*

Email: yuri.im@doctors.org.uk

Background and aims: Occult hepatitis B infection (OBI) is defined as the presence of replication-competent hepatitis B virus (HBV) DNA in the blood or liver tissue of individuals who test negative for the hepatitis B surface antigen (HBsAg). Previous studies have suggested that individuals with OBI could transmit the virus and may be at higher risk of hepatocellular carcinoma (HCC). Despite possible implications for both affected individuals and global HBV elimination goals, the prevalence of OBI is not known. Therefore, we performed a meta-analysis to estimate the global prevalence of OBI.

Method: We systematically searched the MEDLINE, Embase, Global Health and Web of Science databases for articles published between Jan 1, 2010, and August 14, 2019. We included studies on adult populations from which the prevalence of OBI could be calculated, regardless of anti-hepatitis B core (anti-HBc) status or viral load. We excluded studies on individuals <18 years of age and those on antiviral therapy active against HBV. The prevalence was pooled to

determine effect estimates and 95%CI weighted by study size for blood donors, low-risk populations, high-risk populations due to increased HBV exposure risk, and patients with advanced liver disease. We also assessed the effects of study design, HBV serology, HBV endemicity and presence of advanced liver disease on OBI prevalence.

Results: Our meta-analysis included 400 studies and 143, 980, 492 individuals. Amongst anti-HBc-positive individuals (n = 7, 863), OBI prevalence was 7.9% (5.3–10.8) in blood samples (n = 7, 345) and 55.2% (42.9–67.3) in liver samples (n = 367). Amongst anti-HBc-negative individuals (n = 45, 853), OBI prevalence was 1.1% (0.6–1.8) in blood samples (n = 44, 637) and 17.9% (5.1–35.2) in liver samples (n = 302). When assessing studies that included all individuals negative for HBsAg regardless of anti-HBc status and tested OBI in the blood, OBI prevalence was lowest in blood donors (0.2% [0.2–0.4]), followed by low-risk populations (2.5% [1.0–4.5]), high-risk populations due to increased HBV exposure risk (6.4% [4.2–9.0]) and patients with advanced liver disease (15.8% [8.1–25.2]). Endemicity of the country of study was predictive of OBI prevalence in blood donors. The presence of advanced liver disease was associated with an increased prevalence of OBI across case-control studies of patients with cirrhosis or HCC compared to healthy controls ($p < 0.001$).

Conclusion: OBI is common, clinically significant, and underestimated. Our study reports a consistently high prevalence of OBI in HBV-endemic areas and, globally, across high-risk groups. Screening of blood products with both nucleic acid testing (NAT) and anti-HBc might be necessary to eradicate this reservoir of HBV infection globally. OBI should no longer be overlooked in regional and global hepatitis B screening, prevention, and elimination programmes.

Time for universal screening for hepatitis D? A study describing screening patterns, characteristics and outcomes of hepatitis D virus infection

Rohit Nathani[1], Bo Hyung Yoon[2], Carolina Villarroel[3], Sidra Salman[1], Dewan Giri[3], Amreen Dinani[4], Ilan Weisberg[4]. *[1]Icahn School of Medicine at Mount Sinai Morningside-West, Department of Medicine, New York, United States; [2]Icahn School of Medicine at Mount Sinai Beth Israel-Morningside-West, Division of Gastroenterology, Department of Medicine, New York, United States; [3]Icahn School of Medicine at Mount Sinai Beth Israel, Department of Medicine, New York, United States; [4]Icahn School of Medicine at Mount Sinai Beth Israel, Division of astroenterology, Department of Medicine, New York, United States*
Email: rohit.nathani@mountsinai.org

Background and aims: The prevalence of hepatitis D virus (HDV) is as high as 10% in patients with hepatitis B virus (HBV) infection. Asian and European guidelines recommend universal testing for HDV in all HBV surface antigen positive persons. However, the AASLD guidelines recommend testing only those at increased 'risk.' The aim of our study was to identify patterns of screening for HDV and to understand the characteristics and outcomes of those infected with HDV.

Method: A retrospective cohort of patients with chronic hepatitis B (CHB) infection was identified using electronic medical record data in a tertiary health system from 01/2016 to 10/2021. We also identified those who were screened with an HDV antibody test. For this submission, detailed chart review of patients with a confirmed diagnosis of HDV infection was performed. Baseline demographic data, comorbidities, and markers of severity of liver disease (determined by FIB 4 score) and cirrhosis status (based on imaging and clinical criteria) at the time of diagnosis was recorded. We also recorded the type of screening test and the type of clinician performing the screening. Primary outcome was mortality and secondary outcomes included liver decompensation (LD), development of hepatocellular carcinoma (HCC), and need for liver transplant (LT).

Results: Over 6 years 11, 110 patients were diagnosed with CHB and 1390 (12.5%) of them had been screened for HDV infection. A detailed chart review was performed of 86/1390 patients (6.1%) who were positive for HDV infection and had complete data. More than half (58.14%) were male, mean body mass index was 27.88 (SD ± 5.5) units. After CHB, most common co-existing condition was hepatitis C virus (HCV) infection (11.62%). Median FIB-4 score was 1.8 (1.1–4.2) and 53.48% had cirrhosis at the time of HDV diagnosis. Majority (81.4%) of screening tests were ordered at attending clinics by gastroenterologists (90.7%). Among patients with cirrhosis 17 (37%) developed LD with ascites and esophageal varices (82% each) being the most common decompensating events. 12 (13.95%) patients developed HCC and 16 (18.6%) patients needed LT. No patients died during follow-up.

Conclusion: Our study demonstrates that people with HBV who are infected with HDV have high morbidity and increased risk for HCC, LD, and LT. A small proportion of HBV infected persons are screened for HDV and many of them develop liver cirrhosis by the time of diagnosis. Contrary to AASLD guidelines, we found a sizable number of HDV-positive people who do not have co-existing high-risk conditions like Human Immunodeficiency Virus and HCV. Most of the screening for HDV occurred in attending clinics vs trainee/mid-level provider clinics, identifying an area for improving knowledge around HDV. We describe a significant liver-related disease burden in those with HDV and thus universal screening for HDV in people with HBV infection may be reasonable.

Background and aims: Many patients (pts) with chronic hepatitis B virus (CHB) lie in a grey zone (GZ) (i.e. they do not fit into a guideline-defined disease phase). We evaluated the distribution and characteristics of CHB pts enrolled in B-Clear, who were not on nucleos (t)ide analog (NA) therapy, by guideline-defined disease phase and GZ.

Method: B-Clear is an ongoing trial (NCT04449029) to assess the efficacy and safety of bepirovirsen (GSK3228836, BPV)-an antisense oligonucleotide- in pts with CHB. Pts not on NA (N = 230) were categorised as HBeAg positive (eAg+) chronic infection, eAg+ chronic hepatitis, HBeAg negative (eAg-) chronic infection, and eAg- chronic hepatitis, based on HBV DNA, alanine aminotransferase (ALT) and eAg status at baseline as per EASL 2017, AASLD 2018 and APASL 2015 CHB

guidelines. In addition, 'Strict' or 'Common' criteria were applied based upon eAg status and ALT cut-offs of 35/25 IU/ml [males/females] or 40/33 IU/ml [males/females], respectively. Pts in the GZ were categorised into four groups: A (eAg+, normal ALT), B (eAg+, high ALT), C (eAg-, normal ALT), D (eAg-, high ALT).

Results: Of the four guideline-defined disease phases, the highest proportion of pts were eAg+ chronic hepatitis (EASL 16.2%; AASLD 18.8%) or eAg- chronic hepatitis (EASL 16.2%; APASL 8.7%) (Figure); however, the majority of patients (55.5%, 65.9% and 81.2%) fell in the GZ using EASL, AASLD and APASL guidelines, respectively. Most pts in the GZ were eAg-. GZ C was the most common GZ group: 48.5% (EASL), 36.2% (AASLD) and 48.5% (APASL); however, the proportion of pts in other GZ groups differed by guideline. The EASL guidelines had the lowest proportion of pts in the GZ for Asian (48.8%), Black (75%) and White (60.8%) pts. The APASL guidelines had the highest proportion in the GZ for Asian (86%) and Black (95%) pts, while AASLD guidelines had the highest proportion of pts in the GZ for White pts (74.7%). When the criterion for HBV DNA was removed, the highest proportion of GZ pts fell into the eAg-, normal ALT category (52.2% 'Common'; 40.4% 'Strict') and eAg-, high ALT category (21.7% 'Common'; 33.5% 'Strict').

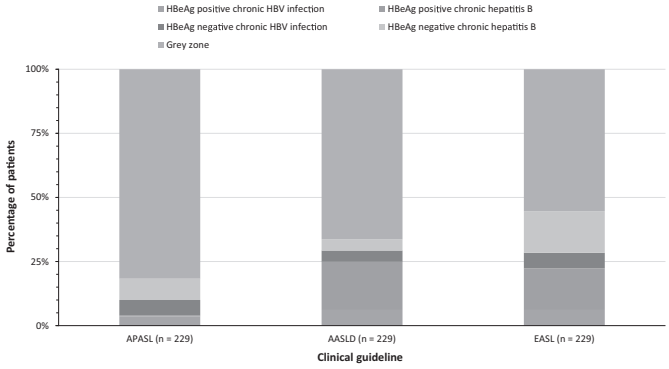

Figure: Percentage of patients in each disease phase by clinical guideline.

Conclusion: Most pts enrolled in B-Clear lie in the GZ. There is a need to understand how best to categorise pts with CHB to improve their overall management. Observations may be limited by the inclusion criteria of the study. [on behalf of the B-Clear study group].

Funding: GSK (209668).

THU394

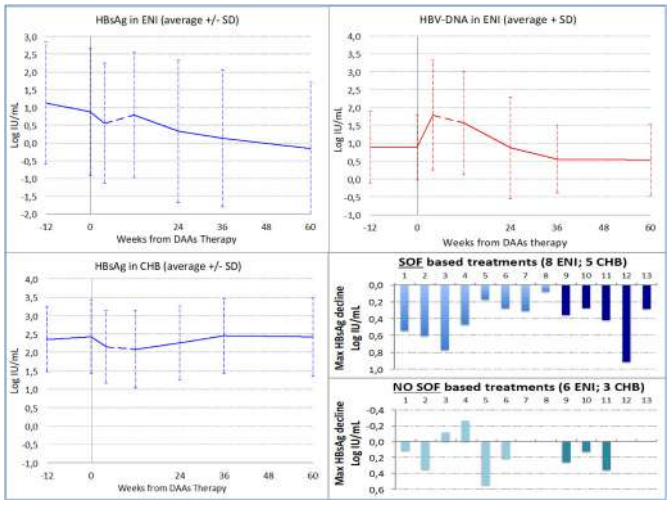
Benign course of HBV reactivations during DAAs in untreated ENI with HBV-HCV co-infections correlates with different HBsAg kinetics compared to NAs treated CHB patients

Piero Colombatto[1], Elena Palmisano[2], Gabriele Ricco[1], Daniela Cavallone[1], Filippo Oliveri[1], Barbara Coco[1], Antonio Salvati[1], Veronica Romagnoli[1], Lidia Surace[1], Maria Linda Vatteroni[2], Mauro Pistello[2], Agostino Virdis[3], Ferruccio Bonino[4], Maurizia Brunetto[1,5]. *[1]University Hospital of Pisa, Hepatology Unit, Pisa, Italy; [2]University of Pisa, Virology Unit, Pisa, Italy; [3]University of Pisa, Internal Medicine Unit; [4]National Reaserch Council; [5]University of Pisa*
Email: p.colombatto@ao-pisa.toscana.it

Background and aims: Direct-acting antivirals (DAA) carry a potential risk of inducing hepatitis B virus (HBV) reactivations in HBV-HCV co-infected patients (pts). However, dynamics and outcomes may be different according to the phase of HBV infection. Our aim was to investigate HBsAg and HBV-DNA kinetics across DAAs therapy in untreated carriers with HBeAg Negative Infection (ENI) and in HBeAg negative Chronic Hepatitis B (CHB) pts receiving Nucleos (t)ide Analogs (NA).

Method: We prospectively enrolled 15 (F/M: 4/11, median age: 62.1y) ENI with HBV-DNA persistently 2, 000 IU/ml, and 8 CHB (F/M: 3/6, median age: 54.8y) pts under NA (entecavir: 6; tenofovir: 3) with concomitant HCV infection (genotype 1a:4; 1b:7; 2a/c:3; 3a:7; 4d:2) who received DAAs with Sofosbuvir (SOF:13) or without (NO-SOF:10) for 8 (4), 12 (12) or 24 (7) weeks (w). HBsAg (Abbott) and HBV-DNA (Roche) were measured at: –12w, DAAs baseline (BL), 4w, End of Therapy (EOT), EOT + 12w (24w), EOT + 24w (36w) and EOT + 48w (60w).

Results: No significant difference between ENI and CHB were observed in BL Liver Stiffness (10.5 vs 15.7 kPa; p = 0, 495), ALT (51 vs 44 U/L; p = 0.495) and HCV-RNA (6.2 vs 6, 0 Log IU/ml, p = 0.561), whereas HBsAg levels were lower in ENI than in CHB (0.88 vs 2.42 Log IU/ml, p = 0.035). At BL HBV-DNA was undetectable or <10 IU/ml in 5 and 3 ENI; it was undetectable in all NA treated CHB and remained so thereafter. All pts achieved SVR for HCV and normalized ALT. During DAAs, HBV-DNA increased >1 Log or became detectable >100 IU/ml in 5 and 2 ENI, respectively (overall: 46.7%), showing a trend for higher mean Log values at 4w (p = 0.100) and at EOT (p = 0.104) as compared to BL (Figure). Mean Log HBsAg levels significantly decreased in ENI from – 12w to BL (p = 0.002), but not in CHB (p = 0.564). During DAAs a significant decline occurred at 4w in both ENI (p = 0.020) and CHB (0.015), followed by a rebound at EOT in ENI only. After DAAs, HBsAg returned progressively to pre-DAAs levels in CHB, whereas continued to decline in ENI (6 cleared HBsAg). Among factors associated to a greater HBsAg decline during DAAs, there was a trend for SOF in the schedule (p = 0.083).



Conclusion: In ENI co-infected with HCV, reactivations of HBV during DAAs led to moderate increases of HBV-DNA, without clinically relevant events. DAAs caused a significant HBsAg decline during therapy, however, such effect did not appear able to modify the pre-treatment individual profile, which was more favorable in untreated ENI than in CHB under NAs.

THU395

Predictors of advanced liver fibrosis in chronic hepatitis B patients in the daily clinical practice

Fadi Abu Baker[1], Saif Mahmud Abu Mouch[2], Yael Kopelman[2], Yana Davidov[3], Ziv Ben Ari[3]. *[1]Hillel Yaffe Medical Center, Gastroenterology and Hepatology, Hadera, Israel; [2]Hillel Yaffe Medical Center, Gastroenterology and Hepatology, Israel; [3]Sheba Medical Center, Center of liver diseases, Israel*
Email: Fa_fd@hotmail.com

Background and aims: Staging liver disease severity using liver biopsy or, more recently, non-invasive tests such as elastography are important in guiding surveillance and assisting with treatment decisions in chronic hepatitis B (CHB) patients. The use of these tests, however, is not widely implemented as they are costly, used in limited centers, and not always covered by health insurances. Thus,

we aimed to elucidate simple clinical predictors of advanced liver fibrosis in patients with CHB in daily practice.
Method: We conducted a two-center, prospective study, recruiting CHB patients presenting to regular clinic visits in our hepatology units. A detailed medical history, including age, gender, ethnicity, BMI, medical background and medications, HBV infection status and treatment, as well as smoking and alcohol drinking habits were documented. Laboratory results performed within 1 month before or after the clinic visit were documented. During the clinic visit, all patients were referred for abdominal ultrasounds and all of them underwent two-dimensional shear wave elastography (2D SWE) to assess hepatic fibrosis. Univariate and multivariable logistic regression analyses were used to determine predictors of advanced fibrosis (F2≤; 7.2KPA<).
Results: Of the 173 patients included in the final analysis, 40 (22%) had evidence of advanced fibrosis on 2D SWE. Age > 50 (OR 3.88, CI 1.49–9.73; p = 0.005), ALT > 40 (OR 7.41, CI 2.44–22.4; p = 0.001), HBV DNA > 2000 (OR 11.44, CI 3.19–41.02; P < 0.001), moderate to severe steatosis on US (OR 5.35, CI 1.82–15.8; P = 0.002) as well as moderate-excessive alcohol consumption and heavy smoking (>20 pack-years) were all independent predictors of advanced fibrosis.
Conclusion: We outlined clinical and laboratory variables that may effectively identify CHB patients at high risk of advanced liver fibrosis. These variables, alone or in combination, may guide the use of invasive or non-invasive tests for liver fibrosis assessment in daily clinical practice, especially in low-resource settings.

Email: lucianadinizsilva@gmail.com

Background and aims: The clinical impact of Metabolic Associated Fatty Liver Disease (MAFLD) in patients with chronic hepatitis B (CHB) has not been completely clarified. Particularly, the crosstalk between sarcopenia and metabolic derangements in CHB is scarcely investigated. Thus, the aims of this study were to assess the prevalence as well as the risk factors associated with sarcopenia and its components, appendicular lean soft tissue index (ALSTI) and handgrip strength (HGS) in HBV-chronically infected patients.
Method: Sarcopenia was assessed by measurements of appendicular lean soft tissue index [ALSTI; ASLT adjusted for body mass index (BMI)] and handgrip strength adjusted for BMI (HGS_{BMI}) using dual-energy-X-ray and dynamometer, respectively. Sarcopenia severity was assessed by gait speed, using the get-up-and-go timed test. Sarcopenia was defined as the lowest quintile for sex specific ALSTI and HGS_{BMI} cut-off values (<0.759 for men and <0.503 for women) and (<1.2 for men and <0.65 for women), respectively, modified from the Foundation for the National Institutes of Health Biomarkers Consortium Sarcopenia Project consensus. Sarcopenic obesity (SO) was defined as the presence of both sarcopenia and body fat percentage >27, 0% and >38, 0% for men and women, respectively. MAFLD was defined according to an international expert consensus statement. A Body Shape Index (ABSI) was used to the assessment of abdominal obesity. The International Physical Activity Questionnaire was used to determine the physical activity level. Associations were investigated by logistic regression models.
Results: Among the 105 outpatients with CHB (mean age, 48.5 ± 12.0 yrs.; 58.1% males; 76.2% without cirrhosis; 23.8% with compensated cirrhosis), SO, low ALSTI and low HGS were found in 4.8%, 21.9% and 10.5% patients, respectively. All SO patients had MALFD and sedentary life. In the multivariate analysis, low ALSTI were positively associated with MAFLD, sedentarism and high ABSI. Low HGS_{BMI} was associated with MAFLD and high ABSI. After adjusting for confounders, in male patients, cirrhosis was independently associated with age >50 yrs., high ABSI and hepatic steatosis.
Conclusion: ASLT abnormalities were associated with MAFLD and abdominal obesity in HBV-chronically infected patients. These findings may contribute to the development of effective strategies to screen the ASLT and metabolic abnormalities in CHB patients, independently of the stage of the liver disease.

THU397
The course of COVID-19 infection in patients with chronic hepatitis B and Delta

Yavuz Emre Parlar[1], Onur Keskin[1], Beril Kirmizigul[2], Genco Gencdal[3], Mujdat Zeybel[3], Mesut Gumussoy[4], Ramazan Idilman[4], Cihan Yurdaydin[3]. *[1]Hacettepe University School of Medicine, Gastroenterology, Turkey; [2]Hacettepe University School of Medicine, Internal Medicine, Turkey; [3]Koc University School of Medicine, Turkey; [4]Ankara University School of Medicine, Gastroenterology, Turkey*
Email: onurkeskin81@gmail.com

Background and aims: SARS CoV-2-induced COVID-19 disease has caused as of November 2021 more than 5 Million deaths. Older age and co-morbidities such as liver cirrhosis have been associated with mortality (Bajaj et al, Hepatology 2020, Hamid et al JCG 2021). Among etiologies of liver disease only alcoholic liver disease was associated with mortality by multivariate analysis. Chronic hepatitis delta (CHD) had not been studied in this context. In the current study the course of COVID-19 disease in chronic hepatitis B (CHB) and CHD patients was explored in 2 academic hospitals.
Method: CHB and CHD patients followed in the gastroenterology departments of Hacettepe and Koç University Medical School Hospitals in Ankara and Istanbul were included in the study (n:551; 302M/249F). Median age was 47. While 479 of the patients had CHB, 77 patients had CHD. 372 of 479 CHB patients were receiving nucleos(t)ide analogs (NAs (TDF:221, ETV:107, LMV-TAF:37), 107 patients were being followed without treatment. 52 patients had cirrhosis. 52 of 77 CHD patients were receiving NAs. Diagnosis of COVID-19 was made by PCR detection of SARS CoV-2 RNA in nasopharyngeal swap specimens.
Results: In the CHB group (n:479), 43 patients (5 of them had cirrhosis) were diagnosed with COVID-19 infection. CHB patients with and without COVID-19 infection did not differ in terms of age, gender and laboratory parameters. No patient had a COVID-related death. ALT-AST reactivation, defined as an increase of ALT to more than 3x ULN, occurred in 3 patients (6.9%) including hepatic decompensation in 1 cirrhotic patient after COVID-19. None of the patients were followed up in the intensive care unit. In CHD patients (n:77; 37 cirrhotic), 8 patients developed COVID-19 infection and 4 had documented hepatic reactivation. None were receiving treatment for CHD. COVID-19 infection developed in 3 cirrhotic patients, of whom one died and one developed hepatic decompensation.
Conclusion: The course of COVID-19 infection is not severe in CHB patients but maybe so in CHD. This may be due to effective antiviral treatment in CHB but lack of it in CHD.

THU398

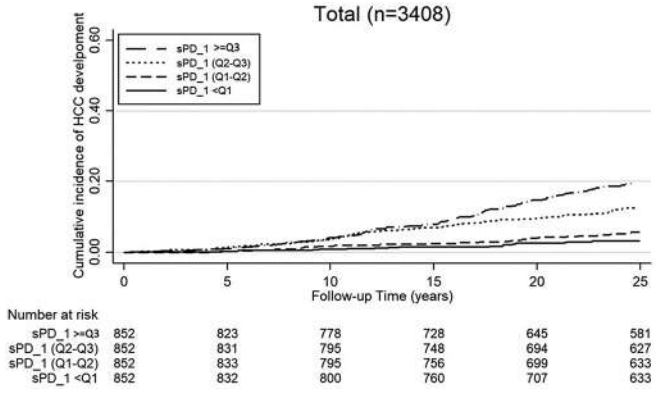
Serum soluble program cell death-1 is predictive of hepatocellular carcinoma in untreated chronic hepatitis B patients

Rachel Wen-Juei Jeng[1,2], Yu-Ju Chu[3], Mei-Hung Pan[3], Hui-Han Hu[3], Wun-Sheng Luo[3], Chien-Yu Su[3], Chen-Tse Chiang[3], Chin-Lan Jen[3], Sheng-Nan Lu[2,4], Li-Yu Wang[5], Chien-Jen Chen[3], Hwai-I Yang[3].
[1]Linkou Chang Gung Memorial Hospital, Department of Gastroenterology and Hepatology, Taiwan; [2]Chang Gung University, College of Medicine, Taiwan; [3]Academia Sinica, Genomic Research Center; [4]Kaohsiung Chang Gung Memorial Hospital, Division of Hepatogastroenterology, Department of Internal Medicine; [5]Mackay Medical College, Taiwan
Email: rachel.jeng@gmail.com

Background and aims: Soluble programmed cell death 1 (sPD-1) is a novel immunological marker which has been reported to be correlated to hepatocellular carcinoma in chronic hepatitis B in a case-cohort study. Although it has strong correlations with some viral markers such as qHBsAg, whether it is a predictor of HCC independent of other known host and viral risk factors remains to be explored. We aimed to investigate the association between sPD-1 levels and HCC development.

Method: Baseline serum samples from 3408 chronic hepatitis B subjects in the REVEAL-HBV cohort were assayed for sPD-1 level. Among them, 2934 with available follow-up serum samples were longitudinally analyzed. The ascertainment of HCC was done through the data linkage with the Taiwan Cancer Registry. Multivariate Cox regression analysis was used to estimate the adjusted hazard ratio (aHR) and 95% confidence interval (CI), adjusted for host and viral factors.

Results: By end of 2017, 344 HCC cases were newly developed. Both the baseline and follow-up sPD-1 level were higher in the HCC versus non-HCC patients. Despite there exists linear correlation between sPD-1 and HBsAg level ($r = 0.92$, $P < 0.001$) or HBV DNA level ($r = 0.59$, $P < 0.001$), a dose-dependent increase of adjusted hazard ratio for HCC along with higher sPD-1 level was observed [sPD1 <Q1 as referent, aHR (95% CI) for Q1-Q2, Q2-Q3, ≥Q3: 1.6 (0.9–2.9), $P = 0.092$; 2.9 (1.5–5.5), $P = 0.001$; and 3.9 (2–7.6), $P < 0.001$] after adjusting age, gender, alcohol drinking, cirrhosis, family history, HBeAg serostatus, HBV DNA and qHBsAg at baseline. This association was even more marked when limited to subjects with low HBV DNA levels (<2000 IU/ml). By repeat measurement, those with sPD-1 level <944 pg/ml (Q1) at baseline or subsequent follow-up had minimal or decreased risk of HCC.



Conclusion: sPD-1 is another useful immunological marker in addition to the current markers used to predict HCC development in untreated CHB patients.

THU399

Parameters related to ALT elevation in patients with HBeAg negative chronic infection

Ulus Akarca[1], Merve Gur[2], Galip Ersoz[1], Zeki Karasu[1], Ilker Turan[1], Fulya Günsar[1]. *[1]Ege University, Gastroenterology, Izmir, Turkey; [2]Ege University, Internal Medicine, Izmir, Turkey*
Email: ulusakarca@gmail.com

Background and aims: The majority of patients with chronic hepatitis B virus infection are in the HBeAg negative chronic infection phase. Elevated transaminase levels and exacerbation of hepatitis can be seen in a small number of these patients. Criteria that can predict which patients will have an exacerbation have not yet been clearly established. If ALT elevation can be predicted in the follow-up of patients, recommendations can be made for close follow-up of these patients. In this study, in patients with HBeAg negative chronic infection who had normal ALT for at least three years, relationships of basal parameters at their first admission with subsequent ALT elevations were investigated.

Method: The files of all hepatitis B carrier patients who applied to the Hepatology Clinic since 2005 were reviewed retrospectively. Patients who had at least 4 years of follow-up, had no evidence of advanced fibrosis, and had not received antiviral therapy were included in the study. Those who had other liver disease, who used more than 2 units of alcohol per day for men and 1 unit for women, who had HCC and who had systemic disease were excluded from the study. After 3 years of normal ALT values, ALT elevation was investigated in patients who were followed for at least 1 more year.

Results: A total of 223 patients were included in the analysis. 106 (47.5%) were male and 117 (52.5%) were female. The mean age was 45.1 ± 11.8. The mean follow-up period was 7.98 ± 2.91 years. The number of patients whose ALT value exceeded the upper limit of normal was 26 (11.7%), and the number of patients with ALT increased more than twice the normal value was 6 (2.7%). While AST, ALP, total protein, albumin, urea, creatinine, prothrombin time, cholesterol and HBV DNA levels were significantly different between those with and without ALT elevations, age and gender were not significant. After three years of follow-up, the parameters associated with ALT elevation were found to be ALT > 26 U/L and albumin <4.3 g/dL, the highest HBV DNA level, according to the results of multivariate analysis; It was found that ALT > 26 U/L and albumin <4.3 g/dL, the lowest albumin level, and the lowest leukocyte count were found to be significant in those who exceeded ALT 2xULN. In our study, prognostic indices were obtained according to multivariate analysis in patients with ALT exceeding the upper limit of normal and ALT >2xULN. The prognostic index obtained in those whose ALT rises more than twice the normal value is = −40.05 + 2.71 (if ALT > 26 and Alb < 4.3)+6.12*Albumin+0.00111*WBC. The predictive value of ALT elevation of this index was investigated by ROC analysis. When cut-off >0.13 was taken, AUC = 0.93, sensitivity 83%, specificity 97% specificity in predicting ALT >2xULN.

Conclusion: A prognostic index derived from ALT, albumin, and WBC can predict an ALT elevation of >2xULN in patients with HBeAg negative chronic infection who remained with normal ALT for at least 3 years.

Clinical evidence for unconventional hepatitis delta virus infections in endemic countries

Mary Rodgers[1], Ana Olivo[1], Christopher Lark[1], Abbas Hadji[1], Pham Duong[2], Nguyen TT Dung[2], Acana Susan Elaborot[3], Dora Mbanya[4], Mia Biondi[5], Jordan Feld[5], Gavin Cloherty[1]. *[1]Abbott Laboratories, Lake Bluff, United States; [2]National Institute of Hematology and Blood Transfusion, Hanoi, Viet Nam; [3]Uganda Blood Transfusion Service, Kampala, Uganda; [4]University of Yaounde I, Yaounde, Cameroon; [5]Toronto Centre for Liver Disease, University of Toronto, Medicine, Toronto, Canada*
Email: jordan.feld@uhn.ca

Background and aims: Although cell culture and mouse studies have demonstrated that hepatitis delta virus (HDV) replication can occur in

the absence of hepatitis B virus (HBV) when other co-infecting viruses are present, such as hepatitis C virus (HCV), clinical evidence for such unconventional HDV infections has not yet confirmed they occur naturally in patients. As conventional HDV infection affects the severity and progression of liver disease, it may also have the same effects in a potential unconventional co-infection.

Method: To determine the prevalence of HDV unconventional HDV/HCV infections, a series of HBV surface antigen negative (HBsAg-), anti-HCV positive specimen panels from Cameroon (N = 87), Vietnam (N = 100), and Uganda (N = 368) were screened for HDV antibodies using two prototype assays on the automated high throughput ARCHITECT instrument.

Results: 23 specimens were positive with both anti-HDV assays and 1 with 1 anti-HDV assay, indicating that the prevalence of potential unconventional HDV infections is 3% (11/368) in Uganda, 13.8% (12/87) in Cameroon, and 2% (2/100) in Vietnam, consistent with the higher prevalence of conventional HDV infections in Cameroon and Uganda compared to Vietnam. Notably, the reported dual anti-HDV positives identified were also negative for HBV core antigen antibodies (anti-HBc-), evidence that these individuals had not had a past history of HBV infection. However, HDV RNA was not detectable in these specimens, confirming that active HDV viremia had been cleared in these patients despite detection of active HCV viremia (HCV RNA+).

Conclusion: These data serve as the first clinical evidence of unconventional HDV infections and indicate that unconventional infections can be cleared even in the continued presence of chronic HCV infection. This study also highlights the need for additional screening for unconventional HDV infections to evaluate their potential impact to patient health.

THU401

Rapid point-of-care test for hepatitis B core-related antigen (HBcrAg) to identify HBV-infected patients eligible for antiviral therapy.

Email: yusuke.shimakawa@pasteur.fr

Background and aims: To eliminate hepatitis B virus (HBV) infection, it is vital to scale up testing services. However, conventional tools to evaluate treatment eligibility, particularly real-time polymerase chain reaction assays (RT-PCR) to quantify HBV DNA, are hardly available and affordable in resource-limited settings. We developed a simple, low-cost, lateral flow rapid diagnostic test to detect hepatitis B core-related antigen (HBcrAg-RDT) and evaluated its performance to diagnose clinically important HBV DNA thresholds (≥2, 000; ≥20, 000; and ≥200, 000 IU/ml) and select patients for antiviral therapy in African patients.

Method: Analytical validation was performed using chemiluminescent enzyme immunoassay (CLEIA, LUMIPULSE G1200, Fujirebio, Japan) as a reference. Clinical validation was conducted using sera from 284 treatment-naïve patients with chronic HBV infection and 75 control participants negative for HBV surface antigen (HBsAg) participated in the PROLIFICA (Prevention of Liver Fibrosis and Cancer in Africa) programme in The Gambia.

Results: Using HBcrAg-CLEIA as a reference, the limit of detection of HBcrAg-RDT was 4.3 log U/ml for serum and plasma, and 4.9 log U/ml for whole blood. None (0/75) of HBsAg-negative samples was detected by HBcrAg-RDT. In 284 treatment-naïve HBsAg-positive patients (median age 36 years, interquartile range: 30–45, 66% were men), hepatitis B e antigen (HBeAg), HBcrAg-RDT, HBcrAg-CLEIA, and HBV DNA were positive in 13%, 23%, 53%, and 58% of the participants, respectively. HBV genotypes were E in 84% and A in 16%. The clinical sensitivity and specificity of HBcrAg-RDT to identify highly viraemic individuals were: 72.7% and 91.7% to diagnose HBV DNA levels of ≥2, 000 IU/ml; 86.7% and 88.7% for ≥20, 000 IU/ml, and 91.4% and 86.3% for ≥200, 000 IU/ml, respectively. A simplified HBV DNA-free treatment algorithm using HBcrAg-RDT had a sensitivity of 96.6% and specificity of 83.2% to identify HBV-infected patients eligible for antiviral therapy by the European Association for the Study of the Liver (EASL) criteria using the reference tests.

Table: Performance of HBcrAg-RDT, HBcrAg-CLEIA, and HBeAg-EIA to discriminate clinically important HBV DNA levels in HBsAg-positive patients (n = 284).

	HBV DNA levels								
	≥2000 IU/ml			≥20 000 IU/ml			≥200 000 IU/ml		
	HBcrAg RDT	HBcrAg CLEIA	HBeAg EIA	HBcrAg RDT	HBcrAg CLEIA	HBeAg EIA	HBcrAg RDT	HBcrAg CLEIA	HBeAg EIA
Cut-off values	Positive	≥3.6 log U/ml	Positive	Positive	≥4.5 log U/ml	Positive	Positive	≥5.3 log U/ml	Positive
Sensitivity (%)	72.7	83.3	47.7	86.7	88.9	61.4	91.4	91.4	70.6
Specificity (%)	91.7	83.9	97.6	88.7	90.4	96.0	86.3	93.2	94.9

Conclusion: HBcrAg-RDT is a rapid (45 minutes), robust (operating temperature up to 39 °C), and inexpensive alternative to HBV DNA quantification potentially allowing the decentralisation of hepatitis care in areas with limited access to laboratory services.

THU402

Prevalence of HBV infection and receiving antiviral treatment for eligible patients in blood relatives from clustering families of HBV infection with unfavorable prognoses and cascading of care linked to treatment in West China

Yuan Yang[1]. *[1]The First Affiliated Hospital of Xi'an Jiaotong University, Department of Infectious Disease, Xi'an, China*
Email: xayangyuan@mail.xjtu.edu.cn

Background and aims: Accumulating evidence had shown that HBV infection had the characteristic of family clustering, and higher risk of progression to cirrhosis or HCC. Although many of the professional organizations provide guidelines related to the prevention and treatment of HBV infection, the cascade of care is still poor.

Method: First- and second-blood relatives from clustering families of HBV infection with unfavorable prognoses, which were defined as those families in which HBV infection patients occurred in three successive generations, and there was more than one patient with HBV-associated cirrhosis of liver or HCC in two generations, were enrolled in the study, and general information and serum samples were collected. Biochemical examinations were performed by the

Department of Laboratory, the First Affiliated of Hospital, Xi'an Jiaotong University. Virologic assessments included, HBV DNA (Roche), HBsAg, anti-HBs, HBeAg, anti-HBe, anti-HBc (Abbott Architect quantitative).

Results: Collected the liver function and virological features of the 1, 568 participants from families with clusters of HBV infection and unfavorable prognoses included in this study. The patients with positive of HBsAg were 1033, and there were 351 (33.98%) patients receiving antiviral therapies. There were 451 (43.66%) patients with HBsAg-positive have not received antiviral treatment who should receive the antiviral treatment according to the 2019 Chronic hepatitis B Guideline of China, with age over 30 years with family with cirrhosis or HCC, or less than 30 years and ALT were elevated over upper limit normal (ULN). Patients were lack of awareness of screening before suggesting by the cascading of care linked to treatment for the blood relatives from clustering families of HBV infection with unfavorable prognoses. There were 535 participants with negative of HBsAg, and there were 278 (51.96%) participants with positive anti-HBc and 160 (29.91%) participants with only anti-HBs positive.

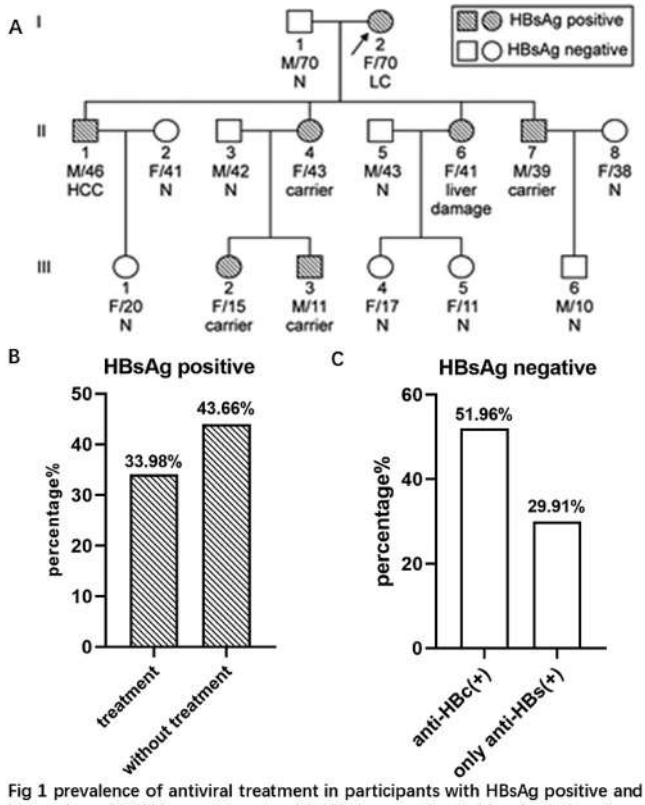

Fig 1 prevalence of antiviral treatment in participants with HBsAg positive and biomarker of HBV in participants with HBsAg negative in blood relatives from clustering families of HBV infection with unfavorable prognoses

A: proband (I-2) was diagnosed at first; first-blood relatives (II-1, II-4, II-5, II-7) and second-blood relatives (III-1, III-2, III-3, III-4, III-5, III-6) were suggested to screen for biomarker of hepatitis B virus, liver function and ultrasound for cascading of care linked to treatment

B: treatment: patients received antiviral treatment before enrolled this study; without treatment: patients should receive antiviral treatment according to the 2019 Chronic hepatitis B Guideline of China with age over 30 years from family with cirrhosis or HCC, or less than 30 years and elevated ALT

Conclusion: There were high prevalence of HBV infection in the families with clusters of HBV infection and unfavorable prognoses, and low prevalence of receiving antiviral therapies for patients eligible for treatment by professional practice guidelines. Cascading of care linked to treatment in families with clusters of HBV infection, could improve the treatment initiation rate.

THU403

Liver inflammation in asian chronic hepatitis B patients with detectable HBV-DNA and normal alanine aminotransferase according to diverse upper limits of normal

Jiacheng Liu[1], Jian Wang[2], Li Zhu[3], Yiguang Li[4], Ming Li[5], Zhonghua Lu[4], Yuanwang Qiu[4], Chuanwu Zhu[3], Weimao Ding[6], Jie Li[2], Rui Huang[2], Chao Wu[2]. *[1]Nanjing Drum Tower Hospital Clinical College of Traditional Chinese and Western Medicine, Nanjing University of Chinese Medicine, Department of Infectious Diseases, Nanjing, China; [2]Nanjing Drum Tower Hospital, The Affiliated Hospital of Nanjing University Medical School, Department of Infectious Diseases, Nanjing, China; [3]The Affiliated Infectious Diseases Hospital of Soochow University, Department of Infectious Diseases, Suzhou, China; [4]The Fifth People's Hospital of Wuxi, Department of Infectious Diseases, Wuxi, China; [5]The Affiliated Infectious Diseases Hospital of Soochow University, Department of Hepatology, Suzhou, China; [6]Huai'an No. 4 People's Hospital, Department of Hepatology, Huai'an, China*
Email: dr.wu@nju.edu.cn

Background and aims: Upper limits of normal (ULN) for alanine aminotransferase (ALT) are different among international guidelines or recommendations for chronic hepatitis B (CHB). We investigated the proportion of significant inflammation in Asian CHB patients with detectable HBV-DNA under diverse ALT ULNs.

Method: CHB patients with detectable HBV-DNA underwent liver biopsy were included from four hospitals. Liver inflammation and fibrosis were assessed by Scheuer's classification. ULN was defined as 40 U/L in EASL 2017 and APASL 2015, 35/25 U/L (male/female) in AASLD 2018, and 30/19 U/L (male/female) in East Asia recommendations 2020. The definitions of significant inflammation and fibrosis were $G \geq 2$ and $S \geq 2$, respectively.

Results: Of 921 patients included, 640 (69.5%) patients had significant inflammation, while 577 (62.6%) had significant fibrosis. 85.6% of patients with significant fibrosis and 42.4% of patients without significant fibrosis had significant inflammation. Among CHB patients with detectable HBV-DNA and normal ALT, the proportions of those with significant inflammation was 43.8% according to the ALT ULN of 30/19 U/L (male/female), while the corresponding proportions were 53.1% and 48.1% according to the ULNs of 40U/L and 35/25 U/L (male/female), respectively. In patients with detectable HBV-DNA and normal ALT levels in absence of significant fibrosis, the proportions of significant inflammation were comparable among different ULNs of ALT by 40 U/L (30.7%), 35/25U/L (27.3%) and 30/19 U/L (25.0%).

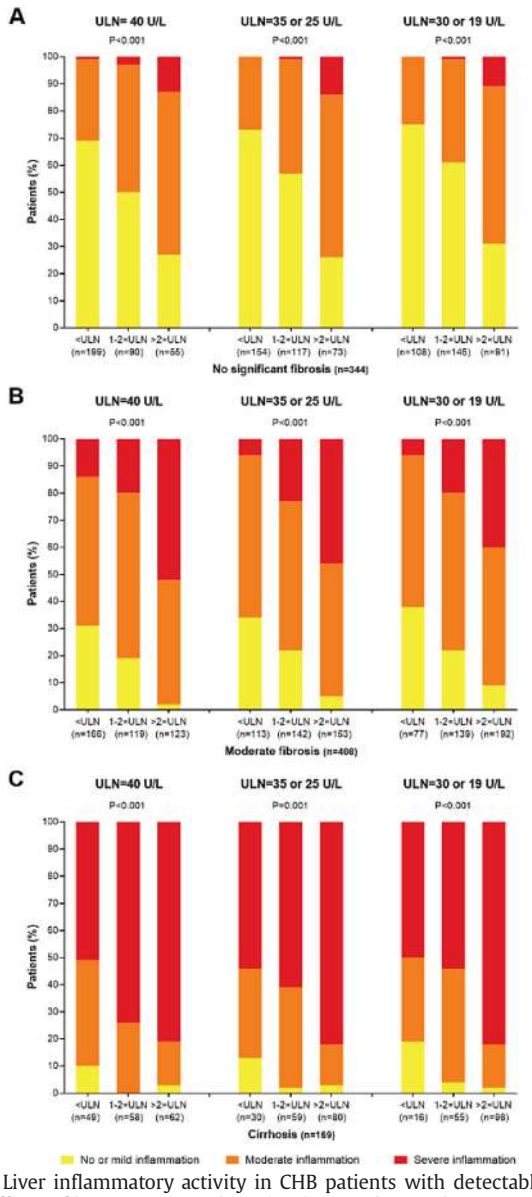

Figure: Liver inflammatory activity in CHB patients with detectable HBV with different fibrosis stages and ALT levels according to diverse criteria of ALT ULN

Conclusion: A quarter of CHB patients with detectable HBV-DNA and normal ALT without significant fibrosis had significant inflammation irrespective of the ALT ULNs. The optimal ULNs of ALT for CHB patients deserve further investigation and novel biomarkers for liver inflammation are urgently needed.

THU404

Diversity of circulating HBV genomes and impact on viral infection

Jules Sotty[1], Aurélie Schnuriger[1], Pierre Bablon[1], Bouchra Lekbaby[1], Jeremy Augustin[1], Morgane Girier-Dufournier[1], Lucas Langlois[1], Celine Dorival[2], Fabrice Carrat[2], Stanislas Pol[3], Helene Fontaine[3], Nazim Sarica[4], Christine Neuveut[4], Chantal Housset[1], Dina Kremsdorf[1], Patrick Soussan[1]. *[1]Inserm Sorbonne Université, CRSA Inserm U938, Paris, France; [2]Inserm Sorbonne Université; [3]Cochin, France; [4]Institut de génétique humaine, Montpellier, UMR 9002, France*
Email: patrick.soussan@inserm.fr

Background and aim: Besides the prototype of HBV infectious particle containing a 3.2 kb partially double-stranded DNA (wtDNA), additional circulating virus-like particles containing pregenomic RNA (pgRNA), spliced-RNA (spRNA) or spliced-derived DNA (defDNA) genomes have been described. Independently, detection of these circulating viral genomes may contribute to the clinical management of HBV infection and/or as a predictive marker of therapy response. Here, the diversity of circulating viral genomes was investigated in chronic infected patients then, its impact on viral lifecycle was explored.
Method: 335 chronic HBV infected patients treated (n = 158) or not (n = 177) were selected from the Hepather French Cohort. Pangenomic qPCRs were set up to quantify the four forms of circulating viral genomes from the same nucleic extract. Principal component analysis and hierarchical clustering were performed to characterize the circulating HBV genome diversity. Viral infection of differentiated HepG2-NTCP cells using blood samples from untreated patients was achieved to study its impacts on viral replication.
Results: Hierarchical clustering of circulating viral genome diversity in bloodstream divided untreated patients in 2 clusters. The cluster 1 (C1) was defined by the predominance (>50% of circulating genomes) of wtDNA while the cluster 2 (C2) contained various amount of the four viral genomes with a majority of pgRNA, wtDNA and defDNA in 77%, 18% and 5% of cases, respectively. Genomic diversity in C2 was associated with a higher level of viral load (7.1 ± 7.3 Log_{10} copies/ml of wtDNA), compared with C1 (6.6 ± 7.1 Log_{10} copies/ml of wtDNA; $p < 0.001$). The greatest proportion of circulating pgRNA forms was preferentially observed in high replicative patients in C1 and unexpectedly, in low replicative patients in C2. Analysis of treated patients reinforced the contribution of HBV replication in the genome diversity occurrence. *In vitro* infection with untreated patient samples from both clusters showed that viral diversity in inoculum modulated the intracellular viral cycle. Before infection, inoculum enrichment with pgRNA particles demonstrated their ability to interfere on viral cycle.
Conclusion: Our data provide evidences for the main role of viral replication in circulating HBV genomes diversity. Novel biomarker of HBV infection, circulating pgRNA genomes may also contribute to modulate the viral cycle in an unconventional process.

THU405

Chronic hepatitis delta with normal ALT and hepatitis D viremia

Sena Arici[1], Adriana Palom[2], Mesut Gumussoy[3], Ramazan Idilman[3], Genco Gencdal[4], Rafael Esteban[5], Mujdat Zeybel[4], Maria Buti[2], Cihan Yurdaydin[4]. *[1]Gulhane Training and Research Hospital, Internal Medicine, ANKARA, Turkey; [2]Hospital Universitario Valle Hebron, Department of Gastroenterology, Barcelona, Spain; [3]Ankara University, School of Medicine, Department of Gastroenterology, Ankara, Turkey; [4]Koç University, School of Medicine, Department of Gastroenterology, ZEYTİNBURNU, Turkey; [5]Universitat Autònoma de Barcelona (UAB), Department of Gastroenterology, Barcelona, Spain*
Email: gencogencdal@yahoo.co.uk

Background and aims: Chronic hepatitis delta (CHD) represents the most severe form of chronic viral hepatitis and the main cause of liver-related mortality due to suboptimal therapy. However, there is data to suggest that CHD runs a less severe course than in the past

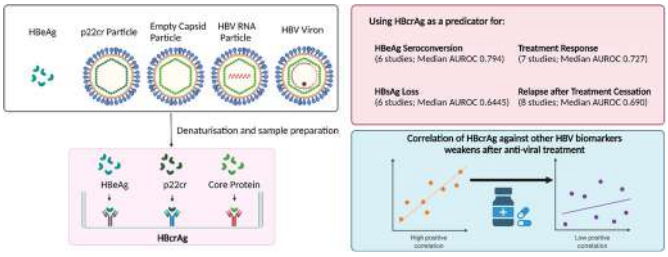
(Rosina et al, Gastro 1999, Wranke et al, JVH 2021). Patients with persistent normal ALT and hepatitis D viremia (PNAV) have been described for chronic hepatitis C and B but not for CHD.
Method: PNAV were arbitrarily defined as patients with normal ALT and hepatitis D viremia on at least four determinations, 3 to 6 months apart within a duration of 2 years among patients who had never received interferon based treatment for CHD. Such patients have been collected between January 2005 to 2021 in 2 academic hospitals in Turkey and one in Spain. A total of 19 patients were found out of a cohort comprising around 420 patients. The 19 patients with PNAV were compared with sex and age-matched control patients with CHD at a 1 to 1.5 ratio. Follow*up of patients ranged from 18 months to 12 years.
Results: ALT, AST and GGT levels were lower and platelets were higher in PNAVs vs control CHD patients (29 IU/L[18–39] vs. 45 [23–178], 30 IU/L[24–43] vs. 52 [21–99] and 18 IU/L [13–48] vs. 57 [14–328], 240 x10^9/L [88–420] vs.114 [52–309], respectively, $p < 0.05$ for all comparisons). HDVRNA levels were similar (3.60 + 1.11 vsç 4.23 + 1.43 IU.ml). Liver biopsy was available in 10 patients. Histologic activity index and fibrosis stage were lower in PNAVs vs controls (8[3–13] vs 10 [8–14] and 2 [0–4] vs 3 [2–6], $p = 0.05$ and $p = 0.014$, respectively). In the PNAV group, 2 patients had fibrosis stage 3 and 4 according to Ishak et al and one patient had cirrhosis on biopsy. Three additional patients had clinical or radiologic evidence of cirrhosis. On long-term follow-up patients normal ALT persisted. HDV RNA became undetectable in one patient.
Conclusion: This study suggests that a small subgroup of CHD patients may present with normal ALT and HD viremia and milder liver disease. However, underestimation due to referral bias is also likely. PNAV patients had compared to CHD patients lower ALT and GGT and higher platelet counts indicative of milder liver disease. Liver biopsy data confirm the latter. However, 3 out of 19 PNAV had clinical or histologic cirrhosis and 2 patients had moderate to severe fibrosis (Ishak score 3 to 4), suggesting that these patients may also need to be considered for treatment. Thus CHD patients with PNAV represent a heterogenous group and need careful assessment.

THU406

Hepatitis B core related antigen, not as good as it seems: a critique and systematic review

Yong Chuan Tan[1,2], Celina Adraneda[1], Ee Jin Yeo[1], Guan Sen Kew[2], Atefeh Khakpoor[1], Seng Gee Lim[1,2]. *[1]Yong Loo Lin School of Medicine, National University of Singapore, Department of Medicine, Singapore; [2]National University Hospital, Division of Gastroenterology and Hepatology, Singapore*
Email: mdcv341@nus.edu.sg

Background and aims: Hepatitis B core-related antigen (HBcrAg) is a new biomarker for Chronic Hepatitis B (CHB) but its performance has not been critically or systematically appraised.
Method: We reviewed the biological pathway of HBcrAg. We also performed a systematic review of PubMed for studies that evaluated the role of HBcrAg in predicting important HBV specific clinical events and/or examined the strength of correlation of HBcrAg against other HBV biomarkers. Area under the receiver operating characteristic (AUROC) curve values and correlational coefficients were consolidated to appraise the predictive accuracy and correlational strength of HBcrAg. Median values from the pooled data were used as estimates and reported.
Results: HBcrAg consists of Hepatitis B core antigen (HBcAg), e antigen (HBeAg), and 22 kDa precore protein (p22cr). Individual contribution of HBeAg, HBcAg, and p22cr to HBcrAg in HBeAg positive CHB patients is 72 ± 10%, 17 ± 8%, and 15 ± 9% respectively. The constituent contribution to HBcrAg in HBeAg negative CHB patients is unknown. HBcrAg has a false positive rate of 9.3% and false negative rate of 12–35%. The new iTACT-HBcrAg assay is more sensitive but does not solve the false positive performance. PubMed search found 58 of 248 papers on HBcrAg suitable for analysis. Median AUROC for use of HBcrAg in predicting HBeAg seroconversion, HBsAg loss, treatment response, and relapse after stopping therapy is 0.794, 0.6445, 0.706 and 0.688 respectively. Median correlation coefficient (r) of HBcrAg with HBV DNA, qHBsAg, HBV RNA and cccDNA is 0.660, 0.4755, 0.698, and 0.590 respectively. Strength of correlation weakens after antiviral therapy.



Conclusion: HBcrAg is a suboptimal biomarker and performs best as predictor of HBeAg seroconversion. Otherwise, its performance is moderate at best, and has poor correlation with HBsAg loss and antiviral therapy.

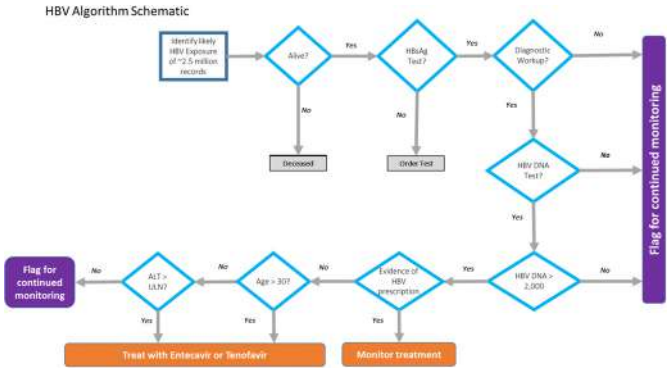
THU407

Utilizing phenotyping algorithms as tools for increasing linkage to guideline-concordant care in patients at risk for hepatitis B

Brooke Wyatt[1], Anna Mageras[1,2], Stephanie Zhang[1], Mark Miller[1], Douglas T Dieterich[1], Andrea Branch[1]. *[1]Icahn School of Medicine at Mount Sinai, New York, United States; [2]Icahn School of Medicine at Mount Sinai, Liver Diseases, New York, United States*
Email: brooke.wyatt@mssm.edu

Background and aims: An estimated 241, 000 (2.9%) NYC residents are living with chronic hepatitis B virus (HBV) infection. Management of HBV with antiviral drugs can slow disease progression and increase longevity. However, in the United States, only ~40–60% of patients with chronic HBV receive guideline-concordant care, and only ~3% of Americans with HBV receive antiviral treatment.
There is a significant need to improve methods for identifying treatment-eligible patients and linking them to care. The Mount Sinai Health System (MSHS) serves the greater NYC area. Through this study, we aim to develop and validate an HBV case-finding algorithm that identifies diagnosed HBV-infected MSHS patients who are not receiving guideline-concordant antiviral treatment or monitoring, as defined by EASL or AASLD. This project builds on our previous success developing an algorithm to identify HCV treatment candidates performing with a sensitivity of 90.0%, specificity of 97.1%, positive predictive value of 85.7%, and negative predictive value of 98.1%.
Method: We will develop an algorithm to search ~2.5 million EPIC electronic medical records (EMRs; data entered 1/2003 to 12/2021). Death record data will be utilized to identify deceased patients. To enhance impact and portability, the algorithm will be written in SQL a versatile, widely used programming language. The algorithm will automate the interpretation of HBV serological data, ALT values, demographic information, and data about antiviral medications; and it will estimate fibrosis stage by calculating the FIB-4 score. It will categorize patients as a) receiving AASLD/EASL guideline-concordant treatment, b) not receiving guideline-concordant treatment and in need of follow-up, c) HBV negative, or d) deceased. Results will be stratified by treatment site. The algorithm is being developed iteratively, assessing each iteration by performing manual chart review at planned stages.
Results: The first iteration of the algorithm identified approximately 1, 000 MSHS patients with an HBV DNA viral load >2, 000 IU/ml and no record of a prescription for any HBV medication. Manual review of a random selection of 100 of these patients' charts revealed that three patients had died, two were children, and four cleared HBV

spontaneously; of the remaining 91 patients, only five were on treatment.



Conclusion: Our preliminary results are highly promising. Once refined and validated, the algorithm will allow us to identify patients in need of HBV outreach and care leading to evaluation for hepatitis D as well. It will also help to highlight clinical settings with suboptimal HBV care in our healthcare system. Applicable to other health systems utilizing EPIC EMR, our algorithm will be vital in streamlining case finding, freeing up resources for patient engagement and care, and advancing viral hepatitis elimination.

THU408

Hepatitis B virus antigen reduction effect of RO7049389 plus NUC with/without Peg-IFN in chronic hepatitis B patients

Jinlin Hou[1], Edward J Gane[2], Wenhong Zhang[3], Jiming Zhang[3], Man-Fung Yuen[4], Tien Huey Lim[5], Rozalina Balabanska[6], Qing Xie[7], Piyawat Komolmit[8], Xieer Liang[1], Wen Zhang[9], Xue Zhou[9], Zenghui Xue[10], Miriam Triyatni[11], Ethan Chen[10], Yuchen Zhang[9], Qingyan Bo[10]. *[1]Nanfang Hospital, Southern Medical University, Guangzhou, China; [2]New Zealand Liver Transplant Unit, The University of Auckland, Auckland, New Zealand; [3]Huashan Hospital, Fudan University, Shanghai, China; [4]Queen Mary Hospital, The University of Hong Kong, Hong Kong, China; [5]Middlemore Hospital, Auckland, New Zealand; [6]Acibadem City Clinic Tokuda Hospital EAD, Sofia, Bulgaria; [7]Ruijin Hospital, Shanghai Jiaotong University School of Medicine, Shanghai, China; [8]King Chulalongkorn Memorial Hospital, Bangkok, Thailand; [9]Roche Pharma Research and Early Development, Roche Innovation Centre Shanghai, Shanghai, China; [10]Roche (China) Holding, Shanghai, China; [11]F. Hoffmann-La Roche, Basel, Switzerland*
Email: qingyan.bo@roche.com

Background and aims: RO7049389 is a Class I HBV core protein allosteric modulator. In addition to potent suppression of HBV replication, in mouse model studies, RO7049389 also induced HBsAg and HBeAg reduction alongside transient and controlled immune responses. Here we report on HBV antigens reduction with RO7049389+NUC ± Peg-IFN in chronic hepatitis B patients (NCT02952924).

Method: NUC-suppressed patients received RO7043989+NUC (Cohort A, n = 32); treatment-naïve patients received RO7049389 +NUC without (Cohort B, n = 10) or with (Cohort C, n = 30) Peg-IFN-alpha for 48 weeks. At Week 48, all patients except those who met NUC stopping criteria (HBV DNA <LLOQ and HBsAg <100 IU/ml) entered a 24-week NUC-alone follow-up period.

Results: In Cohort A, 30 NUC-suppressed patients completed the study; no obvious changes in HBsAg, HBeAg or HBcrAg were observed. In treatment naïve patients, no HBsAg loss occurred among 10 Cohort B and 27 Cohort C patients who completed the study. In Cohort B, at Week 48, HBsAg, HBeAg and HBcrAg showed mean changes from baseline of +0.1, −1.5 log_{10}IU/ml, and −1.2 log_{10}U/ml, respectively; 2/6 HBeAg+ patients achieved HBeAg loss without anti-HBe seroconversion. Two HBeAg+ patients had maximal HBsAg declines of 0.4–0.45 log_{10}IU/ml, both occurring after Grade 3 ALT flare. In Cohort C, at Week 48, HBsAg declined by mean 1.4 log_{10}IU/ml (from mean baseline 4.0 log_{10}IU/ml); 15/18 HBeAg+ vs. 5/10 HBeAg- patients achieved >1 log_{10}IU/ml HBsAg decline. Larger mean HBsAg declines were observed in patients with baseline HBsAg >4 log_{10}IU/ml. Genotype C patients (n = 11) achieved the largest mean HBsAg decline (1.7 log_{10}IU/ml at Week 48) compared to other genotypes. At Week 48, 6/28 and 19/28 patients achieved HBsAg <100 IU/ml and <1000 IU/ml, respectively. At Week 48, HBeAg declined by mean 2.1 log_{10}IU/ml with loss in 7/18 and anti-HBe seroconversion in 6/18. HBcrAg declined by mean 1.8 log_{10}U/ml. RO7049389+NUC ± Peg-IFN was safe and well tolerated up to 72 weeks. Two early terminations in each cohort of A and C were due to non-safety reasons. Grade 2–4 treatment-emergent ALT flares (TEAFs) occurred in 55% of treatment naïve patients, mainly with concurrent HBsAg declines. Spearman's rank correlation analysis showed a significant positive correlation between Grade 2–4 TEAFs and categorical maximal HBsAg declines (Cohort B: p = 0.025, rho 0.697; Cohort C: p = 0.017, rho 0.432).

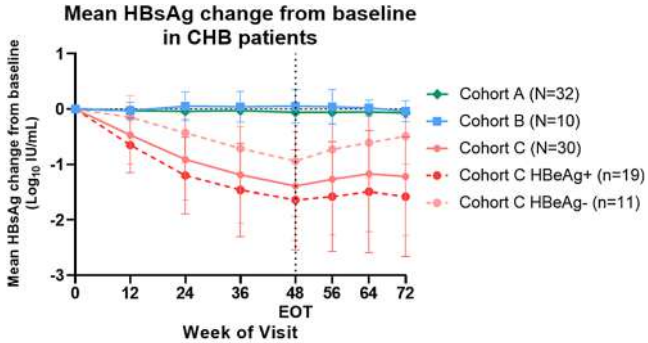


Figure. HBsAg kinetics over 72 weeks.

Conclusion: RO7049389 did not induce obvious HBV antigen reduction in NUC-suppressed patients. RO7049389+Peg-IFN+NUC led to larger HBsAg declines, especially in difficult-to-treat Genotype C patients. HBeAg positivity and high HBsAg baseline levels seemed to positively modulate the ability of RO7049389+Peg-IFN+NUC to reduce HBsAg. Positive correlation between graded TEAFs and categorical maximal HBsAg declines may be consistent with the concept of a "good" ALT flare during RO7049389 ± Peg-IFN treatment.

THU409

Presence of HbeAg, HBV DNA in cord blood and down regulation of TLR9 may act as predictive marker for HBV mother to child transmission

Simanta Kalita[1], Manash Jyoti Kalita[1], Gautam Hazarika[1], Partha Pratim Das[2], Sangit Dutta[2], Anjan Jyoti Talukdar[2], Panchanan Das[2], Subhash Medhi[3]. *[1]Gauhati University, Bioengineering and Technology, Guwahati, India; [2]Gauhati Medical College and Hospital, Guwahati, India; [3]Gauhati University, Guwahati, India*
Email: subhashmedhi@gauhati.ac.in

Background and aims: Hepatitis B virus infection is a global health problem which needs special attention mainly due to mother to child transmission of HBV. Expression pattern of TLR 9 were analysed in venous cum cord blood samples collected from 25 HBsAg+ve mother during delivery from Gauhati Medical College and Hospital, Guwahati, Assam.

Method: HbsAg, HbeAg and HbeAb were detected using ELISA and TLR9 mRNA expression is performed by Real time PCR.

Results: Serological analysis of the venous blood (N = 25) showed the presence of HbeAg in 10 (40%) samples and HBV DNA+ve in 9 (36%) samples. Further, in cord blood samples (N = 25) HbsAg was positive in 17 (68%) and HbeAg was positive in 13 (52%) of the sample. HBV DNA was found to be positive in 13 (52%) of the sample. Among 25 samples, 10 samples (40%) with HbeAg positive status exhibit

downregulation of TLR-9 with mean fold change of 0.55 ± 0.16 (p = 0.001). Similarly 13 (52%) HbsAg positive cord blood samples (mean fold change 0.65 ± 0.18, p = 0.007). 14 (56%) venous HBV DNA positive samples and 12 (48%) cord blood HBV DNA positive samples showed (mean fold change of 0.53 ± 0.18, p = 0.001; mean fold change 0.58 ± 0.16, p = 0.095) significant alteration in favour of downregulation of TLR-9 among the study cohort.

Conclusion: In the study, presence of HbeAg and HBV DNA in cord blood and down regulation of TLR9 may be an indication of vertical transmission of HBV.

Patients with CHD coinfection have greater comorbidities, higher healthcare resource use and costs than CHB monoinfection- results from a Spanish national hospital database

Maria Buti[1], Ankita Kaushik[2], Mertixell Ascanio[3], Josep Darba[4], Nandita Kachru[2]. [1]*Hospital Universitario Valle Hebron;* [2]*Gilead Sciences, Inc.;* [3]*BCN Health Economics and Outcomes Research SL;* [4]*University of Barcelona*
Email: Nandita.Kachru@gilead.com

Background and aims: Chronic hepatitis delta (CHD) coinfection among chronic hepatitis B (CHB) patients is associated with higher morbidity and mortality, given its relatively rapid progression to cirrhosis and liver-related complications. This retrospective study aims to compare baseline comorbidities, healthcare resource use (HRU) and costs in a matched cohort of adult patients with CHD coinfection versus (vs.) CHB monoinfection in a national hospital database in Spain.

Method: The study included subjects ≥18 years having ≥1 ICD-9/10-CM diagnosis code for CHD or CHB in the Spanish National Health System's Hospital Discharge Records Database that covers 192 private and 313 public hospitals, with >40 million patients during the study period (Jan 1, 2000 to Dec 31, 2019). CHD and CHB cohorts were identified from Jan 1, 2001 to Dec 31, 2018 (identification period) with their first diagnosis defined as the diagnosis date, having ≥12 months of continuous enrollment before and after the diagnosis date. CHD and CHB patients were age- and gender-matched (1:3) to evaluate incremental differences in HRU and costs.

Results: The study reported 12, 317 patients diagnosed with CHD or CHB, of which 3, 079 (159 CHD; 2, 920 CHB) met the inclusion criteria; matching yielded 125 CHD and 312 CHB patients. The male to female ratio was significantly higher in CHB vs CHD (roughly 10:1 vs. 5:1; p = 0.0281). CHD patients were significantly more likely to have decompensated (50.40% vs. 20.51%; p < 0.0001) and compensated cirrhosis (24.80% vs. 9.62%; p < 0.0001) than CHB patients; hepatocellular carcinoma and liver transplant rates were at 6.40% vs. 2.56% and 5.60% vs. 1.92%, respectively. Charlson Comorbidity Index score was significantly higher for CHD than CHB (0.84 vs. 0.36; p < 0.0001). CHD patients also reported significantly higher rates of smoking (27.20% vs. 9.94%; p < 0.0001), HCV (11.20% vs. 5.45%; p = 0.0403), HIV (15.20% vs. 5.13%, p = 0.0013), substance abuse (23.20% vs. 5.77%; p < 0.0001) and alcohol abuse (20% vs. 7.37%; p = 0.0003) than CHB patients. Mean per patient per year (PPPY) all-cause healthcare costs totaled to €13, 716 in CHD vs. €7, 177 in CHB, representing 91% higher cost in CHD than CHB patients (p = 0.0002). Consequently, pharmacy, inpatient and outpatient costs were significantly higher for CHD vs. CHB patients; all p < 0.05. Mean PPPY length of stay was significantly higher for CHD than CHB patients (14.20 vs. 10.20; p < 0.0001). Further, mean PPPY number of admissions and readmissions for CHD vs. CHB were at 2.10 vs. 1.80 and 1.30 vs. 0.90, respectively.
